- Pull the APL slip taut and place a 3-0 Vicryl suture between the APL slip, at the level of the metacarpal base, and the EPB (radially) and the tissue deep to the EPL (ulnarily).

Capsular Closure and Rehabilitation

- The capsule is closed and a thumb spica splint is placed for 14 days.

TECH FIG 5 • Abductor pollicis longus suspensionplasty technique. A. Skin incision. B. Distally based slip of abductor pollicis longus. C. Trapezium excision (arrow identifies the trapezium).
TECH FIG 6 • Abductor pollicis longus slip is passed through and around flexor carpi radialis (arrow).

PEARLS AND PITFALLS

| Address MCP joint hyperextensibility | Static laxity is no longer viewed as an absolute indication for capsulodesis or fusion. Rather, dynamic collapse during pinch is a relative indication. |
| Address scaphotrapezial disease | If proximal trapezoid excision is not performed, pain at this articulation may persist. |
| Pinning is not essential; tissue interposition is not essential | Neither pinning for 4 weeks nor tissue interposition is required. Outcomes appear not to be compromised by modest proximal metacarpal migration. However, these elements of the procedure do have a role if concern about any potential for scaphometacarpal impingement exists. |
| Ensure stability of the APL suspension | The APL should be placed through the FCR or around it and should capture some capsule. This technical point will prevent the APL and thumb metacarpal from sliding proximally along the FCR. |
| Joint fusion timing | When necessary, concomitant MCP joint fusion should be performed after tendon harvest and passage to avoid thumb manipulation after fusion. |

POSTOPERATIVE CARE

- First month
  - At 2 weeks, the patient returns for suture removal, wound inspection, and placement of a fiberglass thumb spica cast that allows full motion of the thumb interphalangeal joint, unless MCP joint fusion has been performed.
  - At 4 weeks, the patient returns again, the Kirschner wire is pulled (if one has been placed), and a forearm-based thumb spica Orthoplast splint is fashioned by the hand therapist.
  - Gentle wrist and thumb MCP joint range-of-motion exercises are initiated, as well as thenar isometric exercises. The latter are performed with the thumb in the splint.
- Month 2
  - At 6 weeks, if the patient is comfortable, gentle pinch and grip strengthening exercises are initiated.
  - By 8 weeks, flexion-adduction and opposition exercises are begun.
- Month 3
  - By this time, the patient is usually doing well enough that the splint can be discarded.
  - Grip and pinch exercises are typically continued by the patient via a home program.

- No rigorous attempt is made for the thumb to reach the ring and small finger bases because there is no functional relevance to these activities and they risk stretching the ligament. In addition, passive range of motion is not a part of the postoperative regimen.
- During months 3 to 6, the patient is encouraged to use the hand and to push the exercises vigorously. Typically, patients return to normal activities, including golf and tennis.

OUTCOMES

LRTI Arthroplasty

- Improvements in grip strength typically exceed improvements in key pinch strength. In 1995, Tomaino et al. noted that key pinch strength took at least 6 years to equal preoperative measurements.
- At an average follow-up of 9 years (range 8 to 11), these authors reported on 24 thumbs in 22 patients and found that average grip strength increased 93%, average key pinch strength increased 34%, and tip pinch strength increased 65% compared with preoperative values.
- In contrast to many other studies, stress radiographs showed an average subluxation of the metacarpal base of only 11%
and subsidence of only 13%. This compares favorably with the radiographic outcomes after the hematoma distraction arthroplasty.\(^4,6\)

- Even in series in which proximal migration of the metacarpal base averaged greater than 20%, there has been no significant correlation between maintenance of arthroplasty space height and subjective clinical outcome (FIG 4).\(^5\)

**APL Suspensionplasty**

- My evaluation of outcomes after the APL suspensionplasty found a satisfaction rate and functional return equivalent to the LRTI procedure.\(^13\)

- Evaluation of 23 thumbs in 22 patients at a minimum of 1 year after surgery showed that grip and key pinch strengths were 82% and 77%, respectively, compared to the opposite side. Proximal migration of the metacarpal averaged 50% of the preoperative trapezial height. Experience and the literature show that modest proximal migration does not correlate with outcome.\(^5\)

- In summary, APL suspensionplasty is a simple yet effective treatment alternative for basal joint arthritis. The suspensionplasty technique uses our current understanding of the forces involved during pinch and grip,\(^2\) as well as the role of normal ligamentous anatomy.

**COMPLICATIONS**

- One cause of unsatisfactory outcome after basal joint arthroplasty is residual pain because of failure to address scaphotrapezial or scaphotrapezoidal disease.\(^14\)

- Unaddressed instability of the MCP joint can also impair functional outcome after ligament reconstruction. During lateral pinch, MCP joint hyperextension causes reciprocal deformity more proximally, imposing metacarpal adduction and stressing the reconstructed ligament. Accordingly, early identification of hyperextension in excess of 30 degrees during key pinch should prompt stabilization to protect the integrity of the basal joint ligament reconstruction. Even with a sound ligament reconstruction and appropriate stabilization of the MCP joint, it is theoretically possible to develop recurrent laxity at the basal joint due to stretching of the ligament reconstruction.

**REFERENCES**

DEFINITION
- Trapeziometacarpal joint (basal joint) arthritis is a debilitating condition that most commonly affects women in their 50s and 60s. The stage of arthritis dictates the treatment for this disorder.4,5,20
- Obviously, the perils of this alternative revolve around durability, survivability, and complication rate. Joint resurfacing with the Artelon implant (SBI) may have the most potential in terms of a biologic resurfacing procedure that avoids the use of a semiconstrained device—which has been associated with trapezial component loosening and failure.

ANATOMY
- The anatomy of thethumb metacarpal (TM) joint is extremely complex and has been well studied. The deep anterior oblique ligament (“beak ligament”) is the primary stabilizer of the TM joint.19 More recently, 16 ligaments have been described that stabilize the TM joint. Seven of these ligaments, including the superficial anterior oblique ligament (sAOL), deep anterior oblique (dAOL), dorsoradial, posterior oblique, ulnar collateral, intermetacarpal, and dorsal intermetacarpal directly stabilize the TM joint. The other nine ligaments indirectly stabilize the TM joint by directly stabilizing the trapezium.
- The TM joint is the most complex joint in the hand. It is a biconcave-convex saddle joint with minimal bony constraints. This joint allows flexion-extension, abduction-adduction, and pronation-supination of the thumb. For optimal treatment outcomes with joint replacement, normal kinematics—six degrees of freedom—should be restored as closely as possible.

PATHOGENESIS
- Degeneration of the AOL of the TM joint has been linked to the development of osteoarthritis.
- Pathologic laxity, abnormal translation of the metacarpal on the trapezium, and generation of abnormally high shear forces within the TM joint, especially on the palmar aspect of the joint during pinch and grip motions, occur when the AOL becomes incompetent.
- The base of the metacarpal tends to sublux dorsally with AOL detachment, emphasizing the importance of the AOL. In advanced osteoarthritis, adduction and flexion contractures tend to develop, producing further functional impairment and joint overload.

NATURAL HISTORY
- The vast number of described operations to treat osteoarthritis of the TM joint demonstrates the lack of consensus among treating surgeons as to the best way to approach this disorder. This chapter details the role of resurfacing and implant arthroplasty for the treatment of osteoarthritis of the TM joint.
- Various materials, techniques, and prostheses have been used in the past. Hemiarthroplasty and total joint arthroplasty of the TM joint have largely failed, with mediocre long-term results compared with soft tissue arthroplasty.1,2,5,7,14,20 However, the appeal of a replacement may lie with quicker recovery and more normal kinematics.
- Obviously, the perils of this alternative revolve around durability, survivability, and complication rate. Joint resurfacing with the Artelon implant (SBI) may have the most potential in terms of a biologic resurfacing procedure that avoids the use of a semiconstrained device—which has been associated with trapezial component loosening and failure.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Arthritis of the TM joint often presents with pain at the base of the thumb during pinch and grip (stressful activities for the TM joint). Women are 10 to 15 times more likely than men to develop this disorder. Asian and Caucasian populations have an increased prevalence as well.
- Common offending activities include brushing teeth, opening a jar, picking up a book, or turning a key. All of these activities involve increasing the breadth of grasp or forceful lateral pinch. Usually the pain is localized at the base of the thumb on the dorsal or volar radial aspect of the thenar cone. Patients often feel the joint slipping or subluxing radially.
- A “shoulder sign” is an enlarging prominence (the result of a dorsally subluxing proximal metacarpal on the trapezium and metacarpal adduction) that develops with progressive disease.
- Other causes of pain in the hand should be evaluated (see differential diagnosis list) as well. This is important because any concomitant disease, such as a trigger thumb, may hamper the postoperative therapy regimen and negatively affect the patient’s final outcome.
- The treating physician should also keep the diagnosis of carpal tunnel syndrome in mind, as it coexists in about 44% of patients with TM joint arthritis. Further, the postoperative swelling from a basal joint arthroplasty may exacerbate even mild cases of carpal tunnel syndrome.
- The Allen test should be performed on every patient who is undergoing surgery for basal joint arthroplasty, as the radial artery will be near or in the operative field and may need to be mobilized depending on the exact procedure performed. Any injury to the radial artery should be repaired immediately.
- The stability of the metacarpophalangeal (MCP) joint of the thumb is also critical, as this is a source of postoperative stress on the reconstructed beak ligament from either ligament reconstruction or suspensionplasty procedures.
- MCP joint fusion or volar plate capsulodesis should be performed when the MCP joint hyperextends to greater than 20 degrees.13
- Methods for examining the carpometacarpal (CMC) joint of the thumb include the following:
  - CMC grind test: A positive test is suggestive of degenerative disease.
CMC instability test: Laxity of the TM joint is common in early stages of degeneration, but as the joint degenerates, it usually becomes stiffer.

MCP joint stability test: If the MCP joint is actively hyperextending, this could put undue stress on a reconstructed TM joint and lead to failure. This hyperextendable metacarpophalangeal joint (MPJ) should be stabilized.

Metacarpal base compression test: Glickel11 believed this is more commonly painful in advanced stages rather than milder stages of TM joint disease.

Distraction test: A positive result from this maneuver is thought to be caused by traction on an inflamed TM joint capsule.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Imaging of the TM joint includes a true AP view of the TM joint (called a Robert view or pronated AP), lateral, and posteroanterior 30-degree oblique stress view (with thumb tips pressing against each other).

The most common staging system was originally described by Eaton and Littler:9,10 stage 1 shows slight widening of the joint, possibly from synovitis; stage 2 demonstrates some joint space narrowing and osteophytes smaller than 2 mm; stage 3, osteophytes larger than 2 mm; and stage 4 disease, scaphotrapezial joint space involvement along with TM joint narrowing.

The senior author of this chapter has described a “fifth stage” in which the disease process is pan-trapezial and there is TM, scaphotrapezial, and scaphotrapezial joint degeneration. Scaphotrapezial arthritis can be a source of continued pain and this joint should be evaluated intraoperatively in every patient because, unfortunately, preoperative radiographs are only 44% sensitive and 86% specific for diagnosing arthritis at this joint.23

DIFFERENTIAL DIAGNOSIS

- Scaphotrapezial arthritis
- Scaphotrapezial arthrosis
- Thumb sesamoid arthritis
- Carpal tunnel syndrome
- De Quervain tenosynovitis
- Stenosing flexor tenosynovitis (trigger finger)

NONOPERATIVE MANAGEMENT

- Initial management of TM joint arthritis is nonoperative and includes anti-inflammatory medication, thenar cone muscle isometric strengthening exercises, hand- or forearm-based thumb spica splint immobilization, steroid injections, and activity modification.
- These measures may not alleviate any or all of the patient’s symptoms, but they may help enough to provide temporary relief, allowing the patient ample time to educate himself or herself and to contemplate the treatment alternatives.
- The time afforded by the nonoperative measures may also allow the patient to schedule the operation at a more convenient time.

SURGICAL MANAGEMENT

- There are several options for surgical treatment of TM joint arthritis. Ligament reconstruction and tendon interposition (LRTI), suspensionplasty, and CMC joint fusion are discussed in other chapters. This chapter focuses on the role of resurfacing and implant arthroplasty. Resurfacing is an increasingly attractive option in younger, more active patients in whom one might prefer to avoid trapeziectomy to eliminate the risk of metacarpal subsidence with time. Subsidence can result in recurrent pain and weakness.
- The Artelon (SBI) spacer is a bioabsorbable implant (FIG 1A) that degrades and is replaced with scar tissue that protects the base of the thumb metacarpal and the distal aspect of the trapezium. This implant is ideal for a younger laborer with TM arthritis in whom grip and pinch strength are of critical importance. The attraction of this alternative is that it is a potentially definitive procedure that does not “burn the bridge” of resection arthroplasty in the future.17
- Pyrocarbon resurfacing using the “saddle” implant (Ascension Orthopaedics, Austin, TX; FIG 1B) is an alternative to Artelon. Its design mimics the articular shape of the metacarpal articulating surface, which may more closely restore CMC joint kinematics compared to Artelon implant use. Little information exists in the literature, however, regarding outcomes.
- Total joint arthroplasty, such as with the Avanta CMC implant (FIG 1C), is another option. This is designed to require less immobilization, leading to quicker return of functional abilities, and is ideal (theoretically) for an elderly, lower-demand patient. However, the literature is full of articles describing failures of innumerable prosthetic implants for the TM joint.

Preoperative Planning

- Many other hand pathologies can coexist with TM joint arthritis. These other diagnoses should be evaluated before the day of surgery.
If an Allen test had not been performed previously, it should be performed before the surgery.

**Positioning**
- The patient is positioned supine on the operating table with the affected hand placed on a hand table extension. A tourniquet is placed above the elbow.
- When using a dorsal approach, we tend to keep the hand in neutral pronation–supination, with an assistant holding the hand stable and at times pulling traction or directly stabilizing the thumb with the nail plate parallel to the floor.

**Approach**
- There are several different approaches for soft tissue arthroplasties, but for resurfacing or implant arthroplasties, a dorsal approach seems to work the best and to offer the best visualization.

### ARTELON RESURFACING ARTHROPLASTY

#### Exposure
- A dorsal approach is needed for placement of the Artelon implant between the distal trapezium and the proximal metacarpal of the thumb.
- Make a longitudinal incision centered over the CMC joint. Identify and protect branches of the superficial radial nerve throughout the case, along with the extensor pollicis longus (EPL) and extensor pollicis brevis (EPB).
- After mobilizing and protecting the radial artery, mobilize the EPL and EPB tendons enough to facilitate a longitudinal incision through the capsule. Reflect the capsule enough to completely visualize the joint (TECH FIG 1).
- Visualize the scaphotrapezial joint; if it is found to have substantial degeneration, this joint surface would need to be addressed as part of the procedure.

#### Joint Preparation
- Use a high-speed sagittal saw to remove the distal facet of the trapezium. Take care not to injure the flexor carpi radialis (FCR) or flexor pollicis longus (FPL) tendons, which lie on the volar side of the bony cut. Alternatively, a burr can be used to decorticate the trapezial surface while maintaining its native contour.
- Use a high-speed burr to slightly decorticate the dorsum of the proximal metacarpal to stimulate healing, but not enough to affect the suture anchor fixation (TECH FIG 2).

#### Implant Placement
- The implant (Fig 1A) comes in two sizes; pick the appropriate size to fill the void from radial to ulnar as well as dorsal to volar between the trapezium and the base of the metacarpal. The larger size may be able to be trimmed down to fit more anatomically.
- The Artelon implant is shaped similar to a T, with two wings for the dorsum of the trapezium and metacarpal, with the other part to be placed between the fresh bone edges of the trapezium and the base of the metacarpal.
- Bioabsorbable suture anchors (with 2-0 fiberwire or equivalent) are used to hold the dorsal wings down to the bone (TECH FIG 3). Although cortical bone screws were recommended to secure the implant early on, experience has shown that screws are a frequent source of complication and may pull through the mesh. Screws should be avoided. Suture anchors are much easier and quicker and provide better fixation of the implant.
- After this, close the capsule with absorbable suture and the skin with 3-0 nylon. At the end of the surgery, the patient is placed into a thumb spica splint and will follow up in 2 weeks for suture removal and placement into a thumb spica cast for 4 more weeks.
PYROCARBON RESURFACING ARTHROPLASTY

Exposure
- Make a dorsal longitudinal incision centered over the CMC joint. Identify and protect branches of the superficial radial nerve throughout the procedure, along with the EPL and EPB.
- After mobilizing and protecting the radial artery, mobilize the EPL and EPB tendons enough to facilitate a longitudinal incision through the capsule. Reflect the capsule enough to completely visualize the joint. Subperiosteal release allows the base of the metacarpal to be dislocated dorsal to the trapezium. Place a Hohmann retractor beneath the palmar surface to maintain exposure.

Joint Preparation
- First, place a sizing guide over the surface as a guide toward what the ultimate size implant is likely to be.
- Resect the base using the cutting guide, which is assembled after an intramedullary rod is inserted. Just the articular surface is removed.
- Start broaching. Ensure that the broach is started just volar to the central portion of the cut to ensure that the implant is not placed too dorsal (TECH FIG 4).

Implant Placement
- Check stability with the final implant in place (TECH FIG 5A). Gentle cross-palm pressure before capsular closure should not cause dislocation.
- The implant comes in four sizes. If the trial is not stable, upsizing the implant may be necessary.
- Close the capsule with absorbable suture and the skin with 4-0 nylon.
- At the end of the surgery, the patient is placed into a thumb spica splint and will follow up in 2 weeks for suture removal and placement into a thumb spica splint for 4 more weeks.
- Radiographs are checked at that time to ensure that the implant is reduced (TECH FIG 5B).

TECH FIG 3 • Appearance of the resurfacing arthroplasty after stabilization of the Artelon implant with suture anchors.

TECH FIG 4 • Extramedullary guide to plan placement of saddle implant.

TECH FIG 5 • A. Saddle implant in place. B. Postoperative lateral radiograph showing implant in place.
TOTAL JOINT REPLACEMENT

Exposure

- We use a technique and surgical approach similar to that described by Badia and Sambandam² for implanting a Braun-Cutter trapeziometacarpal joint prosthesis (or Avanta CMC implant; Small Bone Innovations, Morrisville, PA; Fig 1C) using bone cement.

Joint Preparation

- Make a 4-cm longitudinal incision over the dorsal aspect of the base of the thumb. Identify and protect branches of the superficial sensory radial nerve. Perform further dissection between the EPL and EPB tendons, isolating and protecting the dorsal branch of the radial artery.
- Open the dorsal capsule of the trapeziometacarpal joint longitudinally. Reflect the periosteum and the dorsal capsule radially and ulnarily as a single flap to be repaired later (TECH FIG 6).

Exposure

- We use a technique and surgical approach similar to that described by Badia and Sambandam² for implanting a Braun-Cutter trapeziometacarpal joint prosthesis (or Avanta CMC implant; Small Bone Innovations, Morrisville, PA; Fig 1C) using bone cement.

Joint Preparation

- Using a sagittal saw, remove about 8 mm of the thumb metacarpal base. This resection is necessary to provide enough exposure to the trapezium (TECH FIG 7A,B).
- Release the adductor pollicis if required to allow abduction of the thumb metacarpal away from the palm. At this point, longitudinal traction and flexion are applied to better expose the trapezial surface.
- Use a rongeur to remove the marginal osteophytes and flatten the joint surface of the trapezium.
- With imaging, identify the center of the trapezium with a small burr. Enlarge the center hole to create a deep channel within the trapezium where the polyethylene cup will be cemented (TECH FIG 7C).
- For the thumb metacarpal, use a guide to open the intramedullary canal, which is broached with a burr to allow for an ample cement mantle (TECH FIG 7D).

TECH FIG 6 • The first compartment is opened from the volar side and the strands of the abductor pollicis longus (APL) are inspected. A strand of the APL that inserts on the base of the metacarpal in the bone area that will be resected should be freed from its insertion and tagged for later repair. (Courtesy of Small Bone Innovations, Morrisville, PA.)
Implant Placement

- Place the implant and perform a trial reduction so that motion and fluoroscopic images can be assessed. If there is any bony impingement at the periphery of the residual trapezium, this can be addressed before placing the permanent prosthesis.
- For final placement, first cement the trapezial cup in the trapezium, taking care to impact the cement beneath the sub cortical bone.
  - Once the cup has been inserted but before the cement has cured, insert the thumb metacarpal component with bone cement (TECH FIG 8A).
  - The two components are linked, but because this stem is collarless, it is important to maintain adequate neck length (to prevent subsidence) until the bone cement has cured. Make sure the stem neck does not impinge on the edge of the trapezium (TECH FIG 8B).
- Assess stability and circumferential motion to ensure there is no impingement on the implant.
- Close the capsule–periosteal flap with absorbable suture.
- After inserting the implant and before closure, use intraoperative fluoroscopy to check proper alignment and placement of the prosthesis (TECH FIG 8C).
- Close the skin and subcutaneous tissue with a resorbable suture and place a well-padded short-arm thumb spica splint.

**TECH FIG 8 • A,B.** The components are cemented into place, the trapezium first and the metacarpal second. Compression should be maintained until the bone cement has completely set. C. Postoperative lateral radiograph showing implant in place. (A: Courtesy of Small Bone Innovations, Morrisville, PA.)

PEARLS AND PITFALLS

**Preoperative**
- Always do an Allen test before surgery.
- Always evaluate the thumb MCP joint for active instability–hyperextension.

**Intraoperative**
- Use extreme caution mobilizing the radial artery. Often bipolar electrocautery facilitates mobilization, especially of the deep perforators at the volar base of the TM joint.
- Evaluate the scaphotrapezial joint, as preoperative radiographs are not good at predicting disease.
- Be careful when sawing or drilling not to injure structures deep to the bone.
- After making the bone cuts on the trapezium and burring the proximal metacarpal, drill and place the suture anchors far enough away from the prepared bone to avoid inadvertent breakout in the fresh cancellous bone surfaces.
- Once the implant has been secured and the capsule repaired, do not manipulate by the thumb, as this may put undue stress on the soft tissue repair.
- After the procedure, before contaminating the sterile field, release the tourniquet and observe the reperfusion of the hand to ensure that no unexpected arterial injury occurred.

**Postoperative**
- Have a postoperative therapy protocol for patients to follow.
- The cast immobilization is discontinued at 6 weeks postoperatively if Artelon resurfacing has been used and at 2 weeks if CMC replacement has been performed. A custom Orthoplast thumb-based spica splint (Johnson & Johnson, New Brunswick, NJ) is worn full time for protection, except during showers and therapy.

POSTOPERATIVE CARE

- At the end of the surgery, the patient is placed into a thumb spica splint to keep the thumb in opposition. At 2 weeks postoperatively, the sutures are removed and placement into a thumb spica cast continues for 2 more weeks.
Formal therapy is usually not required after total joint replacement. In the case of resurfacing, therapy will focus on range-of-motion exercises only for postoperative weeks 4 to 6, advancing to thenar isometrics for weeks 6 to 8. At 8 weeks postoperatively, the patient will start grip and pinch strengthening exercises; the splint is also discontinued at this point.

**OUTCOMES**

Several long-term studies have shown better than 90% satisfaction and pain relief with soft tissue arthroplasties, but long-term outcome studies do not exist for the Artelon implant, and most of the literature for total joint arthroplasty for TM joint arthritis is not favorable.

**COMPlications**

- Superficial branch of the radial nerve injury
- Damage to flexor tendons during saw use
- Radial artery injury
- Dislocation or subsidence of total joint implant
- Subluxation of TM joint
- Continued pain or discomfort
- Failure to recognize other sources of pathology in the hand and wrist

**REFERENCES**

DEFINITION
- Arthrosis of the wrist often presents with functional movement, but with substantial disability due to pain. The purpose of wrist denervation is to decrease pain by surgically dividing the nerves that transmit the afferent pain signal from the wrist.

ANATOMY
- The posterior interosseous nerve (PIN) is considered to be the most important nerve innervating the wrist joint.
- Other nerves involved are branches from the anterior interosseous nerve (AIN), the radial nerve, the dorsal branch of the ulnar nerve, the palmar branch of the median nerve, and recurrent intermetacarpal nerve branches.

PATHOGENESIS
- Common causative conditions include scaphoid nonunion advanced collapse, scapholunate advanced collapse, degeneration secondary to crystalline arthropathy, inflammatory arthritis, and trauma.

NATURAL HISTORY
- The natural history of wrist arthrosis is slow progression, but the correlation between radiologic staging and symptoms is sometimes poor.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with wrist arthrosis present with wrist pain, weakness of the grip, swelling, and stiffness.
- Often there is a sensation of grating during wrist movement, and occasionally clicking or clunking.

Some patients report a history of wrist injury years previously, but many do not recall any wrist trauma.
- It is important to inquire about neurologic symptoms to identify any associated compressive neuropathy at the carpal tunnel, the canal of Guyon, or both.
- Examination of the wrist usually reveals dorsoradial swelling, loss of movement, weak grip strength secondary to pain, and crepitation.

Local Anesthetic Blocks
- Although controversial in the literature, selective injection of a local anesthetic can be used to predict the results of wrist denervation.
- Local anesthetic is injected about 1 cm ulnar and 3 cm proximal to the tubercle of Lister, delivering 1 mL Marcaine 0.5% around the PIN (FIG 1A). The needle is pushed forward through the interosseous membrane to deliver 1 cc of local anesthetic adjacent to the AIN.
- One cc Marcaine is then injected under the branches of the radial nerve (FIG 1B), under the dorsal cutaneous branch of the ulnar nerve (FIG 1C), under the palmar branch of the median nerve (FIG 1D), and finally between the base of the second and third metacarpals to block the recurrent intermetacarpal branches.
- The wrist is examined before the injections and again 20 minutes afterward. Baltimore Therapeutic Equipment is used where available.
- A decrease in pain rating by 90% and an increase in work output of more than 200% indicate a significant improvement.
- Patients with these results are considered good candidates for surgical denervation.

FIG 1 • One mL of 0.5% bupivacaine is injected to block the posterior and anterior interosseous nerves (A), the branches of the radial nerve (B), the branches of the dorsal cutaneous ulnar nerve (C), the palmar branch of the median nerve (D), and the branches of the intermetacarpal nerve. (Reprinted from Hunt T, Herlas-Palou C. Wrist denervation. In Chunk K. Operative Techniques: Hand and Wrist Surgery. Philadelphia: Elsevier, 2008:209–230.)
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Posteroanterior and lateral radiographs of the wrist confirm the degenerative changes in the wrist joint.
- If there is any doubt about the degree of degeneration, an advanced imaging study (eg, MRI) or wrist arthroscopy can provide more precise information, but these are seldom required.

DIFFERENTIAL DIAGNOSIS
- Wrist denervation is a good option for patients with wrist pain secondary to degeneration. It is important to rule out other causes of pain, such as infection.
- Patients with frank wrist instability and patients with active inflammatory arthritis are unlikely to benefit from wrist denervation.

NONOPERATIVE MANAGEMENT
- For patients with wrist degeneration, conservative management, including anti-inflammatory drugs and splints, should be tried before considering surgery.

SURGICAL MANAGEMENT
- Wrist denervation is indicated in a patient with considerable pain due to wrist degeneration, recalcitrant to conservative measures.
- Alternatives to wrist denervation include open or arthroscopic wrist débridement, radial styloidectomy, partial carpal arthrodesis, proximal row carpectomy, and wrist arthrodesis. Some of these procedures can be combined with a denervation.

Positioning
- The patient is positioned supine with the affected arm on a hand table, under regional block, with a high arm tourniquet, and the procedure is carried out under loupe magnification.

Approach
- Standard denervation of the wrist is carried out through four incisions: dorsal, dorsal–ulnar, volar–radial, and dorsal, over the base of the metacarpals.
- A partial denervation is carried out through one dorsal incision.

PARTIAL DENERVATION OF THE WRIST
- Partial denervation involves excision of the PIN with or without excision of the AIN just proximal to the radiocarpal joint.
- Make a 2-cm transverse dorsal incision 3 to 5 cm proximal to the wrist.
- Incise the fourth extensor compartment in a longitudinal direction and retract the extensor tendons ulnarward.
- Isolate the PIN on the radial floor of the fourth extensor compartment.
  - The PIN travels with the posterior interosseous artery and veins.
- Excise a 1-cm segment of nerve.²,³
- Retract the fourth compartment extensor tendons radially and make a small window in the interosseous membrane.
- Excise a segment of AIN just deep to the interosseous membrane.
- Close the extensor retinaculum with absorbable suture and close the skin in a routine manner.
- Apply a soft dressing with or without a temporary splint.

FULL DENERVATION OF THE WRIST
- A full wrist denervation involves four separate incisions (TECH FIG 1).

Incision 1
- Make the same transverse incision described for a partial denervation 3 to 5 cm proximal to the wrist on the dorsal forearm.
- If a more distal incision is used, some articular branches from the PIN may not be completely eliminated.
- Excise the PIN (TECH FIG 2A) and branches of the AIN (TECH FIG 2B) as discussed above.

Incision 2
- Make a 2- to 3-cm dorsal–ulnar incision over the wrist at the level of the ulnar head.
Dissect to the level of the extensor retinaculum.

In the subcutaneous flap, isolate the dorsal branch of the ulnar nerve along with its small articular branches to the wrist joint (TECH FIG 3).

Divide these small branches close to the point where they enter the extensor retinaculum.

**Incision 3**

- Make a 2- to 3-cm volar–radial incision centered over the radial artery at the level of the wrist and distal forearm.
- Resect a portion of perivascular tissue from around the radial artery.

**Incision 4**

- Make a 2-cm transverse incision over the dorsal base of the second and third metacarpals.
- Dissect through the fascia to expose and resect the recurrent intermetacarpal branches (TECH FIG 4).
- Close in standard fashion.
- Apply a soft dressing with or without a temporary splint.
PEARLS AND PITFALLS

| Indications | ■ Patients with wrist degeneration and substantial pain but some useful wrist movement  
|            | ■ Avoid denervation in patients with frank wrist instability or active inflammatory arthritis.  
|            | ■ Use local anesthetic blocks to help in patient selection.  |
| Options    | ■ Partial denervation  
|            | ■ Full denervation  
|            | ■ Denervation combined with other procedures  |
| Alternatives to denervation | ■ Arthroscopic or open wrist débridement  
|            | ■ Radial styloidectomy  
|            | ■ Partial carpal arthrodesis  
|            | ■ Proximal row carpectomy  
|            | ■ Wrist arthrodesis  |

POSTOPERATIVE CARE

■ Early range of motion is initiated but little formal therapy is required.  
■ A removable splint may be provided for comfort initially.  
■ Patients usually return to work 2 to 4 weeks after surgery.  

OUTCOMES

■ Wrist denervation is successful in providing pain relief in the long term in two thirds of patients.  
■ A partial wrist denervation seems to provide good results initially, but there is often deterioration after 12 months.  

COMPLICATIONS

■ Although there is a theoretical risk of causing a neuropathic Charcot joint, to our knowledge this has never been reported.  
■ This proves that a complete denervation of the wrist joint is never achieved.  
■ Neuroma formation has been reported in 2% of patients.  

REFERENCES

DEFINITION
- Arthritis between the radial styloid and the distal aspect of the scaphoid can lead to pain, weakness of grip, and limitation of motion. This arthritis can occur in the early stages of a variety of pathologic states of the radiocarpal joint.
- Radial styloidectomy is a technique that involves resection of the distalmost aspect of the articular surface of the distal radius.
- A radial styloidectomy can be performed as a distinct procedure via an open incision or by arthroscopic means. It is more commonly undertaken as an adjunct procedure with reconstructive or salvage procedures for scaphoid nonunions, carpal instabilities, Kienböck disease, or posttraumatic arthritis of the radiocarpal joint.9,17

ANATOMY
- The radial styloid is the distalmost projection on the lateral aspect of the terminal end of the radius (FIG 1A,B).
- When viewed from the lateral aspect, the styloid has a gentle slope volarly, placing it below the midcoronal longitudinal axis of the radius.
- The intra-articular component of the radial styloid encompasses part of the scaphoid facet.
- The extra-articular aspect of the styloid serves as the origin of several dorsal, palmar, and radial extrinsic ligaments that are vital to normal carpal kinematics (FIG 1C).
- The palmar radiocarpal ligaments serve as a constraint to radiocarpal pronation, ulnar translation, and distal pole scaphoid stabilization. Global disruption of this complex has been implicated in perilunate dislocation. The palmar radiocarpal ligaments are composed of the following structures:
  - The radial collateral ligament (RCL) is a thin structure that originates from the tip of the radial styloid and inserts into the waist and distal aspect of the scaphoid. The integrity of the ligament is always sacrificed with a radial styloidectomy, but no untoward effects have been reported.3,4
  - The radioscaphocapitate (RSC) ligament originates from the palmar cortex of the distal radius coursing distally and ulnarily, attaching to the waist and proximal cortex of the distal pole of the scaphoid and the body of the capitate.3,4
  - The long radiolunate ligament (LRL) originates from the palmar cortical margin of the distal radius immediately adjacent and medial to the RSC ligament. It is separated from the RSC by a distinct sulcus that serves an arthroscopic landmark.3,4
  - The dorsal radiocarpal (DRC) ligament originates broadly from the dorsal rim of the distal radius around the tubercle of Lister, coursing ulnarily, distally, and obliquely to insert on the dorsal tubercle of the triquetrum.
  - The radialmost fibers of this ligament also insert on the dorsal lunate.
  - The DRC ligament, in concert with the dorsal intercarpal ligament, has a crucial role in maintaining normal carpal kinematics and carpal stability and preventing ulnar translation of the carpus.3,4,15

FIG 1 • A,B. The radial styloid outlined on a standard PA and lateral wrist radiograph. C. Palmar and dorsal extrinsic ligaments of the radiocarpal joint. Note the broad origin of the dorsoradial ligament. The radial collateral ligament originates from the tip of the styloid. The radioscaphocapitate and long radiolunate ligaments are separated by a well-defined sulcus readily seen arthroscopically.
Siegel and Gelberman\textsuperscript{13} examined the effect of three different styloidectomy configurations on palmar radiocarpal ligament integrity in a cadaver model (FIG 2).

- The most conservative osteotomy (short oblique) removed only 9% of the RSC and none of the LRL ligaments.
- A vertical oblique osteotomy sacrificed 92% of the RSC and 21% of the LRL ligaments.
- A transverse styloidectomy was the most aggressive and resulted in loss of 95% of the RSC and 42% loss of the LRL ligaments.

Nakamura et al\textsuperscript{10} examined the effect of radial styloidectomy on carpal alignment and ulnar translation in cadaveric limbs. They demonstrated that as a larger segment of the radial styloid was resected (FIG 2), a greater tendency toward ulnar translation, as manifested by decreased stiffness, was observed. No frank ulnar translation with axial loading was observed.

- Based on their analysis, they recommended that no more than 3 to 4 mm of radial styloid should be resected. This correlated with a short oblique styloidectomy as described by Siegel and Gelberman.
- Although ulnar translation is a stated complication of overly vigorous styloidectomy, Viegas et al\textsuperscript{14} demonstrated in a cadaver model that ulnar translation can occur only with resection of the DRC, RSC, LRL, and SRL ligaments.

PATHOGENESIS AND NATURAL HISTORY

Scapholunate Instability

Watson and Ballet\textsuperscript{16} reviewed radiographs of individuals with scapholunate dissociation to establish the sequential progression of arthritis in the scapholunate advanced collapse (SLAC) wrist (FIG 3).

- SLAC I: Degenerative changes are confined to the radial styloid area.
- SLAC II: Changes are characterized by joint space narrowing involving the entire radioscapoid articulation.
- SLAC III: Changes involve additional arthritis between the capitate and lunate.

Several authors have examined the mechanics of scapholunate dissociation in cadaver models and have demonstrated that scapholunate instability leads to a shift in the contact pressures from the proximal pole of scaphoid articulation with the radial articular surface toward the distal pole of the scaphoid with the dorsal lip of the radial styloid.\textsuperscript{6,7} The pathomechanics of these changes can occur even before the frank radiographic appearance of scapholunate diastasis is present (ie, static scapholunate instability). Prolonged exposure to these abnormal contact stresses leads to the predictable arthritic changes described above.
■ Scaphoid nonunion
  ■ With an unstable scaphoid fracture, the proximal pole of the scaphoid remains firmly fixed to and extends with the lunate through an intact scapholunate interosseous ligament. The distal pole adopts a flexed posture, which can then impinge upon the radial styloid, leading to abnormal contact stresses and arthritic changes.
  ■ The natural history of scaphoid nonunion has not been established by rigorous prospective analysis. Nonetheless, most surgeons believe that unstable scaphoid fractures result in abnormal carpal kinematics with a dorsal intercalated segment instability (DISI) deformity and subsequent arthritis (scaphoid nonunion advanced collapse [SNAC] wrist).
  ■ Inoue and Sakuma reviewed 102 patients with scaphoid nonunions clinically and radiographically; they found that arthritis initially developed at the scaphoid–radial styloid articulation and subsequently the midcarpal joint. All patients had radiographic arthritis within 10 years of injury. They also demonstrated that although radiographic progression did not correlate with wrist pain, it did correlate with a decrease in grip strength and range of motion.

■ Impingement after triscaphe (scaphoid-trapezoid-trapezium) fusion
  ■ Rogers and Watson reviewed 93 patients after triscaphe fusion and found a 33% incidence of painful impingement between the fusion mass and the radial styloid that resolved after limited radial styloidectomy. They hypothesized that the fixed scaphoid could no longer be accommodated in the fossa and impacted upon the radial styloid.

■ Proximal row carpectomy
  ■ Although not all surgeons routinely perform a radial styloidectomy in the setting of a proximal row carpectomy, a recent cadaveric study demonstrated that radial deviation after proximal-row carpectomy was limited by impingement of the trapezoid on the radial styloid.

PATIENT HISTORY AND PHYSICAL FINDINGS

■ Patients with clinically significant radial styloid arthritis or impingement frequently complain of pain along the dorsal radial aspect of the wrist that is exacerbated by extension of the wrist or gripping activities. They may also note focal swelling or a decrease in the range of motion.
  ■ A complete physical examination of the radiocarpal, the midcarpal, and the first carpometacarpal joints is necessary to assess for associated conditions and to rule out alternative diagnoses.
  ■ Styloid impingement typically causes radial-sided wrist pain that is exacerbated by radial deviation, extension, and loading of the wrist.
  ■ Physical findings of styloid impingement are centered around the anatomic snuffbox (FIG 4).
  ■ The anatomic snuffbox is triangular, with its radial border formed by the extensor pollicis brevis tendon, its ulnar border by the extensor pollicis longus tendon, and its proximal border by the dorsal rim of the distal radius at the level of the styloid. The waist of the scaphoid and a small segment of the trapezium are palpable in the floor of the snuffbox, more readily with ulnar deviation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

■ Plain radiographs of the wrist
  ■ To diagnosis and stage SNAC and SLAC (FIG 5)
  ■ To rule out scaphoid fracture or other acute injury
  ■ Stress radiographs (clenched fist and radial–ulnar deviation posteroanterior) of the wrist can yield information concerning dynamic impingement between the scaphoid and the radial styloid.
DIFFERENTIAL DIAGNOSIS

- DeQuervain stenosing tenosynovitis: Tenderness usually extends along the extra-articular component of the radial styloid, proximally and radially over the first dorsal compartment. A positive Finkelstein test is highly suggestive of this disorder.
- Scapho-trapezoid-trapezial arthritis: focal tenderness in the distal-ulnar aspect of the snuffbox under the extensor pollicis long tendon along the axis of the second metacarpal
- Thumb carpometacarpal instability or arthritis: tenderness distal to the anatomic snuffbox that is worsened by loading of the thumb ray (CMC grind test)
- Scaphoid fracture: After an acute injury, special imaging (bone scan or MRI) may be required to rule out an acute scaphoid fracture.
- Preiser disease
- Inflammatory arthritis (ie, rheumatoid)
- Radial sensory neuritis or neuroma
- Tenosynovitis of the extensor carpi radialis longus and brevis
- Not uncommonly, styloid impingement coexists with other diagnoses, especially basilar thumb arthritis and De Quervain stenosing tenosynovitis.

NONOPERATIVE MANAGEMENT

- Individuals with chronic SLAC or SNAC wrist arthritis frequently present with acute pain after a recent injury. After obtaining an accurate medical history of prior injury and radiographic assessment, the chronicity of the problem is usually evident. In this situation, a course of conservative treatment with activity modification, nonsteroidal anti-inflammatory drugs, rest in a forearm-based thumb spica splint, and selective corticosteroid injection in the radial styloid area is appropriate.
- If the arthritic changes are truly isolated to the area of articulation between the scaphoid and the styloid, the surgeon may elect earlier operative intervention with the theoretical goal of slowing or preventing progressive arthrosis and the need for a more extensive reconstructive procedure.

SURGICAL MANAGEMENT

- Isolated radial styloidectomy is a limited procedure to treat the early stage of progressive posttraumatic arthritis. It cannot be expected to prevent its pathologic progression. It can also be employed as a temporizing solution in a low-demand individual or in a patient unfit or unwilling to undertake a more extensive procedure and postoperative rehabilitative course.
- In that instance, patient expectations with respect to motion and pain relief must be assiduously managed.
- Arthroscopic radial styloidectomy has the theoretical advantages of being minimally invasive and allowing more precise control of the level of bony resection to minimize injury to the palmar radiocarpal ligaments. In addition, arthroscopic evaluation of the radiocarpal and midcarpal joints can allow for diagnosis and treatment of concomitant intra-articular pathology. In some cases, final staging of the severity of articular degeneration can be made only by direct visualization with diagnostic wrist arthroscopy (FIG 6). An isolated radial styloidectomy or a more extensive reconstructive procedure can be done at the time of arthroscopy or at a later time, after the implications of the arthroscopic findings are discussed with the patient.

Positioning

- The patient is positioned supine on a stretcher with an attached hand table and the arm centered on the hand table with the shoulder abducted 90 degrees. A mini-fluoroscopy unit is draped in a sterile fashion and placed in a plane perpendicular to the hand table.
- For arthroscopic procedures, the arm is stabilized to the hand table with a strap that allows countertraction.
- The shoulder is abducted 90 degrees, the elbow is flexed 90 degrees, and finger traps are placed on the index and middle fingers.
- The forearm is suspended in a standard wrist traction tower with 8 to 12 pounds of traction employed.
- A mini-fluoroscopy unit is draped in a sterile fashion and placed in a plane parallel to and above the hand table.
- Alternatively, the hand can be suspended via finger traps using a nonsterile overhead traction boom (ie, an arthroscopic shoulder holder); in this case, the wrist traction tower will not be an impediment to intraoperative fluoroscopic assessment.

Approach

- A radial styloidectomy can be performed in conjunction with other reconstructive procedures such as proximal-row carpectomy, intercarpal fusion, or bone grafting for a scaphoid nonunion. In these instances, the primary procedure usually requires wide exposure through a standard dorsal approach to the wrist.
- An isolated styloidectomy can be performed through a limited radial incision.
- An arthroscopic styloidectomy can be performed through standard arthroscopic portals.
OPEN RADIAL STYLOIDECTOMY

- Palpate the distalmost aspect of the radial styloid on the volar radial aspect of the wrist. Make an incision from that point for 2 or 3 cm proximally and obliquely between the first and second extensor compartments (TECH FIG 1A).
  - Alternatively, a transverse incision may provide a more cosmetically pleasing scar but also may limit exposure.
- At this level, there will be arborization of the terminal branches of the radial sensory and lateral antebrachial cutaneous nerves in the subcutaneous tissue. Use blunt dissection and gentle retraction to expose the first and second compartments.
  - Distal placement of the incision may place the dorsal branch of the radial artery at risk and should be recognized.
- Incise the extensor retinaculum in the 1–2 interval and expose the radial styloid by subperiosteal dissection. Alternatively, the radius can be approached through the floor of the first compartment (TECH FIG 1B).
- Expose the radial styloid by sharp dissection (TECH FIG 1C).
- Using a sharp osteotome, remove the distal 3 to 4 mm of radial styloid. The plane of the cut should be perpendicular to the articular surface (TECH FIG 1D).
- Fluoroscopic imaging of the level of resection can be useful at this point in the procedure.
  - A narrow malleable retractor can be placed in the radiocarpal joint to prevent damage to the scaphoid as the styloid is being resected (TECH FIG 1E).
- After styloidectomy, fluoroscopic examination with the wrist in radial and ulnar deviation to assess for impingement confirms adequacy of the resection level (TECH FIG 1F,G).
- Loosely reapproximate the periosteum with resorbable suture, allow the extensor compartments to fall back into their anatomic position, and suture the skin. A bulky dressing and volar splint holding the wrist is applied.

**TECH FIG 1** - Open radial styloidectomy. A. A 2- to 3-cm oblique skin incision is made between the first and second extensor compartments. Note the branches of the radial sensory and lateral antebrachial cutaneous nerves. B. The first dorsal compartment is then opened. C. The radial styloid is extraperiosteally exposed by sharp dissection. D. An osteotome is used to resect the distal 3 to 4 mm of radial styloid. The osteotome should be angled perpendicular to the joint surface. E. The resected radial styloid is removed. F,G. Preoperative and postoperative PA radiographs of the wrist with early scaphoid nonunion advanced collapse [SNAC] undergoing open radial styloidectomy. (Courtesy of Dr. John J. Fernandez.)
**ARTHRITIS**

**POSTOPERATIVE CARE**
- If the radial styloidectomy is performed concomitantly with another reconstructive procedure (PRC, four-corner arthrodesis, scaphoid bone grafting and fixation), the rehabilitation is dictated by the requirements of that additional procedure.

- After either open or arthroscopic radial styloidectomy, the postoperative dressing and sutures are removed in 7 to 10 days. Early active, active-assisted, and passive motion is initiated under the guidance of a hand therapist. Usually a removable splint is used initially for patient comfort. As the patient’s symptoms permit, graded strengthening and unrestricted activities are allowed.

OUTCOMES

- Stubbins and Barnard\(^1\) first described a radial styloidectomy as part of an operative treatment strategy for scaphoid nonunion in 14 patients in 1948. They thought that the styloidectomy removed impingement, enhanced exposure of the scaphoid, and provided material for bone grafting from the same operative field. Since that time there have been no series of outcomes in the indexed English literature for outcomes after isolated open radial styloidectomy. Several reports of radial styloidectomy performed with open reduction and internal fixation of scaphoid nonunion or with triscaphe fusion have demonstrated good pain relief but no significant improvement in range of motion.\(^{12,16}\)

- Page et al\(^{11}\) presented their experience with the arthroscopic technique in 22 patients to the European Federation of National Associations of Orthopaedics and Traumatology in 2003. In short-term follow-up, they reported 75% good and satisfactory results.

- Radial styloidectomy is most often performed as a limited procedure to address posttraumatic arthritis of the wrist early in its pathogenesis. While it can provide long-lasting symptomatic relief, it cannot be expected to halt the progression of the arthritis. A successful radial styloidectomy could be one in which a more extensive reconstructive procedure was delayed by several years.

COMPLICATIONS

- Incomplete resection leading to persistent pain
- Excessive resection leading to extrinsic ligament incompetence and wrist instability with ulnar translation
- Nerve injury to the terminal branches of the radial sensory nerve or lateral antebrachial cutaneous nerve
- Arthrofibrosis
- Infection
- Complex regional pain syndrome

REFERENCES

DEFINITION
- Proximal row carpectomy (PRC) involves removal of the proximal carpal row (scaphoid, lunate, and triquetrum).
- PRC has been described as a treatment option for a number of pathologic conditions:
  - Scaphoid nonunion advanced collapse (SNAC) wrist
  - Scapholunate advanced collapse (SLAC) wrist
  - Kienböck disease
  - Chronic or missed perilunate dislocation
  - Scaphoid osteonecrosis or Preiser disease
  - Wrist deformity or contracture

ANATOMY
- The proximal row of the wrist consists of three bones: scaphoid, lunate, and triquetrum.
- The proximal row moves as a single unit through intercarpal ligamentous attachments and bony congruity.
  - The proximal row flexes with radial deviation and extends with ulnar deviation.
- The capitate, in the distal row, articulates with the lunate.
  - The proximal capitate articular surface is relatively, although not completely, congruous with the lunate facet of the radius.

PATHOGENESIS
- A number of pathologies may eventually result in wrist degeneration requiring PRC. Patients experience progressive pain and limitation in motion, often requiring PRC to improve symptoms.
  - SNAC and SLAC
    - Stage I: Degenerative changes along the radial half of the radioscaphoid articulation. In SNAC wrists, the degenerative changes are typically limited to the articulation between the distal scaphoid fragment and the radius.
    - Stage II: Degenerative changes involving the entire radioscaphoid articulation (FIG 1). In SNAC wrists, the articulation between the proximal scaphoid fragment and the radius is preserved, and instead stage II degeneration occurs in the scaphocapitate joint.
    - Stage III: Degenerative changes at the capitolunate joint. The radiolunate joint is spared.
  - Kienböck disease
    - Stage I: Normal plain radiographs with wrist pain and positive MRI finding
    - Stage II: Sclerosis without collapse of the lunate
    - Stage IIIa: Lunate collapse without instability
    - Stage IIIb: Lunate collapse with carpal instability
    - Stage IV: Fixed carpal instability with pan-carpal degenerative changes
  - Missed perilunate dislocation
  - Scaphoid osteonecrosis (Preiser disease)
  - Congenital or spastic wrist and hand flexion contractures may be so severe that a PRC allows deformity correction that tendon-lengthening procedures alone would be unable to correct.

PATIENT HISTORY AND PHYSICAL FINDINGS
- It is important to seek the cause of the wrist degeneration.
- Mechanical wrist pain is aggravated by use and relieved by rest. The history must support this for the proposed treatment to be successful.
- The history defines the patient’s symptoms, level of severity, and progression over time, as well as any previous attempts at treatment.
- Limited and painful wrist motion with diminished grip strength tends to be a common denominator regardless of the initial source of pathology.
  - Normal range of motion: wrist extension, 70 degrees; wrist flexion, 75 degrees; radial deviation, 20 degrees; ulnar deviation, 35 degrees
  - Normal grip strength: Mean grip for males is 103 to 104 for the dominant extremity and 92 to 99 for the nondominant extremity. Mean grip for females is 62 to 63 for the dominant extremity and 53 to 55 for the nondominant extremity.
  - Radioscaphoid joint line tenderness on palpation implies radioscaphoid arthritis.
  - Swelling over the dorsal and dorsoradial aspects of the wrist can be associated with radiocarpal and intercarpal arthritis. Most often dorsoradial wrist swelling will be visible and palpable in cases of SLAC and SNAC.

FIG 1 • Intraoperative photograph showing wear at the dorsal half of the scaphoid fossa seen with SLAC wrist, as indicated by the black arrow. Cartilage integrity is preserved in the lunate fossa, as indicated by the red arrow.
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs assist with making the underlying diagnosis (eg, SNAC wrist, SLAC wrist, Kienböck disease).
- The surgeon should evaluate the articular facets and surfaces, specifically of the proximal capitate and lunate facet of the radius.
- The surgeon should evaluate for other sources of limited wrist motion, diminished grip strength, and pain (eg, thumb carpometacarpal arthritis, scapholunate instability without degenerative changes, fracture).
- Although MRI may assist in making the underlying diagnosis (eg, Kienböck disease, Preiser disease, scaphoid avascular necrosis) and evaluating the joint surfaces, it is rarely used.

DIFFERENTIAL DIAGNOSIS
- Triangular fibrocartilage complex or distal radioulnar joint pathology
- Extensor carpi ulnaris, flexor carpi ulnaris, flexor carpi radialis tendinitis
- De Quervain tenosynovitis
- First carpometacarpal arthritis
- Scapholunate or lunotriquetral instability without degenerative changes
- Midcarpal arthritis

SURGICAL MANAGEMENT
- Regardless of the initial source of pathology when considering treatment via PRC, the integrity of the articular cartilage and the congruity between the proximal capitate and the lunate facet of the radius are critical. This determination is often made intraoperatively.
- Indications
  - SLAC and SNAC wrist degeneration: stage I, II, or III (only if the degenerative changes at proximal capitate are limited to thinning or minor fissuring)

Preoperative Planning
- Plain radiographs of the wrist should be reviewed. The surgeon should scrutinize the location of degenerative changes, should know the amount of radial styloid beaking (and potential need for radial styloidectomy), and should note any previous fractures or hardware (may need to be removed).
- The surgeon should discuss and obtain consent for alternative procedures from the patient (ie, if one should find excessive degenerative changes at the capitate, one might proceed with intercarpal arthrodesis).
- Regional anesthesia, general anesthesia, or a combination of the two (for postoperative analgesia) is suitable.

Positioning
- The patient is supine with the arm on a radiolucent armboard.
- A nonsterile tourniquet preset at 250 mm Hg is on the upper arm.
- The shoulder, elbow, and hand are positioned such that the hand rests in pronation at the center of the armboard (if a dorsal approach is planned).

INCISION AND EXPOSURE
- Make a dorsal longitudinal skin incision over the fourth dorsal compartment or a transverse incision across the dorsal wrist crease just distal to the tubercle of Lister.
  - The longitudinal incision is more extensile and versatile.
  - The transverse incision tends to be more cosmetic.
- Expose the extensor retinaculum.
  - Maintain full-thickness flaps when elevating soft tissues off the extensor retinaculum to minimize the risk of damage to the radial and ulnar sensory nerves (TECH FIG 1A).
  - Incise the extensor retinaculum in line with extensor pollicis longus (EPL) with scissors and transpose the EPL radially, dorsal to the retinaculum.
- Incise the radial septum of the fourth dorsal compartment and expose the wrist capsule by retracting the fourth compartment extensor tendons ulnarly and the EPL and radial wrist extensor tendons radially.
- Look for the distal extent of the posterior interosseous nerve (PIN) in the proximal portion of the incision on the radial floor of the fourth compartment. Perform a PIN neurectomy after coagulating the accompanying vessels. Create a distally based “inverted-U” capsular flap by first incising the wrist capsule transversely over the radiocarpal joint (from radial to ulnar) and then, at the margins, extending the incision distally (TECH FIG 1B).
  - Making a U-shaped capsular hood provides flexibility should one elect to add a dorsal capsular interposition arthroplasty in the setting of mild midcarpal arthroplasty.
  - The dorsal branch of the radial artery is radial to the second compartment, so take care at the radial aspect of the capsulotomy.
- Inspect the articular cartilage on the proximal capitate and lunate facet of the radius for any degenerative changes.
  - If the cartilage is in good condition, proceed with PRC; if not, consider alternative procedures (TECH FIG 1C).
ARTHRITIS

A. Superficial branches of the radial nerve and the dorsal cutaneous branch of the ulnar nerve. The dorsal branch of the radial artery is in danger deeper in the dissection as the wrist joint capsule is incised. B. Intraoperative photograph showing the distally based U-shaped dorsal capsular flap. This flap is centered over the capitate. The radial margin is just adjacent to the ulnar border of the extensor carpi radialis brevis tendon. The proximal margin is taken directly off the dorsal lip of the radius. (Red arrow points to distal articular surface of the hamate; the triquetrum has not yet been removed. Black arrow points to the dorsal lip of scaphoid fossa.) The ulnar margin is just radial to the extensor digiti minimi. C. Wear on the ulnar aspect of the head of the capitate is visualized in this case. (Arrow points to a cartilage defect on the capitate head.) Arthrosis affecting the non-weight-bearing portion of the capitate does not preclude the use of a proximal row carpectomy but one may want to include a capsular interposition. This is usually employed in older, lower-demand individuals.

TECHNIQUES

CARPECTOMY

- Precisely ensure the anatomy and which bones are to be removed.
  - Consider intraoperative fluoroscopy if there is any question.
- Note the location of the radioscaphocapitate ligament at the waist of the scaphoid. Protect it and the other volar extrinsic ligaments while removing the proximal carpal row.
- Avoid iatrogenic injury to the cartilaginous surfaces of the capitate head and lunate facet of the radius.
- Osteotomize the scaphoid at its waist with a straight osteotome to facilitate scaphoid excision.
  - Place the osteotome such that it parallels the flexor carpi radialis tendon to minimize the risk of transection (TECH FIG 2A,B).
- The distal pole of the scaphoid is particularly difficult to remove (especially with SNAC wrist deformities).
  - Consider using a threaded Kirschner wire (0.062 inch) or a large threaded Steinmann pin (5/32 inch) as a joystick to control the bone to be removed (TECH FIG 2C).
  - Try to create tension between the proximal carpal bones during dissection (a combination of no. 15 blade; Beaver blade; periosteal, Freer, or Carroll elevator; and small straight or curved curettes is valuable; TECH FIG 2D).
- If possible, remove the carpal bones whole rather than piecemeal. This facilitates removal when possible and ensures that no portions are left behind (TECH FIG 2E).
ASSESSMENT OF REDUCTION AND IMPINGEMENT

- Once the proximal row is removed, seat the capitate into the lunate facet on the radius to evaluate congruity.
- Check for impingement between the trapezium and radial styloid with extreme radial deviation.
- The trapezium has been shown to be volar to the styloid, making impingement less common than once thought.
- If radial-sided impingement is a concern, proceed with a radial styloidectomy.

RADIAL STYLOIDECTOMY

- See Chapter HA-86.
- Elevate the tendons of the second and then the first extensor compartments off the radial styloid through the same dorsal incision.
  - Take care to avoid injuring the dorsal branch of the radial artery just radial to the second dorsal compartment.
- The styloidectomy can be performed from proximal-radial to distal-ulnar with a straight osteotome (remove no more than 5 to 7 mm) (**TECH FIG 3**).

**TECH FIG 3** - The amount of radial styloid that is removed and the direction of the osteotomy. The origin of the radioscaphocapitate ligament is carefully preserved.
### TECHNIQUES

#### WOUND CLOSURE

- Close the capsule with nonabsorbable 2-0 suture.
- Plain radiographs or fluoroscopic images should be obtained in AP and lateral planes to ensure that the capitate is seated in the lunate fossae.
  - While uncommon, radiocarpal subluxation is possible with a PRC.
  - Maintenance of the volar ligaments (especially the radioscaphocapitate, which is most at risk during removal of the scaphoid) minimizes any risk of radiocarpal instability after PRC.
- Close the retinaculum with nonabsorbable 3-0 suture, leaving the EPL superficial to the retinaculum.
- Consider placing a drain in the subcutaneous tissues, to be removed in 24 to 48 hours.
- Close the skin with a 3-0 nonabsorbable running subcuticular Prolene stitch with “rescue loops” to facilitate removal at 10 to 14 days.
- Cover the incision with nonadherent gauze.
- Fashion a sugar-tong splint over a bulky dressing.
- Keep the fingers and the thumb free proximal to the metacarpophalangeal joints.
- Hold the wrist at neutral or slight extension (10 degrees).

#### PROXIMAL ROW CARPECTOMY WITH INTERPOSITION ARTHROPLASTY

- If mild to moderate chondral changes are noted on the capitate head, a PRC may still be indicated with the addition of an interpositional arthroplasty between the capitate head and lunate fossae.
- Use the previously created distally based inverted U-shaped capsular flap as the interpositional material.
- Place three simple stitches (2-0 PDS) connecting the dorsal capsular flap to the palmar capsule.
- Place and tag all stitches into the dorsal capsule (passing from deep to superficial) and into the palmar capsule (passing from proximal to distal) before tying them down to the palmar capsule (TECH FIG 4A).
- Loosely reapproximate the lateral margins of the dorsal flap to the residual dorsal capsule after interposing the dorsal capsule (TECH FIG 4B).
- Postoperative management is not altered.

### TECH FIG 4 • A. Sutures are passed in a mattress fashion through dorsal capsule, volar capsule, and then dorsal capsule to interpose the dorsal capsular flap between the capitate and lunate fossa. (Arrow points to the head of the capitate.) B. The dorsal capsule interposed between the capitate (shown above) and the radius (shown below) after the PDS sutures have been tied down.

| Damage to the radial sensory and dorsal ulnar sensory branches | Dissect directly down to the extensor retinaculum and elevate subcutaneous fat in full-thickness flaps off the extensor retinaculum to minimize the risk of nerve injury. |
POSTOPERATIVE CARE

- PRC tends to be an outpatient procedure; an overnight stay may be necessary for postoperative pain or nausea.
- A short splint is applied in the operating room with the wrist in neutral and the fingers and thumb free at the metacarpophalangeal joints.
- Passive thumb and finger motion is encouraged immediately postoperatively, along with elevation and ice for the first 48 hours.
- At the first postoperative follow-up visit (in 10 to 14 days) the splint is removed, plain wrist AP and lateral radiographs are obtained to ensure the capitate is located in the radial lunate facet, and sutures are removed.
- At 2 weeks postoperatively, gentle active wrist extension and flexion and radioulnar deviation are added and a removable cock-up wrist splint or custom Orthoplast wrist splint is worn between exercises.
- Scar massage can begin once the incision is healed.
- Edema control may be necessary with compressive dressings.
- The removable splint can be removed as the patient feels comfortable (typically in 3 to 4 weeks).
- At 6 weeks, objective measurements of wrist extension, flexion, radioulnar deviation arcs, grip and pinch strength should be obtained.
- Therapy is initiated if the patient seems to be struggling to regain wrist or finger motion.
- At 3 months, full activities are encouraged.

OUTCOMES

- A broad range in grip strength outcome has been reported postoperatively.
- 60% to 100% grip strength of the contralateral wrist (and a 20% to 30% increase in postoperative grip versus preoperative grip) can be expected.3,7
- A decrease in postoperative wrist motion can be expected, as well as a decrease in flexion extension by 20%, a decrease in radioulnar deviation by 10%,3 and a 72- to 75-degree arc of motion in flexion and extension.2,7
- Satisfactory pain relief can be expected in 80% to 100% of patients.3,5
- Return to work for manual laborers after PRC has been unpredictable, varying from 20% in one series3 to 85% in another.5
- Age less than 35 years has been shown to be predictive of early failure with PRC.

COMPLICATIONS

- Incomplete removal of the carpal bones (typically distal scaphoid)
- Use of pins has been associated with pin site infections and rapid degenerative changes when placed through the radiocapitate articulation (because of this, pins are not routinely recommended as they once were).
- Reflex sympathetic dystrophy
- Excessive styloidectomy and compromise of the radioscaphocapitate ligament
- Compromise of the radioscaphocapitate ligament can lead to ulnar carpal subluxation.
- Conversely, failure to check intraoperatively for radial-sided impingement may lead to radial-sided wrist pain postoperatively.
- Damage to sensory nerves (radial sensory and dorsal ulnar branches)
- Progressive arthritis

REFERENCES

DEFINITION

- Limited wrist arthrodeses are salvage procedures for post-traumatic and degenerative conditions of the wrist as well as symptomatic instabilities.
- The goal is to reduce pain by selected fusion of the affected joints, thereby sparing motion, and improving the function of the remaining joints.

ANATOMY

- The carpus consists of four bones in the proximal row (scaphoid, lunate, triquetrum, pisiform) and four bones in the distal row (trapezium, trapezoid, capitate, hamate).
- The scaphoid and lunate bones are intimately joined by the scapholunate ligament both dorsally and volarly. This ligament is the keystone to the motion of the wrist.
- Numerous other named ligaments hold the carpal bones stable as the wrist moves through its five planes of motion (flexion, extension, radial and ulnar deviation, and circumduction).
- Most reconstructive wrist procedures require a dorsal approach to the wrist. The wrist and finger extensor tendons are separated into six compartments by the dorsal extensor retinaculum. The most common interval for exposure of the wrist is the 3–4 interval between the extensor pollicis longus and extensor digitorum communis tendons.

PATHOGENESIS

- Distraction forces across the joint and twisting motions while the wrist joint is being loaded can lead to a ligament injury.
- Failure of the scapholunate interosseous ligament, either by trauma or inflammatory arthritis, allows the scaphoid to flex and the lunate to extend, leading to dorsal intercalated segment instability.17,30 When this occurs, abnormal loading of the carpal bones results. This leads to degenerative arthritis, particularly at the radioscaphoid joint due to the abnormal distribution of force across this elliptical joint.7 This has been termed scapholunate advanced collapse (SLAC).
- Scaphoid nonunion advanced collapse (SNAC), perilunate dislocations, calcium pyrophosphate dihydrate deposition, and rheumatoid arthritis can also lead to this pattern of arthritis.
- Other ligament injuries, Kienböck disease, and localized arthritis can lead to wrist pain, instability, and deformity.

NATURAL HISTORY

- Much of our knowledge of the natural history of scaphoid nonunion was reported by Mack et al.18 We have learned that most ununited fractures of the scaphoid and SLAC wrists develop progressive osteoarthritis in a predictable pattern.
- Cyst formation and bony resorption are the hallmarks of arthritis and are usually seen 5 to 10 years after injury.
- Arthritis of the radioscaphoid joint can appear within a year after scaphoid nonunion. At that point most patients become symptomatic.12,28

PATIENT HISTORY AND PHYSICAL FINDINGS

- Typically, the patient describes a traumatic injury to the wrist. The absence of trauma should not exclude traumatic causes.
- Painful wrist motion and a limited arc of motion are common findings.
- Methods for examining the wrist include the following:
  - Finger extension test. The wrist is passively flexed while the examiner resists active finger extension. A positive test yields pain and may represent periscaphoid inflammatory changes, radiocarpal or midcarpal instability, or Kienböck disease. A negative test essentially excludes dorsal wrist syndrome, Kienböck disease, midcarpal instability, and SLAC as the cause of pain.
  - Anatomic snuffbox palpation. The examiner palpates the anatomic snuffbox with the index finger while moving the wrist from radial to ulnar deviation. A positive test yields severe pain at the articular–nonarticular junction of the scaphoid. Periscaphoid synovitis, scaphoid instability, and radial styloid arthrosis from SLAC are possible causes.
  - Triscaphe (scaphoid–trapezium–trapezoid [STT]) joint palpation. The examiner palpates the second metacarpal proximally until it falls into a recess, the triscaphoe joint. Pain with palpation indicates pathology of the distal scaphoid or the triscaphoe joint.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs, including AP, lateral, oblique, and scaphoid views, should be obtained.
- The stage of wrist arthritis, as seen on plain radiographs, helps to determine the treatment options. Watson and Ballet classified the radiographic findings into stages I–III.
  - Stage IV, not originally described, demonstrates arthritis in most all joints of the wrist. Fortunately, the radiolunate joint is rarely involved and serves as the basis for several treatment options.
  - Arthritis involving the radiolunate joint is usually seen only in patients with inflammatory wrist arthritis.

DIFFERENTIAL DIAGNOSIS

- SNAC
- SLAC
- Arthritis after perilunate dislocation
- Gout
- Pseudogout
- Rheumatoid arthritis
- Infectious arthritis
- Kienböck disease

NONOPERATIVE MANAGEMENT

- Nonoperative measures include rest, anti-inflammatory medications, splinting, occasional casting for flare-ups of arthritis, and cortisone injections.
SURGICAL MANAGEMENT

- **Indications**
  - Four-corner (capitate–hamate–lunate–triquetral [CHLT]) arthrodesis
  - Stage II or III SLAC wrist arthritis
  - Chronic symptomatic volar intercalated segmental instability (VISI) deformity or midcarpal instability
  - STT arthrodesis
    - Chronic static or dynamic scapholunate instability
    - Scapho–trapezium–trapezoid arthritis
    - Kienböck disease
    - Radiocarpal instability
  - Lunotriquetral arthrodesis
    - Lunotriquetral ligament tears
    - Posttraumatic instability
  - Scapholunate arthrodesis
    - Posttraumatic instability
    - Scapholunate instability
    - Dorsal intercalated segmental instability (DISI) deformity
  - Scaphocapitate arthrodesis
    - Scaphoid nonunion
    - Chronic DISI deformity with rotatory scaphoid instability
    - Kienböck disease
    - Lunate nonunion
  - Radiolunate arthrodesis
    - Rheumatoid arthritis primarily involving the radiolunate joint
    - Ulnar translocation of the carpus (relative indication)

Preoperative Planning

- The patient’s history and pertinent physical examination findings are reviewed.
- Any prior surgical scars are noted.
- All radiographs are reviewed, noting any associated pathology that might need to be simultaneously addressed to yield the best outcome.
- Postoperative pain control should be discussed with the patient and the anesthesia team, and a local or axillary block should be considered for prolonged pain relief after surgery.

Positioning

- The patient is placed in the supine position on the operating table with the arm draped to the side on a radiolucent armboard.
- A tourniquet is used to control bleeding during the procedure.

Approach

- The wrist is approached through a dorsal longitudinal incision between the third and fourth extensor compartments.
  - Alternatively, the 4–5 extensor compartment interval may be used to better visualize the lunate–triquetrum–capitate–hamate articulations.
  - The extensor pollicis longus (EPL) tendon sheath is opened and it is released both proximally and distally. The tendon is allowed to be transposed out of its compartment in a radial direction.
  - Although the EPL tendon is typically exposed and subsequently transposed, a more limited incision beginning just distal to the tubercle of Lister and proceeding distally may avoid significant exposure of the EPL tendon altogether.
  - All joints are exposed fully and a precise decortication is performed down to bleeding bone.
  - In almost every case, bone graft is harvested from the distal radius and used to augment the fusion.
  - Iliac crest graft may be substituted but is associated with higher morbidity.

FOUR-CORNER (CHLT) ARTHRODESIS USING KIRSCHNER WIRE FIXATION

- Make a standard dorsal longitudinal incision between the third and fourth extensor compartments using the tubercle of Lister as a landmark (TECH FIG 1A).
- Incise the retinaculum over the third extensor compartment.
- Incise the radial septum of the fourth extensor compartment and retract the tendons ulnarily.
- Perform a ligament-splitting dorsal approach to the carpus as described by Berger et al.4
  - This capsular incision allows access to the carpus while preserving the dorsal intercarpal ligament and dorsal radiotriquetral ligament (see Chap. HA-44).
  - Inspect the radiolunate joint for articular cartilage wear (TECH FIG 1B).

TECH FIG 1 • A. Skin incision is centered just ulnar to the tubercle of Lister. (Fingers are to the right or bottom in all intraoperative photos.) B. The radiolunate joint should be inspected for arthritis. If lunate cartilage is not preserved, a total wrist fusion may be required. (continued)
Identify and excise the scaphoid either piecemeal with a rongeur or sharply using a scalpel (TECH FIG 1C).
- Kirschner wires and tenaculum clamps facilitate the visualization and excision of the distal volar scaphoid.
- Take care to protect the volar radioscapophacitate ligament.
- Once the scaphoid is excised, decorticate the opposing joint surfaces of the lunate, triquetrum, capitate, and hamate (TECH FIG 1D).
- Longitudinal traction with fingertraps helps to distract these joints, making decortication easier.
- Thorough removal of the volar-third cartilage from the lunate and capitate facilitates correction of the pre-existing DISI deformity but shortens the intercarpal bone distances. This may restrict final wrist range of motion.
- Once these joint surfaces are denuded, harvest distal radius bone graft and place it into the fusion bed.

Use a 0.062 Kirschner wire to joystick the lunate into a more flexed position, and apply dorsal pressure to volarly translate the capitate on the lunate. Place one or two 0.062 Kirschner wires across this joint (TECH FIG 1E).
- Verify correction of the DISI deformity using fluoroscopy.
- Pin the lunotriquetral joint and the capitohamate joint with two 0.062 Kirschner wires (TECH FIG 1F).
- Intraoperative fluoroscopic images should reveal a stable triangular construct of Kirschner wires traversing the four bones (TECH FIG 1G,H).
- The Kirschner wires may be cut under the skin or left external, depending on the surgeon’s preference.
- After irrigation, close the capsule with absorbable suture, and repair the extensor retinaculum, leaving the EPL tendon transposed subcutaneously.
- Close the skin in a routine manner.
- Apply a large bulky dressing including a dorsal and volar forearm-based splint.

FOUR-CORNER ARTHRODESIS USING A CIRCULAR PLATE9,13,29

The approach, scaphoid excision, and joint preparation are analogous to those described above.
- Place a 0.062 Kirschner wire through the distal radius articular surface. Use a separate 0.062 Kirschner wire as a joystick to hold the lunate reduced in neutral alignment while advancing the Kirschner wire across the radiolunate joint in a dorsal to volar direction.
- Obtain fluoroscopic images to verify correction of the dorsally tilted lunate.
- After volarly translating the capitate (as described above) and fully correcting the DISI deformity, secure the triquetrum to the hamate and the lunate to the capitate with two additional Kirschner wires.
- Place these Kirschner wires as volar as possible to avoid interference during rasping and plate placement.
- Center the power rasp over the four bones in the AP and lateral planes and bury the rasp down to subchondral bone.
Ideal rasp placement does not always coincide with the central point between the four bones.
- Pack bone graft, obtained preferably from the distal radius or iliac crest, between the four prepared bones.
- Center the plate over the four bones in the AP and lateral planes and place the circular plate into the bony crater created by the rasp.
- Rotate the plate to maximize screw purchase into each of the four bones. Two screws should be planned for each of the four carpal bones.
- All screws must be placed in a unicortical fashion.
- Place the first screw through the plate into the lunate. Do not tighten this screw completely or it will cause the circular plate to tilt up and compromise screw fixation in the remaining bones.
- Place a second screw into the hole opposite the first screw. This sets the plate position.
- Check a lateral fluoroscopic image to ensure the plate is well seated and there is no impingement with wrist extension.
- Fill in the remainder of the holes with screws.
- Placing the screws opposite one another and tightening them sequentially helps prevent malpositioning of the plate.
- Obtain final images to check screw length and position, carpal reduction, and construct stability (TECH FIG 2).
- Close the wound as described above. Apply the dressing and splint.

### SCAPHOID–TRAPEZIUM–TRAPEZOID (STT) FUSION

- Make a transverse or dorsoradial incision centered over the STT joint.
- Protect the superficial radial nerve branches, and coagulate the small perforators from the dorsal branch of the radial artery (TECH FIG 3A).
- Make a longitudinal capsulotomy over the STT joint, and reflect the capsule to expose the bone surfaces (TECH FIG 3B).
- Verify scaphoid alignment with fluoroscopy. The ideal scapholunate angle is 41 to 60 degrees.
Failure to correct this malalignment could lead to persistent pain. Overcorrection of an increased scapholunate angle may limit postoperative motion.

C. Kirschner wire position in the trapezium and trapezoid bones before advancement into the scaphoid bone. A separate pin traversing the trapezio-trapezoidal joint is added for stability.

Remove only the dorsal 70% of the articular cartilage from the three bones. Preserving the volar 30% maintains the intercarpal bone distances but still ensures successful fusion. Perform a radial styloidectomy. Resect no more than 3 or 4 mm of the styloid to avoid iatrogenic injury to the origin of the radioscaphocapitate and long radiolunate ligaments. Fixation may be accomplished with Kirschner wires or a circular plate. Place two 0.045 Kirschner wires anterograde into the trapezium and trapezoid (TECH FIG 3C). Add a third 0.045 Kirschner wire in an ulnar to radial direction from the trapezoid toward the trapezium. The above wires are preset in place and should be advanced across the joints after bone graft placement. Harvest cancellous bone graft from the distal radius and pack it into the interstices of the STT joints. Reduce the joints and advance the preset Kirschner wires. The Kirschner wires can be cut and buried under the skin or left out of the skin to facilitate removal. Perform a routine closure and apply a well-padded forearm-based thumb spica splint.

TECH FIG 4

A. Lunotriquetral joint during decortication. (Fingers are at top in all images.) B. Lunotriquetral joint fusion construct with a partially threaded cannulated screw and a derotation pin.

LUNOTRIQUETRAL FUSION

Make a transverse incision over the dorsal and ulnar aspect of the radiocarpal joint. Retract the extensor tendons and incise the capsule transversely to expose the lunotriquetral joint. Remove any remaining lunotriquetral ligament with a small rongeur. Decorticate the lunotriquetral articulation, leaving the volar 25% of the joint surface intact to maintain intercarpal distances (TECH FIG 4A). Harvest distal radius bone graft and pack it into the void created. Place two cannulated screw guidewires through the triquetrum, and after reducing the joint, advance the pins across the lunotriquetral joint into the lunate. Verify pin position using fluoroscopy. Advance two partially threaded cannulated screws over the guide pins across the lunotriquetral joint (TECH FIG 4B). Make sure the thread length on the screw is short enough to allow compression across the lunotriquetral joint. Alternatively, headless screws, staples, or Kirschner wires may be used for fixation. Perform routine wound closure and apply a wrist splint.

SCAPHOLUNATE FUSION

Use a standard dorsal incision ulnar to the tubercle of Lister and perform a longitudinal capsular incision. Place two dorsal joystick Kirschner wires, one into the palmar-flexed scaphoid distally, directed proximally and ulnarly, and a second into the dorsiflexed lunate proximally, directed distally. When these two wires are brought together the joint is reduced.
Decorticate the bone surfaces and obtain bone graft from the distal radius.
Reduce the scaphoid and lunate with the Kirschner wires and hold them in place with a Köcher clamp.
Verify scapholunate reduction via fluoroscopy before proceeding.

SCAPHOCAPITATE FUSION^3,27

- Use the 3–4 extensor compartment approach followed by a longitudinal capsulotomy directly over the scaphocapitate interval between the second and fourth compartments.
- Denude the articulating scaphoid and capitate surfaces of articular cartilage down to bleeding cancellous bone.
- For cannulated screw fixation, make a V-shaped incision on the radial aspect of the wrist superficial to the radial styloid. A styloidectomy performed through this incision creates a superior view of the lateral aspect of the scaphoid. Preset two guidewires in the scaphoid, aimed toward the capitae (radial to ulnar).
  - A radial styloidectomy is an option to facilitate accurate positioning of the Kirschner wires.
  - Compression screws (our preference), Kirschner wires, or staples may be used for fixation.
- Harvest distal radius cancellous bone graft and place it between the two prepared bones.
- Reduce the articulation, advance the guidewires, and verify pin placement with fluoroscopy.
  - Obtain a scapholunate angle of about 45 degrees.
- Advance the threaded compression screws across the scaphocapitate joint (TECH FIG 5).

**Pitfalls**

- A Kirschner wire inserted into the dorsal lunate may be used as a joystick to effect correction.
- Stabilize the lunate in the reduced position with provisional Kirschner wires from the radius into the lunate.
- Harvest bone graft from the distal radius or iliac crest and pack the graft tightly into the palmar radiolunate joint.
- Secure the lunate to the radius with Kirschner wires, headless screws, staples, or small blade plates.
- Pack the remaining bone graft into the dorsal radiolunate joint.
- Perform a routine closure and apply a splint.
POSTOPERATIVE CARE

- The sutures are removed from the wound in 10 to 14 days and a short-arm cast is applied.
- Immobilization is typically 8 to 12 weeks, but this period may be shortened if stable fixation is obtained with screws.
- Plain radiographs are taken at the first postoperative visit and at all subsequent visits until signs of consolidation at the fusion site are noted.
- At this time, the pins are removed and a functional brace is applied to support the wrist but still allow controlled range of motion of the wrist during supervised therapy.
- Strengthening begins about 12 to 16 weeks after surgery.

OUTCOMES

- Nonunion rates range from 4% to 63%, depending on the joints being fused and the stresses placed across the joints before fusion.\(^5,11,16,20\)
- For limited wrist fusions, a loss of grip strength on the order of 25% can be expected.\(^5,11,16,20\)
- About 50% of patients will have some chronic wrist pain.\(^5,11,16,20\)
- For stage I and II SLAC arthritis, four-corner arthrodesis yields clinical results comparable to those of proximal row carpectomy (FIG 1).\(^10,23,30\)
- Stage III SLAC arthritis can be managed with either a four-corner fusion or a proximal row carpectomy with dorsal capsular interposition.\(^23\)

---

**FIG 1** • Nine-year follow-up of four-corner fusion. A,B. Maximal active wrist extension and flexion. (continued)
In patients 35 years of age or younger at the time of proximal row carpectomy, subjective and objective function may decline over time, and they may eventually require a wrist fusion. Circular plate fixation for capitate–lunate–triquetrum–hamate fusion is a newer trend. Weiss et al reported a union rate approaching 100% and high patient satisfaction. However, several subsequent studies have documented higher nonunion rates, higher hardware failure rates, higher pain scores, and an overall lower rate of patient satisfaction compared to other traditional methods of fixation.

**COMPLICATIONS**

- Pin tract infections
- Osteomyelitis
- Avascular necrosis of the lunate
- Radiolunate arthritis
- Reflex sympathetic dystrophy
- Tendon ruptures
- Persistent wrist pain
- Nonunion
- Fracture through fusion
- Neuapraxia
- Hardware failure
- Neuroma
- Pseudarthrosis

**REFERENCES**

**FIG 1 (continued)** C, D. AP and lateral radiographs.

DEFINITION
- Wrist arthritis occurs when the codependent joints of the wrist lose the ability to rotate, thereby impairing normal wrist kinematics.
- Wrist arthritis can originate from many causes, including osteoarthritis, degenerative arthritis, and inflammatory arthritis.
- While sacrificing motion at the wrist, arthrodesis has been shown to reliably relieve pain.

ANATOMY
- The wrist is perhaps the most complex set of joints in the body.
- The eight bones of the wrist work together to provide motion in multiple planes, governed by the complex array of soft tissue ligaments that unite them.
  - Single ligament disruptions can cause degenerative change in nonadjacent bones and at times unlikely sites.
- In broad terms, the wrist is divided into two distinct rows of bones.
  - The distal row, including the trapezium, trapezoid, capitate, and hamate, is united to the hand and shows little gross motion relative to the metacarpals.
  - As such, the most significant articulations in the wrist occur in the proximal row bones, which are the scaphoid, lunate, and triquetrum. These proximal row bones allow the wrist to flex, extend, deviate both radially and ulnarily, and pronosupinate.

PATHOGENESIS
- Because of the many possible routes to the eventual destruction of the wrist joint, it is difficult to describe a single chain of events that leads to end-stage arthritis, most suitably treated by complete wrist fusion.

NATURAL HISTORY
- Causes of wrist degeneration and the often-predictable pattern and pace of wear are detailed in other chapters.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients describe pain and stiffness as their major reasons for presentation. Pain limits their function and their strength.
  - Most patients are less concerned with motion loss if their dominant extremity is not involved.
  - If their dominant wrist is involved, patients prefer to preserve some motion even if faced with low-grade persistent pain after treatment. In this clinical setting complete wrist fusions are less often performed as the index operation.
- Physical examination findings include tenderness, soft tissue swelling, loss of motion, and pain with motion. Pinch and grip strength are reduced compared with age-matched peers and the uninvolved contralateral extremity.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Wrist arthritis is best studied with standard posteroanterior and lateral radiographs of the wrist.
  - These images often reveal the cause of the degeneration together with its pattern and progression.
  - Special attention is paid to the alignment of the wrist and the bone stock available for fusion and fixation.
  - Computed tomography helps plan limited fusions or salvage procedures when arthritis may have spared areas of the midcarpal or proximal carpal rows.

DIFFERENTIAL DIAGNOSIS
- Limited wrist arthritis
- Extrinsic joint contracture (including calcific tendinitis)
- Inflammatory arthritis and synovitis (ie, rheumatoid, gout, or pseudogout)
- Infection
- Connective tissue diseases

NONOPERATIVE MANAGEMENT
- In most every case, the first form of treatment for wrist arthritis is nonoperative:
  - Nonsteroidal anti-inflammatory medications (NSAIDs)
  - Disease-modifying medications (if the cause of the degenerative process can be identified and is appropriate)
  - Splinting
    - A custom-made thumb spica splint allows interphalangeal motion of the thumb but limits painful wrist motion.
  - Local steroid injections placed in the wrist

SURGICAL MANAGEMENT
- Alternative motion-sparing procedures, including partial wrist fusions and proximal row carpectomy, should be considered before performing a complete wrist fusion, especially in patients who have at least 60 degrees of wrist flexion–extension and have isolated articular degeneration.
- Wrist arthroplasty remains in its infancy and is associated with high revision rates and frequent implant design changes.
- Wrist arthroplasty after arthroplasty is more difficult due to bone stock loss.
- Wrist arthrodesis after arthroplasty is the final treatment method for end-stage wrist degeneration due to multiple causes or as a salvage procedure in patients who have failed the more limited procedures mentioned above.
  - Arthrodesis can be obtained reliably and provides a stable wrist in a high-demand patient.1,2,11,13
  - In patients who have undergone lower extremity joint replacements and therefore require support for ambulation, fusion of the wrist is generally regarded as a reliable procedure.
The two most popular methods used to fuse a wrist are plate osteosynthesis and rod osteosynthesis.2,8,13

The chief considerations when choosing between these two options are the desired position of fusion, the quality of the bone and available soft tissue coverage, and the possibility of future infection.

The strongest grip is achieved when the wrist is fused in 20 to 30 degrees of extension. Advocates of fusion in this position favor the use of a plate and screw construct that is fabricated to reproduce this position.2,3,5,11 Straight wrist fusion plates are also available, and all these devices include screws and plates that match the size of the radius and the metacarpal.

A neutral wrist position obtained with rod osteosynthesis may be more favorable for activities of daily living, including perineal care.2,3,5,11

Plate and screw constructs rely on solid screw purchase and stable soft tissue coverage. If good-quality bone and viable soft tissues are not present, as might be the case in a patient with severe rheumatoid disease, intramedullary rod fixation may be a more effective means of fixation.

In patients taking aggressive disease-remitting medications, the possibility of late infection should be considered. These patients may benefit from metal removal, which is often more easily accomplished after rod osteosynthesis.

Preoperative Planning

While the use of aspirin may be continued, warfarin (Coumadin) and clopidogrel (Plavix) should be discontinued to avoid bleeding and flap complications.

Radiographs should be reviewed before performing a wrist arthrodesis. Specific attention should be paid to the amount of available bone stock and the bony alignment.

Intraoperative evaluation will require a fluoroscopic device. Appropriate alignment, reduction, and implant length should be confirmed before closure.

Positioning

Patients are placed supine with the operative hand extended on a hand table extension.

A tourniquet is applied to the proximal arm over padding.

Before anesthesia is induced, the patient’s comfortable shoulder position should be assessed. The armboard should not place the shoulder above this position. This test is especially important in rheumatoid patients with limited joint mobility.

Approach

Both arthrodesis procedures are performed through a standard dorsal approach to the wrist.12–14 A longitudinal midline dorsal incision ulnar to the tubercle of Lister is used.

The extensor pollicis longus tendon is released from its sheath and retracted radially.12

The fourth extensor compartment is subperiosteally elevated from the dorsum of the distal radius and retracted ulnarly.

The posterior interosseous nerve can be dissected free and excised.

The dorsal capsule is incised in line with the skin incision and elevated off the carpus.12

This exposure allows for performance of concomitant procedures such as a distal ulna excision and dorsal tenosynovectomy.

PLATE AND SCREW OSTEOSYNTHESIS

In addition to the approach described above, the proximal portion of the third metacarpal is exposed subperiosteally.

Expose the radioscaphoid, radiolunate, scaphocapitate, capitolunate, and third carpometacarpal joints (TECH FIG 1A), clean them of any remaining cartilage and soft tissue, and then fully denude them to below the subchondral bone.

Maintain the general bony geometry to allow the prepared carpal bones to interdigitate effectively.

A combination of a no. 15 blade, small curettes, and rongeurs is usually adequate for preparing the joint surfaces. Use of a water-cooled power Burr and repeated penetration of the articular surfaces with a 0.045-inch smooth Kirschner wire are sometimes helpful.

The triquetrolunate, triquetrohamate, scaphotrapezial-trapezoid, and capitohamate joints may be left undisturbed if not arthritic.

If one expects to remove the plate at a second surgery, the second and third carpometacarpal joints can be left intact. This limits the fusion mass to the radiocarpal and midcarpal joints, preserving motion at the carpometacarpal level.

Obtain autologous bone graft from the distal radius in two forms, a corticocancellous graft and cancellous bone chips.

Measure the distance from the base of the third metacarpal to the radius platform and harvest a cortico-cancellous bone graft of equal length from the dorsal radial surface of the distal radius.

Take care to avoid disrupting the radial cortex of the distal radius (and thereby destabilizing the bone) and removing the cortex on which the plate will eventually sit.

Outline the graft using a wire driver and a 0.045-inch Kirschner wire, and then harvest it with a sharp osteotome and mallet.

After removing this graft, harvest cancellous bone from the site and tightly pack it between the prepared bony surfaces.

In cases of severe deformity, the carpus may be held in general alignment with temporary Kirschner wires.

Key the corticocancellous graft into the space between the third metacarpal base and the radius platform.

This graft will be located directly under the plate (TECH FIG 1B).

Choose the desired wrist fusion plate and secure it distally to the third metacarpal with appropriately sized screws.

Plate options include a long bend, a short bend, and a straight plate (Synthes USA).

In selected instances, the second metacarpal may be used rather than the third metacarpal.

With the carpus aligned and the prepared joints reduced and grafted, apply the plate to the distal radius in a com-
Fusion with Steinmann rods is performed using a technique similar to that described above, typically in patients with advanced inflammatory arthritis.

- Because bone loss and deformity are substantive, precise joint preparation and reduction is not possible and the goal is generation of a fusion mass.
- Typically, cancellous autograft taken from the distal radius is used between the prepared bony surfaces.

Fixation may be accomplished using an intramedullary rod inserted through the head of the third metacarpal (TECH FIG 2A–D).

- As an alternative, two rods can be inserted between the second and third, and third and fourth metacarpals (TECH FIG 2E,F). These are usually smaller pins that produce an interference fit in the radius shaft.
- Placing an intramedullary rod through the third metacarpal head necessitates an incision in the dorsal web space and in the sagittal band.
  - Metacarpophalangeal joint replacement may eventually be required.
- Choose the largest pin that will fit within the metacarpal and advance it retrograde through the reduced carpus and into the radius.
- A second smaller derotation pin can be placed through the radial styloid into the carpus and metacarpals to prevent rotation.
- Alternatively, a figure 8 wire can be placed around the third metacarpal and through the radius to compress the construct.
- If the metacarpophalangeal joints have already been replaced, two Steinmann pins through the second and third and third and fourth intermetacarpal spaces.

**PEARLS AND PITFALLS**

- The third metacarpal should be aligned with the radius. This alignment is essential when applying a plate.
- Patients prefer to be in slight wrist extension without significant radial or ulnar deviation; significant deviation into flexion or radial deviation leads to problems and weakness. Patients already stiff at neutral may prefer a neutral position.
- Bilateral fusions may not be preferred but rarely affect function.²
- If the proximal row has displaced, proximal row carpectomy and fusion has been shown to be successful.³
- If the ulnar head appears arthritic or prominent, it will need to be addressed using a Darrach procedure, hemiresection techniques, or head replacement. If not addressed, it may be a source of pain postoperatively.

**TECH FIG 2 • A,B.** Complex wrist collapse secondary to rheumatoid arthritis treated with an intramedullary rod and wiring. Ulnar impaction symptoms developing at the distal radioulnar joint. C,D. Less severe wrist disease in a different patient was treated with a Darrach resection and wrist arthrodesis. E,F. PA and lateral radiographs after wrist arthrodesis in a different patient with rheumatoid arthritis was undertaken using two Steinmann pins inserted through the second and third, and third and fourth intermetacarpal spaces. (A–D: Courtesy of P.J. Stern, MD; E,F: Copyright Thomas R. Hunt III, MD.)
POSTOPERATIVE CARE

- Patients are placed into a removable brace 2 weeks after surgery and started on active finger flexion-extension exercises as well as pronation and supination.
- Patients with an extensor lag due to dorsal swelling are started on a program of dynamic extension with an outrigger splint until full active extension is regained.
- Strengthening is reserved for when the radiographs demonstrate union. Union usually takes 6 to 8 weeks but is prolonged in smokers. Comorbidities may also affect healing rates.
- If patient compliance is an issue, a cast may be used for the first 4 weeks to protect the construct with plate osteosynthesis.
- A cast is recommended for 4 to 6 weeks when using Steinmann rods until the patient’s wrist is nontender.
- Therapy may also need to be modified depending on any additional procedures performed.

COMPLICATIONS

- Infection
- Nonunion, delayed union, and malunion
- Dorsal wrist tenderness
- Tendon adhesions and ruptures
- Neurammas and complex regional pain syndromes
- Pin migration
- Wound breakdown

OUTCOMES

- Wrist arthrodesis boasts a high fusion rate, a high satisfaction rate, and a low complication rate.\(^1,5,7,8,9,13\) It is for this reason that fusion of the wrist is selected in patients who can tolerate fewer trips to the operating room for secondary procedures.
- While more satisfying than rod stabilization in rheumatoid patients (74% vs. 37%), plate fixation may require tenolysis or plate removal after arthrodesis.\(^1,11\) Satisfaction may be affected by the patient’s underlying disease.
- Housian and Schroder\(^6\) found that plate removal was common (15%) due to the complications listed above but was successful in relieving symptoms.

REFERENCES

DEFINITION

- In the past, the gold standard for the treatment of end-stage wrist degeneration and debilitating pain was fusion of the wrist joint. As a salvage procedure, arthrodesis can provide reasonable pain relief and relative preservation of upper extremity function. Unfortunately, fusion of the painful wrist does not guarantee pain relief, nor does it come without functional impairment.

- In contrast, total wrist arthroplasty provides an attractive motion- and function-sparing alternative to wrist arthrodesis. Pain relief is achieved, along with preservation of wrist motion and function.

- Multiple studies have demonstrated that patients consistently prefer motion-sparing procedures over arthrodesis.

- In much the same vein as arthroplasty efforts in the other major joints, early wrist replacement designs were successful in both relieving pain and maintaining function. Unfortunately, early wrist prostheses failed to achieve the long-term survivorship results provided by joint replacements in the shoulder, hip, and knee joints.

- Early prosthetic designs suffered from significant biomechanical design flaws. Difficulties arose with implant centering, balance, and fixation.

- Significant improvements in implant design have capitalized on modularity, better material considerations, and improved anatomic designs to provide improved longevity.

- Current designs strive to achieve the following:
  - A more anatomic wrist joint than previous wrist designs, either through component design or implant instrumentation
  - Stable distal fixation by using screw fixation into the carpus while at the same time avoiding the lever arm created by a stem inserted into the third metacarpal
  - The three most popular wrist designs in the United States today are the Universal 2 (KMI/Integra), the Re-Motion (Small Bone Innovations [SBI]), and the Maestro (Biomet) (FIG 1).
  - The Universal 2 Total Wrist prosthesis is an improved version of the original wrist of the late Dr. Jay Menon (FIG 1A). A great debt of gratitude is owed to Dr. Menon for popularizing distal screw fixation to the carpus.
  - The Uni2 design uses a flat carpal cut, screw fixation distally into both the second metacarpal and hamate, and a modular, distally based polyethylene cap that articulates with a proximal cobalt chrome radial component. The improved design attempts to preserve the distal radioulnar joint (DRUJ).
  - The Uni2 wrist is the prosthesis with which there is the greatest clinical experience to date. The results are encouraging.
  - The Re-Motion Total Wrist is essentially the prosthesis marketed initially by Avanta and then SBI with new and improved instrumentation (FIG 1B). It is fundamentally a prosthesis designed to resurface the distal radius.
  - A concave, cobalt chrome radial component articulates with a convex, distally based, polyethylene cap snapped over a flat carpal plate. The carpal plate is anchored to the carpus with a radial screw that does not penetrate the second metacarpal, and a second screw placed ulnarly. About 15 degrees of “wiggle” or intended motion is built into the
snap fit of the polyethylene cap with the carpal plate. No attempt is made to preserve the DRUJ with this implant.

- Many Re-Motion wrist replacements have been performed in conjunction with ulnar head replacement arthroplasty. Preliminary results with the Re-Motion wrist are encouraging.¹

- The Maestro Wrist is the most recent implant to enter the wrist joint replacement market (FIG 1C,D). It differs significantly in design from the Uni2 and the Re-Motion wrists, having been conceived to resemble successful total hip, knee, and shoulder designs, which use a metal convex component articulating with a concave polyethylene component.

- The convex metallic distal component articulates with the proximally based, concave polyethylene body. This UPMWPE body is direct compression molded onto a cobalt chrome (CoCr) alloy radial body with a modular titanium stem. The distal component is composed of a CoCr alloy carpal plate (with or without scaphoid augment) and carpal body and a titanium capitate stem. All components are modular.

- Unlike the Uni2 and the Re-Motion wrists, it is not always necessary to attempt fusion of the distal pole of the scaphoid to the surrounding carpus. The Maestro Wrist has a provision to replace the entire scaphoid using a carpal plate incorporating a modular radial augment.

- The modular radial stem component is designed to fill the distal radius canal to prevent loosening and provide stability. The instrumentation used to prepare the distal radius is designed to preserve the DRUJ.

- The excitement over these three wrist replacement systems has stimulated other investigators to work with companies in producing a total wrist replacement. These other wrist replacement systems are in various stages of design but offer promise for even further advancement of the technology.

**ANATOMY**

- The wrist joint consists of the distal radial articular surface, the distal ulna and triangular fibrocartilage complex, eight carpal bones arranged into proximal and distal rows, and five metacarpal bases.

- Four significant articulations exist: the radiocarpal joint, the midcarpal joint, the carpometacarpal joints, and the DRUJ. A combination of interosseous, intrinsic, and extrinsic ligaments provides stabilization (FIG 2).

- The proximal row of the carpus articulates with the distal radius to form the radiocarpal joint. The distal carpal row articulations with the metacarpal bases form the carpometacarpal joints. Within the distal carpal row, the center of wrist motion is located at the head of the capitate, slightly palmar to the center of the head. This center of rotation may or may not be colinear with the third metacarpal shaft, depending on each patient’s anatomy.

- Proximally, the center of wrist motion lies ulnar to the radial intramedullary canal. Normal anatomic parameters of the distal radial articular surface include a volar tilt of 11 degrees and a radial inclination of 22 degrees.

- The sigmoid notch of the distal radius provides the articulation for the DRUJ. Strong dorsal and palmar radioulnar ligaments provide DRUJ stability.

**PATHOGENESIS**

- End-stage wrist degeneration, a common endpoint of multiple pathways, involves loss of joint space and carpal collapse. The primary indication for total wrist arthroplasty is joint destruction secondary to the effects of rheumatoid arthritis.

- The classic pattern of deformity and destruction involves the radiocarpal and midcarpal joints and the DRUJ. Attenuation of the extrinsic wrist ligaments destabilizes the carpus, often resulting in an ulnar and volar translation of the wrist (FIG 3).²

- Joint replacement is also indicated to manage the pain, deformity, and loss of motion coincident with end-stage arthritis resulting from osteoarthritis, posttraumatic arthritis, or avascular necrosis. Total wrist arthroplasty can provide a salvage option for functional deformities such as scapholunate advanced collapse (SLAC) or irreparable trauma to the distal radius or carpus.
MAESTRO PROSTHESES

The senior author’s personal experience is primarily with the Maestro prosthesis, and thus the technique of the Maestro total wrist arthroplasty is presented here.

Although approved for implantation with cement, most wrists are implanted without cement fixation.

Cement is usually preferred in cases of significant absent bone stock and in revision situations.

Carpal Preparation

Position the carpal resection guide to allow resection of 2 to 3 mm of the capitate head. It is held in position with two 0.062-inch Kirschner wires (TECH FIG 1A, B).

Place the first wire into the capitate neck and the second into the metaphysis of the third metacarpal, ensuring that the guide is parallel to the third metacarpal axis.

TECHNIQUES
With proper placement, the ulnar guide wing will lie close to the triquetrum–hamate articulation and the radial wing will bisect the scaphoid at its distal third.

Loosen the thumbscrew on the carpal resection guide to allow insertion of the radial resection guide boom (TECH FIG 1C).

With the wrist in neutral, score the radius through the cutting slot in the guide to provide a reference for the distal radial resection (TECH FIG 1D).

Remove the radius resection guide and use the carpal resection guide handle to stabilize the carpal guide during carpal resection.
- Cut the scaphoid, capitate head, hamate edge, and triquetrum at a 90-degree angle to the axis of the forearm—jig (TECH FIG 1E,F).
- As an alternative, the scaphoid can be completely removed and a carpal plate incorporating a scaphoid augment used.

**Capitate Reaming and Selection of Carpal Plate**
- After removing the carpal resection guide and Kirschner wires, remove the proximal carpus.
- Place a guidewire into the capitate at the apex of the resection, directly into the center of the capitate (TECH FIG 2A). This may or may not coincide with the center of the third metacarpal. Attention is focused on the capitate and not the capitate–third metacarpal relation.
- Ream the capitate (TECH FIG 2B).
- The depth of reaming can be verified under fluoroscopy. A direct indication of the trial stem size is indicated by depth marks on the reamer.
- Provisionally determine the trial carpal plate by the curvature and width of the remaining proximal carpal surface. The plate should lie flush with the hamate and proximal capitate surfaces.
- Three separate scaphoid augments are available (TECH FIG 2C).
- Assemble the plate and stem and insert them into the reamed capitate and onto the resected carpal surface. (TECH FIG 2D).
- With adequate plate fitting, alignment is such that a radial screw will easily be inserted into the second metacarpal and an ulnar screw inserted into the hamate.

**Radius Resection**
- Insert a 0.062-inch Kirschner wire directly into the center of the medullary canal of the radius (TECH FIG 3A).
- The correct insertion point is in the lower corner of the dorsal-ulnar quadrant of the radius articular surface (TECH FIG 3B). This corresponds to a point near
the center of the radius and immediately below the
groove of the tubercle of Lister. Correct wire place-
ment is confirmed under fluoroscopy.
- The perfectly placed Kirschner wire is overdrilled
  with the cannulated drill bit to a minimum depth of
  40 mm.
- Remove the Kirschner wire and successively ream the ra-
dius by hand until the reamer chatters on the in-
tramedullary canal.
- The final reamer is left in the canal and the radius re-
section guide boom and guide are attached (TECH
FIG 3C,D).
- Align the proximal portion of the guide over the
score mark made on the dorsal cortex and secure it
with Kirschner wires.
- After removing the reamer and guide boom from the
medullary canal, cut the radius.
- The saw cut should follow exactly the contour of the
resection guide and should not enter the DRUJ, thus
maintaining its normal anatomy.
- Place the appropriate radius intramedullary guide into
the canal and insert the chisel guide until flush with the
resected surface (TECH FIG 3E).
- Insert the chisel into each side of the guide in sequence and gently tap it until fully seated.
- After removing the chisel and guide, remove the chiseled bone from the distal radius. Reinsert the intermedullary guide, and over this, broach the distal radius to the templated size desired (TECH FIG 3F,G).

**Trial of Carpal and Radial Components**

- Insert the previously assembled trial components for the carpal and the radial stem-body assembly (TECH FIG 4A).
- With the wrist in full flexion, a standard-size carpal head is snap fit to the carpal plate (TECH FIG 4B).
- The wrist is distracted and extended for reduction (TECH FIG 4C). About 2 to 3 mm of joint separation with distraction indicates appropriate tension. The carpal head may be adjusted to a +2 or +4 size until tension is appropriate. Satisfactory radial and ulnar deviation should be demonstrated.
- Excessive tissue tension can be remedied with additional radial resection. Distal ulnar impingement can be addressed with a Darrach-type resection of the distal ulna.
- Remove the trial components; if the proper tension has been achieved, perform final irrigation.

**Carpal Body Insertion and Fixation**

- Assemble the carpal implant and inject bone cement, if indicated, into the capitate. Insert the stem of the assembled prosthesis into the capitate and impact it.
- Insert a single 0.062-inch Kirschner wire into the ulnar screw hole using the drill guide. Verify under fluoroscopy that the wire is directed centrally into the central portion of the hamate.
- Insert a second Kirschner wire through the radial screw hole and verify that it is through the trapezoid into the intermedullary canal of the second metacarpal.
- Overdrill both Kirschner wires with the cannulated drill bit (TECH FIG 5). Screw depth can be measured directly from the score marks on the drill bit.
- Place the appropriate-size screws and verify placement fluoroscopically if needed.

**Radial Body Insertion and Fixation**

- Assemble the radial stem to the radial body. If indicated, inject bone cement into the radius, and impact the stem until fully seated.
- Reduce the wrist components and take final radiographs (see Fig 1C).

**Closure**

- Close the wrist capsule and dorsal retinaculum with non-absorbable sutures.
- If the distal ulna was resected, the capsular closure should include a secure closure of the DRUJ.
- The placement of a drain before closure is at the surgeon’s preference.
- Close the skin and place a sterile bulky dressing and palmar splint.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Approach</th>
<th>Careful preservation of the wrist capsule and dorsal retinaculum ensures that adequate tissue will be available for closure.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Radius resection</td>
<td>Radius resection sets the tension on the implant. Close attention should be given to placing the radial guidewire into the absolute center of the medullary canal of the radius, as confirmed by radiographs. Guidewire placement is a key component of overall alignment.</td>
</tr>
<tr>
<td>Scaphoid excision</td>
<td>The distal pole of the scaphoid can be routinely removed as part of the carpal resection. Excision of the distal pole of the scaphoid and replacement with a radially augmented carpal plate significantly decreases the difficulty of the operative procedure in regard to insertion of the distal component.</td>
</tr>
<tr>
<td>Center of wrist motion</td>
<td>The center of motion is located at the head of the capitate. This may or may not coincide with the center of the third metacarpal, depending on individual patient anatomy. Attention should be focused on the capitate and not the capitate–third metacarpal relationship.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Early finger motion is begun as allowed by the bulky postoperative bandage. Any drains placed are removed within 24 hours.
- The splint is removed at the 1-week follow-up visit and a cast or splint is placed for an additional 1 to 3 weeks.
- Splint removal with gentle active motion several times daily is permitted at 2 weeks after surgery.
- If a distal ulna resection was performed, the forearm is splinted in neutral rotation for at least 3 weeks before starting forearm rotation exercises.
- More vigorous active and passive range of motion is begun at 4 weeks postoperatively.

OUTCOMES

- The results of a prospective study evaluating the use of the Universal 2 total wrist replacement in rheumatoid patients showed that this wrist provides good early outcomes in this cohort of patients if severe preoperative wrist laxity is not present.
- The authors reported significant improvement in range of motion and an improvement in the DASH score (Disabilities of the Arm, Shoulder and Hand) of 14 points at 1 year and 24 points at 2 years.
- Three prostheses were unstable and required further treatment.
Early results of the Maestro wrist replacement have been encouraging. A recent series of 14 patients with a minimum follow-up of 24 months (average 28 months) revealed that all patients had satisfactory pain relief postoperatively.

- Motion (FIG 4) improved from an average of 28 degrees flexion and 27 degrees extension before surgery to 41 and 43 degrees, respectively, postoperatively. Radial and ulnar deviation averaged 19 and 23 degrees, respectively.
- No significant complications were noted.15

### COMPLICATIONS

- Short-term complications include early postoperative wound concerns, superficial infections, and deep infections.
- The most significant long-term complication encountered is implant loosening. Loosening is not an immediate indication for revision but does necessitate close clinical and radiographic monitoring for progression.
- Implant instability may result from poor component placement, implant loosening, ligamentous instability, or component wear. Each case must be dealt with individually after determining the cause of such instability.
- Periprosthetic fracture is also an infrequently seen complication. Two options are available for salvage of loose or fractured prostheses: component revision or wrist arthrodesis.13,14

### REFERENCES

DEFINITION
- Dr. William Darrach described the distal ulna resection that bears his name in the early 1900s for the treatment of a post-traumatic volar distal radioulnar joint (DRUJ) dislocation. This operation continues to have a place for the treatment of a variety of afflictions of the DRUJ.
- In an effort to preserve some of the critical stabilizing soft tissue elements of the distal ulna, alternative treatments to complete ablation of the distal ulna have been developed.
  - Bowers\(^3\) published his results of the hemiresection-interposition technique (HIT). This procedure differs from the Darrach in that the weight-bearing seat and pole are resected, preserving the styloid and soft tissue elements of the triangular fibrocartilage (TFC).
  - Watson et al\(^{21,22}\) advocated the matched resection procedure.
  - The essential element is matching the profile of the resected distal ulna to the medial side of the radius.

ANATOMY
- The DRUJ is formed by the articulation between the sigmoid notch and the head of the ulna (FIG 1A, B). The sigmoid notch is the articular cartilage surface on the medial aspect of the distal radius. This concave surface matches the corresponding convex surface or “seat” of the distal ulna. The arc of curvature of the sigmoid notch ranges between 47 and 80 degrees, with an average radius of 12 to 18 mm.
- The articulation is constrained loosely, allowing both forearm rotation through a 150-degree arc and proximal and distal migration as well as dorsal and palmar translation of the ulna relative to the radius during forearm rotation. The articular cartilage-covered “cap” of the distal ulna can be divided into two functional regions. The seat of the ulna is the concave portion that articulates with the sigmoid notch. The arc of curvature ranges between 90 and 135 degrees, with an average radius of 8 to 13 mm. This region is covered by articular cartilage around 270 degrees of its surface. This is the region that supports the compressive loads of the distal radius during most activities of daily living and can be considered the fulcrum for load support.
- The pole is the distal portion of the ulna that lies deep to the cartilaginous TFC. This region supports the centrum of the TFC as compressive loads pass from the ulnar carpus to the bony elements of the forearm. The medial-distal portion of the ulna projects as the ulnar styloid. The base of the styloid contains the critical attachment of the deep layer of the TFC, the ligamentum subcruentum (FIG 1C).
- Distal to this, and in a more peripheral location, is the attachment of the superficial layer of the TFC. The dorsal and volar portions of the TFC are thickened, forming the limbi of the TFC, the volar and dorsal radioulnar ligaments. These ligaments play critical roles in stabilizing the DRUJ.

PATHOGENESIS
- Conditions that cause DRUJ degenerative change or altered DRUJ mechanics can lead to pain and DRUJ dysfunction. Most commonly, distal ulna resection is performed in patients with inflammatory arthropathy, usually rheumatoid arthritis. Frequently, treatment of the DRUJ is performed in conjunction with other bone or soft tissue reconstructions.
- DRUJ instability secondary to trauma or attritional changes of the supporting soft tissue elements can lead to degenerative change of this articulation.
- Malunions of the distal radius can negatively affect the sigmoid notch by alterations in angulation or length and can disrupt DRUJ kinematics.
- A less common cause of DRUJ arthritis is primary osteoarthritis, which may also lead to osteophytes and loose bodies.

FIG 1 • Diagrammatic representations of the bony anatomy (A) and relationship of the radius and ulna at the distal radioulnar joint (DRUJ) (B). C. Soft tissue elements of the DRUJ, including the deep (ligamentum subcruentum) and superficial peripheral attachments of the triangular fibrocartilage.
Developmental conditions, such as Madelung deformity, can alter DRUJ joint mechanics. Painful forearm rotation and degenerative changes as well as ulnar impaction can develop.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- **Patients with DRUJ problems present with pain and limited forearm rotation.**
  - In isolated DRUJ arthrosis, the patients usually localize their pain at the DRUJ articulation.
  - In patients with concomitant associated pathology of the soft tissue elements and DRUJ stabilizers, the ulnar-sided pain is more diffuse.

- Pain occurs with activities that require forearm rotation, such as turning doorknobs, turning keys in locks, starting a car, and opening jars. Lifting activities with the arm away from the body are difficult since the DRUJ is loaded in this position.
- Limited forearm motion may be secondary to an arthritic DRUJ; however, other conditions (eg, capsular contracture) must be considered.

- Prominence and deformity of the distal ulna is common in patients with inflammatory changes and in patients with distal radial fracture malunions.
- Inspection is usually unremarkable in patients with isolated DRUJ osteoarthritis. In contrast, DRUJ deformity and prominence is common in patients with rheumatoid arthritis. Fullness due to synovial proliferation may be visible and secondary attritional changes of surrounding soft tissue elements, such as extensor tendon rupture, can lead to abnormal hand posture.
- Radial malunions with shortening and angulation produce visible prominence of the distal ulna (FIG 2).

- Tenderness with pressure on the dorsal aspect of the DRUJ is frequently elicited. In patients with associated impaction or TFC pathology, tenderness may be more diffuse. Palpable crepitance with rotation is often present. Compressing the distal ulna into the sigmoid notch while rotating the forearm elicits painful crepitation and is suggestive of arthritis.
- Pain on the ulnocarpal stress test is indicative of TFC pathology.
- Pain on application of pressure in the interval between the ulnar styloid and flexor carpi ulnaris tendon is indicative of TFC or capsuloligamentous pathology (foveal sign).
- Piano key maneuver: Visible dorsal winging or instability of the distal ulna is noted. If the ulna is dorsally prominent, the examiner can manually reduce the ulna into the sigmoid notch. The ulna spontaneously dorsally subluxates when pressure is removed. Winging is associated with loss of structural support of the DRUJ.
- Grip strength is frequently limited secondary to painful compressive loading of the DRUJ.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs are usually sufficient to supplement physical examination findings. It is essential to obtain a neutral forearm rotation, posteroanterior (PA) lateral view (FIG 3A) to accurately assess ulnar variance, styloid morphology, inclination of the sigmoid notch, and position of the ulnar styloid. These factors are important in selecting the appropriate surgical management for disorders of the distal ulna.
- Thin-section CT scanning can provide useful additional information about DRUJ articular surfaces and subluxation.
- MRI evaluation is rarely necessary to diagnose arthritic disorders of the DRUJ but can be useful when detailed information about the radioulnar ligaments or surrounding bony ligaments of the TFC is necessary (FIG 3B).

**FIG 2** • Loss of the soft tissue support with or without associated degenerative change or malunion of the radius with resultant sigmoid notch incongruity leads to dorsal prominence and winging of the ulna relative to the radius. **A.** Dorsal prominence of the ulna relative to the radius is seen in a patient with a radial malunion. **B.** Radiograph of a wrist of a patient with rheumatoid arthritis shows the volar translation and secondary changes in the carpus that are associated with dorsal ulna prominence.

**FIG 3** • **A.** The zero-rotation view is taken with the patient’s shoulder abducted at 90 degrees, the elbow flexed 90 degrees, and the wrist pronated in the PA position. The ulnar styloid is seen in full profile in this view. This view is the standard radiographic view used to determine ulnar variance. **B.** While not part of the routine imaging evaluation for the triangular fibrocartilage, MRI can confirm the diagnosis for related conditions. This MRI in a patient with an ulnar-positive wrist shows a discrete intense lesion at the ulnar base of the lunate consistent with ulnar impaction.
DIFFERENTIAL DIAGNOSIS

- DRUJ arthritis
- Inflammatory
- Osteoarthritis
- Traumatic
  - Iatrogenic (e.g., altered joint mechanics after ulnar shortening)
- DRUJ instability
- TFC tears
- Ulnar impaction
- Lunotriquetral ligament tears or instability
- Extensor carpi ulnaris tendinitis
- Extensor carpi ulnaris instability
- Pisotriquetral disorders
- Nerve entrapment (canal of Guyon)
- Nerve injury (e.g., neuromas of dorsal ulnar sensory nerve)
- Madelung deformity with DRUJ dysfunction

NONOPERATIVE MANAGEMENT

- Patients with mild symptoms and minimal functional impairment may be managed with oral anti-inflammatories, intra-articular injections, or splinting.
- Splinting must include the elbow to eliminate forearm rotation.

SURGICAL MANAGEMENT

- Maintaining the distal ulna has gained recent popularity as resection can be associated with considerable postoperative complications and functional disability. Meticulous attention to preoperative, intraoperative, and postoperative detail is essential for a successful result.

Adjunctive Procedures

- After complete or partial resection of the distal ulna, convergence between the radius and ulna can develop. Loss of the weight-bearing fulcrum of the ulna seat can yield convergence with grip or loaded lifting with the arm extended and the forearm in neutral rotation (FIG 4).

- Adjunctive procedures incorporate some type of tendon transfer or interpositional material to stabilize the resected ulnar stump (FIG 5). The pronator quadratus, extensor carpi ulnaris, and flexor carpi ulnaris tendons have been used alone and in combination.
- In addition to tendon transfer, some authors have recommended suturing the ulnar capsule to the dorsal ulnar stump to help stabilize the remaining ulna. Kleinman and Greenberg advocated use of a dynamic pronator quadratus interosseous transfer in conjunction with an extensor carpi ulnaris distal tenodesis for failed distal ulna resections. More recently, allograft soft tissue interposition has been advocated, as well as distal ulna implant arthroplasty.
- Most adjunctive procedures have been described for treatment of a failed symptomatic Darrach procedure; however, they can be incorporated during the initial surgery. Symptomatic convergence tends to develop in a relatively younger, higher-demand patient. If distal ulna resection is necessary in this patient population, use of an adjunctive procedure is recommended.

Preoperative Planning

- The ideal candidate for a Darrach resection is a patient with a relatively low-demand upper extremity that does not require the load-bearing DRUJ.
- Coexisting pathology is frequently present in patients with distal ulna dysfunction, especially in patients with inflammatory arthropathy. Assessing for associated tenosynovitis and tendon ruptures is necessary.
- The status of the radiocarpal joint is critical. Patients with loss of radial-sided carpal support due to tenosynovitis often have ulnar translation. In advanced cases, the carpus may abut the distal ulna and isolated Darrach resection without carpal stabilization is contraindicated to avoid exacerbating ulnar translation.
- If a limited resection of the distal ulna is considered, one must evaluate the length of the ulna, ulna variance, and position of the styloid. If stylocarpal abutment exists, it will persist after limited resection. Therefore, consideration needs to be...
given to a joint leveling procedure or styloid recession in conjunction with limited resection.

- Alternatively, a complete distal ulna resection that addresses the ulna head as well as the styloid or a Sauvé-Kapandji DRUJ arthrodesis may be considered.

**Positioning**

- The patient is positioned supine. The operative arm is extended with the shoulder abducted at 90 degrees. The arm is supported on a standard table used for upper extremity surgery.
- A tourniquet is used.
- The motion of the elbow and shoulder should be noted before surgery. Limited passive motion can create awkward arm positioning.

**Approach**

- The incision used for distal ulna resection is based on whether the resection is performed alone or in conjunction with other procedures (FIG 6).
- The recommended approach for distal ulna resections is dorsal, deep to the fifth extensor compartment.
- A medial approach between the extensor carpi ulnaris and flexor carpi ulnaris tendons is not recommended. This approach has greater potential for disrupting the linea jugata, with resultant potential extensor carpi ulnaris destabilization.

**COMPLETE DISTAL ULNA RESECTION: THE DARRACH PROCEDURE**

**Incision and Dissection**

- Frequently, Darrach resection is performed in conjunction with other procedures, especially in patients with inflammatory arthropathies. In this situation, the surgical incision is usually dorsal midline longitudinal, which enables all aspects of the wrist reconstruction (wrist fusion, arthroplasty, tenosynovectomy, tendon transfer, etc.) to be completed via a single approach.
- If the Darrach procedure is to be performed independently, a single oblique or chevron dorsal approach is made (Fig 6) overlying the fifth dorsal compartment.
- During the dissection to the retinacular layer, take care to avoid injury to the transverse retinacular branch and dorsal sensory branch of the ulnar nerve that pass from the medial forearm to the dorsal hand between the ulnar styloid and pisiform (TECH FIG 1A).
- Keep the oblique incision or distal limb of the chevron approach parallel to this nerve to minimize this complication.
- Frequently, dorsal capsular reinforcement is necessary after distal ulna resection. This is especially true in patients with inflammatory arthropathies and multiple extensor tendon ruptures.
- When performed in conjunction with other procedures, raise opposing extensor retinacular flaps so that one of the flaps can be used to reinforce the dorsal capsule and create a stabilizing extensor carpi ulnaris sling during closure (TECH FIG 1B,C).
- When performed as an isolated procedure, raise a retinacular flap from the margin of the fourth dorsal compartment (TECH FIG 1D).

**Capsulotomy and Osteotomy**

- Perform a longitudinal capsulotomy deep to the fifth dorsal compartment (TECH FIG 2A). This capsular approach starts proximal to the dorsal radioulnar ligament and proceeds in a proximal direction.
- Extend the capsular release parallel and just proximal to the dorsal radioulnar ligament to facilitate exposure. Take care during the deep periosteal dissection.
to elevate and maintain as thick a periosteal sleeve as possible.

- Osteotomize the distal ulna using a power oscillating saw just proximal to the sigmoid notch (TECH FIG 2B). Enough ulna is sacrificed to completely decompress the DRUJ. Keep resection to 2 cm or less.

- Intraoperative fluoroscopic guidance is frequently helpful to assist with the location of the osteotomy.

- Once the distal pole and seat are resected, there is no advantage to preserving the ulnar styloid, and the entire styloid should be removed with the distal ulna.

TECH FIG 1 • (continued) B,C. Opposing retinacular flaps are raised to provide wide exposure and access to all extensor compartments. This approach is frequently necessary in patients with concomitant extensor tendon dysfunction. One of the flaps can then be used to reinforce the capsule deep to the extensors at the termination of the procedure. D. The fifth compartment is opened, exposing the extensor digiti quinti proprius tendon. An ulnarly based retinacular flap is raised, preserving the wall of the fourth dorsal compartment for later repair.

TECH FIG 2 • A. A longitudinal capsulotomy exposes the distal ulna (arrow) and allows access to the distal metaphysis, depending on the reconstruction being performed. B. The distal ulna has been osteotomized just proximal to the sigmoid notch. The resection should be less than 2 cm and should clear all abnormal bony elements that may affect rotation from within the sigmoid notch.
**Wound Closure**
- Meticulous attention to closure is imperative.
- Perform a secure multilayered closure. Perform separate closure of the periosteal and capsular layers with nonabsorbable sutures.
- Suture the retinacular flaps for capsular reinforcement.
- Transpose the EDQP tendon dorsal to the extensor retinaculum. This does not create any functional disability (**TECH FIG 3**).
- Routine skin closure follows.

**DISTAL ULNA HEMIRESECTION-INTERPOSITION TECHNIQUE**
- The surgical approach for the HIT procedure as developed by Bowers is identical to the Darrach resection. The difference lies in the treatment of the bone and soft tissue interposition after bone resection.
- Instead of resecting the distal ulna at the proximal margin of the sigmoid notch, the osteotomy removes the seat and pole of the ulnar head (**TECH FIG 4A,B**). The entire shaft and the styloid are left intact.
- After resection, the forearm is rotated through a full arc. This ensures that prominent osteophytes or bone that may interfere with forearm rotation have been removed.
- The resected shaft should be round in cross-section and should taper distally. The resection is lateral to the insertion of the deep portion of the TFC, so the integrity of both the deep and superficial components of the TFC is maintained. If the TFC is incompetent or cannot be made functionally competent by reconstruction, then there are no advantages over the Darrach complete distal ulna resection.
- Convergence of the radius and ulna develops after ulnar head resection. To mitigate this, the ulnarily based capsular flap raised during the approach is interposed between the radius and resected ulna. Interposition bulk may be increased by using a free tendon graft (**TECH FIG 4C**).
Modification

- In an effort to avoid an interpositional tendon graft, Adams Advocates a modification of the HIT procedure.
- In this technique, an ulnar-based retinacular flap is raised from the radial margin of the extensor carpi ulnaris sheath.
- Only 3 to 7 mm of bone is resected, and the ulna is tapered distally in a dowel shape. The fovea is not violated, thereby preserving all TFC attachments.
- The retinacular flap is then interposed and sutured to the volar DRUJ capsule. As in other procedures, attention is paid to avoid stylocarpal impingement.

MATCHED DISTAL ULNA RESECTION

- In this modification, developed by Watson, the distal ulna is resected in a long, sloping convex curve that matches the opposing concave radius (TECH FIG 5).
- The surgical approach is identical to the approaches listed for prior procedures. Although Watson advocated a transverse incision just proximal to the DRUJ, I prefer a more utilitarian longitudinal or chevron incision as previously described.
- The entire 270-degree arc of the ulna is addressed. Similar to the HIT procedure, great care is taken after bone resection to ensure full, unimpeded forearm rotation. Any osteophytes or prominent bone that may interfere with rotation must be removed.
- This technique differs from the HIT procedure since the ulna is reshaped over a longer distance and no interposition material is used. While this technique is advocated to preserve the ulnar sling, by necessity the resection sacrifices both the deep and superficial insertions of the TFC. Any resultant stability of the residual stump of the ulna is generated only by soft tissue scarring.

TECH FIG 4 (continued) C. After osteotomy and removal of the ulnar head, the space is filled with a free tendon graft that provides bulky tissue and mitigates impingement of the resected ulna against the medial wall of the distal radius.

TECH FIG 5 A B. The matched resection osteotomy is more proximal than the Bowers osteotomy (A) and is resected in a long, sloping curve matching the opposite concave surface of the radius through a complete 270-degree arc (B).
**PEARLS AND PITFALLS**

**Indications**
- Consider distal ulna resection as a final salvage procedure. Consider alternative procedures that will preserve the load-bearing fulcrum of the DRUJ. Distal ulna resections are tolerated in a relatively older, lower-demand patient.

**Associated conditions**
- Diagnose and treat associated bone and soft tissue pathology. Consider the effects of distal resection on the radiocarpal joint.

**Approach**
- Meticulous attention to soft tissue handling and avoiding injury to cutaneous nerves is essential. Raise retinacular and capsular flaps carefully so they can be used for stabilization or interposition if necessary. Avoid destabilizing the extensor carpi ulnaris. If the extensor carpi ulnaris sheath is violated and stability needs to be restored, reconstruct the sheath using retinacular flaps.

**Bone resection**
- Decompress the entire length of the sigmoid notch when performing a Darrach resection. Avoid removing the insertions of the TFC during the HIT procedure. Ensure that full forearm rotation is possible after bone resection. Similarly, after partial distal ulna resection, eliminate any remaining osteophytes or bony prominences to ensure full range of motion. Assess for postresection stylocarpal impingement, and correct length if impingement is present.

**Convergence and instability**
- Consider additional procedures that may stabilize or prevent symptomatic convergence and impingement, especially in the younger, more active, higher-demand patient.

**Aftercare**
- Maintain neutral forearm rotation with a long-arm or Munster-type splint for the first 3 postoperative weeks. Allow gentle forearm rotation until 6 weeks postoperatively. Full activity is allowed at 3 months postoperatively.

**POSTOPERATIVE CARE**
- Postoperatively, the extremity is maintained in a long-arm bulky dressing with the elbow at 90 degrees and the forearm supinated for 3 weeks. At 3 weeks postoperatively, long-arm splinting between exercises and at night begins and persists until 6 to 8 weeks postoperatively. Strengthening without splint immobilization can begin at that time.

**OUTCOMES**
- In general, distal ulna resections are associated with relief of pain and restoration of function. Elderly patients with lower demands on the upper extremities tend to have more favorable results than younger, active, higher-demand patients.
- Good results regarding relief of pain and recovery of function can be expected in 60% to 95% of patients with rheumatoid arthritis. Early clinical reports on the Darrach resection demonstrated marked improvement in pain and range of motion in greater than 80% of patients; however, other series do not present such optimistic clinical results.
- Leslie et al in 1990 and Melone and Taras in 1991 demonstrated 85% and 86% favorable results, respectively. Fraser et al’s 1999 study supported the use of the Darrach resection in patients with rheumatoid arthritis, finding 85% good to excellent results in 23 patients with rheumatoid arthritis versus only 36% satisfactory results in 27 patients with posttraumatic arthritis.
- George et al demonstrated satisfactory results in 21 patients treated with Darrach resections compared to a group who underwent Sauvé-Kapandji resection. They concluded that results were comparable and unpredictable. Despite reported complications, authors have advocated the use of the Darrach resection for patients with rheumatoid arthritis, emphasizing attention to correct technique as a critical factor in the procedure’s success.
- Compiled results using the HIT procedure for a variety of afflictions indicate that 76% of patients are pain-free and 24% report mild pain.
- Minami et al demonstrated better clinical outcomes using the HIT or Sauvé-Kapandji procedure than the Darrach procedure in 61 patients with osteoarthritis. This study supports the use of the Darrach procedure for the lower-demand, elderly patient. Van Schoonhoven and Lanz advocate use of partial resection of the ulnar head in cases of instability or radial malunion associated with arthrosis. These authors feel that maintaining the remaining contact of the TFC adds a biomechanical advantage to prevent secondary problems after resection.
- Two publications on the matched resection report good to excellent results in 24 of 32 patients with posttraumatic or mechanical disorders of the DRUJ and no or mild pain in 44 patients, most with rheumatoid arthritis. Weinzeig and Watson report excellent results in their entire series of 97 wrists over 21 years. Pain was improved in 14 of 15 patients with rheumatoid arthritis in Srikanth et al’s clinical study.

**COMPLICATIONS**
- Persistent pain
- Distal ulnar stump instability (coronal, sagittal)
- Radioulnar impingement
- Loss of forearm rotation
- Ulnar translation due to loss of ulnar support in rheumatoid arthritis
- Extensor tendon rupture
- Soft tissue irritation
- Cutaneous nerve injury
- Stylocarpal impingement
- Complex regional pain syndrome
- Extensor carpi ulnaris tendinitis or instability

**REFERENCES**

DEFINITION

- Disorders of the distal radioulnar joint (DRUJ) are a significant source of wrist pain for patients.
- The etiology of symptoms referable to this joint includes displaced fractures or malunions of the distal radius, which cause pain with forearm pronation–supination, and tears of the triangular fibrocartilage complex (TFC), which result in DRUJ instability, mechanical symptoms, and pain.
- Both Madelung deformity\(^2\)\(^3\) and rheumatoid arthritis (RA) can display secondary incongruity of the DRUJ, causing pain and loss of forearm rotation. Radial head fracture treated by resection and subsequent shortening of the radius (Essex-Lopresti lesion) also can result in painful incongruity or instability of the DRUJ.
- Management of DRUJ pain, incongruity, or instability alone is challenging, but the Sauvé-Kapandji procedure is one solution that treats all three disorders.\(^1\)\(^1\),\(^2\)\(^5\)

ANATOMY

- The DRUJ is a distal articulation in the biarticulate rotational arrangement of the forearm that allows one degree of motion: pronation and supination. The sigmoid notch of the radius is concave, with a 15-mm radius of curvature.
- The ulnar head is semicylindrical, with a radius of curvature of 10 mm, and has an articulate convexity of 220 degrees. It is surrounded by the ulnolunate and ulnotriquetral ligaments, which originate from the palmar radioulnar ligament near the ulnar styloid.
- The TFC is a fibrocartilaginous disc originating at the junction of the lunate fossa and the sigmoid notch inserting at the base of the ulnar styloid. Its central portion is cartilaginous and avascular and is designed for weight bearing.
- The peripheral margins, the dorsal and palmar radioulnar ligaments, are thick lamellar cartilage designed for tensile loading. They are well vascularized from the palmar and dorsal branches of the anterior interosseous artery and from the ulnar artery.
- The ulnar styloid acts as a strut on the end of the ulna to stabilize the ulnar soft tissues of the wrist. The sheath of the extensor carpi ulnaris (ECU), the ulnocarpal ligaments, and the TFC attach at the base of the ulnar styloid and together are known as the TFCS.
- The radius of curvature of the head of the ulna does not equal that of the sigmoid notch. In the extremes of pronation–supination, less than 10% of the ulnar head may be in contact with the notch. In pronation, the ulnar head translates 2.8 mm dorsally from a neutral position and in supination the ulnar head translates 5.4 mm volarily from a neutral position.
- The stability of the DRUJ comes from the joint surface morphology, the joint capsule, the dorsal and palmar radioulnar ligaments, the interosseous membrane, and the musculotendinous units that cross the joint, primarily the ECU and pronator quadratus (PQ). The PQ actively stabilizes the joint by coapting the ulnar head in the sigmoid notch in pronation and passively by viscoelastic forces in supination. The ECU is retained over the dorsal distal ulna by a separate fibro-osseous tunnel deep to and separate from the extensor retinaculum, allowing unrestricted rotation of the radius and ulna.\(^1\)\(^8\)

PATHOGENESIS

- Traumatic injury to the wrist can lead to derangement of the DRUJ, which can result in instability and eventually painful degenerative changes.
- Distal radial malunions with dorsal or volar subluxations or dislocations of the DRUJ produce secondary rupture, elongation, or functional shortening of the distal radioulnar ligaments.
- Arthritis of the DRUJ is a common complication of Colles fractures, particularly when fractures involve the sigmoid notch.
- Congenital disorders such as Madelung disease as well as traumatic epiphyseal closures of the distal radius can produce marked positive ulnar variance with dorsal dislocation of the DRUJ.
- In the rheumatoid wrist, progression of distal radioulnar synovitis typically results in the “caput ulnae syndrome” as described by Backdahl, which consists of the following:
  - Wrist weakness with pain on pronation and supination
  - Dorsal prominence of the ulnar head
  - Limitation of pronation and supination
  - Swelling of the distal radioulnar area
  - Secondary tendon changes with possible extensor tendon rupture and ECU subluxation\(^1\)
- If allowed to progress without intervention, the carpus will eventually fall in a more ulnarward and palmarward direction, with strength, mobility, and function all suffering.\(^2\)\(^1\)
- A chronically unstable DRUJ without degenerative changes can be treated with various soft tissue reconstructions, depending on the abnormalities and underlying pathology.
- As a group, many of these reconstructions fail to restore stability; even if stability is restored, limitation of forearm motion persists.

NATURAL HISTORY

- The natural history of DRUJ derangement is painful limitation of forearm rotation, often with additional functional deficits.
- When positive ulnar variance exceeds a few millimeters, additional limitations of wrist flexion–extension as well as radial–ulnar deviation movements can occur.
PATIENT HISTORY AND PHYSICAL FINDINGS

- Clinical evaluation begins with a detailed and accurate history.
- A history of fracture involving the forearm or wrist is clearly important. Patients may recall a specific injury involving damaging forces of torque with axial load applied to the involved wrist and forearm.
- The patient’s occupation or hobbies may give insight into the mechanism of injury as well as the most important functional deficits currently experienced by the patient.
- A complete medical history is important, including questions about inflammatory arthritis or osteoarthritis.
- DRUJ pathology most often causes ulnar-sided wrist pain, diminished grip strength, limited forearm pronation and supination, and limited wrist ulnar deviation.
- Pain is exacerbated with activity and increases with resisted rotation of the forearm.
- With large ulnar length discrepancy (positive ulnar variance), limited flexion-extension also can be seen.
- During the physical examination, the clinician should determine whether loss of forearm rotation is solely due to DRUJ pathology or if there is a concurrent problem at the proximal radioulnar joint or interosseous membrane. Other sources of wrist pain and dysfunction must be ruled out.
- The clinician should check for instability or chronic dislocation of the joint, comparing the injured with the uninjured wrist.
- The patient’s normal and affected wrist and forearm ranges of motion, both active and passive, should be measured. A rigid endpoint with loss of motion suggests bony pathology such as fracture malunion, whereas a soft end point with limited motion suggests soft tissue contractures.
- The clinician should carefully palpate, ballotte, and compress around the DRUJ and compare the findings to the opposite side. Grip strength measurements should be checked bilaterally.
- When evaluating patients with RA, the clinician should try to distinguish the pain and instability of the DRUJ from radiocarpal and midcarpal joint symptoms by careful palpation, ballottement, and compression of areas around the DRUJ, comparing the degree of symptoms elicited by forearm rotation versus wrist flexion-extension.
- Examinations to perform include:
  - Piano key test. The test, which isolates DRUJ disorders, is positive if it causes pain and/or crepitus.
  - Selective anesthetic injections. The test is positive when precise, selective injection of anesthetic into the area eliminates pain and improves function. Injections help to confirm pathologic changes and can be used to distinguish intra-articular from extra-articular lesions.
  - Lunocarpal compression test. A positive test reproduces the ulnar-sided wrist pain and grinding by translating force across the TFC. It also isolates pathologic changes in the TFC.
  - Lunotriquetral (Regan) shuck test. Pain, sometimes with increased joint mobility and grinding, represents a positive test. This test detects and assesses abnormalities or pathologic conditions associated with the lunotriquetral joint.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard neutral rotation posteroanterior (PA), lateral, and ulnar variance radiographs of the wrist should be obtained and compared with the normal side. The clinician should look for evidence of fractures, arthritic changes, bone lesions, and distal ulna position relative to the radius.
- Forearm and elbow radiographs are obtained if there is a history of an elbow injury (especially a radial head fracture) or forearm injury.
- If lunocarpal abutment is suspected, a PA radiograph is obtained with the forearm in pronation and the fist clenched. This will increase ulnar variance and potentially reveal ulna impaction.
- CT is best to evaluate subluxation and articular congruity of the distal radioulnar joint. To assess the distal radioulnar articular surfaces, simultaneous views are obtained of both extremities with the forearms in neutral rotation, full supination, and full pronation.
- MRI with single-injection gadolinium arthrography (MRA) is a good way to evaluate TFC lesions as well as the integrity of the scapholunate and lunotriquetral interosseous ligaments.

DIFFERENTIAL DIAGNOSIS

- Extensor carpi ulnaris tendinitis or subluxation
- Flexor carpi ulnaris tendinitis
- Pisotriquetral arthritis
- Lunotriquetral ligament tear
- TFC tear
- Acute DRUJ dislocation

NONOPERATIVE MANAGEMENT

- A trial of nonoperative management is helpful for some patients with DRUJ disorders.
- Minor strains of the DRUJ capsule or sprains of other ulnar-sided wrist ligaments may respond to rest, ice after activity, wrist splints, and oral anti-inflammatory medications.
- Easily reducible dislocations of the DRUJ can be treated by immobilization in a rigid splint or cast for 6 weeks.
- Inflammation of the ulnar-sided wrist tendons often accompanies DRUJ problems.
- Tendinitis should be treated first with stretching exercises, other physical therapy modalities, and sometimes a steroid injection before addressing the DRUJ surgically.

SURGICAL MANAGEMENT

- The Sauvé-Kapandji procedure is especially useful for patients with RA. Despite advanced radiographic findings of radiocarpal or midcarpal arthritis, complaints of wrist pain can be relieved in many RA patients by addressing the DRUJ pathology with a Sauvé-Kapandji procedure.
- Commonly, resection of the distal end of the ulna, the Darrach procedure, is recommended for patients with RA and ulnar-sided wrist pain. However, the inflammatory changes and deforming forces acting on the hand and wrist in RA tend to cause palmar and ulnar translocation of the wrist, resulting in decreased mobility, strength, and function. Removal of the distal ulna exacerbates and accelerates the problem.
With the Sauvé-Kapandji procedure, the retained distal ulna provides bony support for the ulnar corner of the wrist to help stabilize against the palmar-ulnar slide of the carpus (FIG 1). In addition, the important attachments of the ulnocarpal complex are preserved.\(^{21}\)

The Sauvé-Kapandji procedure is also beneficial in the treatment of DRUJ disorders resulting from trauma.

In cases of wrist trauma with ulnar-sided ligamentous injury and incompetence, retaining the ulnar head, as is performed with a Sauvé-Kapandji reconstruction, maintains the ulnocarpal buttress and the TFC to allow a more physiologic transmission of load from the hand to the forearm.

The osteotomy made in the ulna in the Sauvé-Kapandji procedure allows as much shortening as is needed to match the level of the radius while retaining supination and pronation.

Other surgical options include hemiresection and interposition arthroplasty, matched resection of the distal part of the ulna, Darrach resection, and more recently prosthetic replacement.\(^2\)

**Preoperative Planning**

The clinician should review preoperative radiographs and carefully assess whether fixation of the ulna head can be performed before any osteotomy or if an osteotomy and excision of the ulna segment needs to be done first to restore proper length and head position into the sigmoid fossa.

**Positioning**

- The patient is positioned supine with the upper extremity on a hand table.
- A pneumatic tourniquet is placed on the arm.
- An intraoperative fluoroscope is draped sterile and made available throughout the procedure.

---

**AUTHOR’S PREFERRED TECHNIQUE FOR THE SAUVÉ-KAPANDJI PROCEDURE**

**Incision and Dissection**

- Make a straight longitudinal incision, 6 to 8 cm long, along the ulnar border of the distal forearm.
- An alternative incision may be used if additional procedures are planned at the same sitting. For example, in patients with RA, often the Sauvé-Kapandji procedure needs to be combined with another soft tissue procedure such as a dorsal wrist synovectomy, tenosynovectomy, or tendon transfer to treat extensor tendon ruptures that result from the caput ulnae syndrome. If that is the case, start the incision more dorsally to facilitate exposure for the additional procedure, and then extend it proximally and obliquely to expose the distal ulna.

**TECH FIG 1** • Identification and mobilization of the dorsal sensory ulnar nerve, which is tagged with a rubber dam. Notice a dorsal branch under the probe.

- Identify the dorsal cutaneous branch of the ulnar nerve and protect it throughout the case (TECH FIG 1).
- Expose the distal 4 to 6 cm of the ulna extraperiosteally through the interval between the ECU and flexor carpi ulnaris (FCU).
**Osteotomy of the Ulnar Diaphysis**
- Select the appropriate level for an osteotomy of the ulnar diaphysis (TECH FIG 2A).
- Cut the bone just proximal to the flare of the ulnar head; this will leave enough of the distal ulna to accommodate two fixation screws.
- Confirm with fluoroscopy that the proposed osteotomy site is appropriate.
- Make a second cut proximal and parallel to the first (TECH FIG 2B), and remove a 10- to 14-mm segment of ulna (TECH FIG 2C). Resect the periosteum in the region of the gap and irrigate thoroughly to remove bone debris.
- If there is a positive ulnar variance, remove a correspondingly longer segment of the ulna so that when the ulnar head is recessed to neutral ulnar variance, the resulting gap will be adequate.
- Save the removed bone for subsequent grafting into the DRUJ arthrodesis site (TECH FIG 2D).

**Distal Radioulnar Joint Exposure and Preparation**
- Expose the DRUJ with a dorsoulnar capsulotomy just radial to the ECU tendon.
- Denude both the ulnar head and sigmoid fossa of the radius of all remaining cartilage to create flush surfaces of cancellous bone on each side of the arthrodesis site, and pack the harvested cancellous bone from the removed ulna segment (TECH FIG 3).
- In patients with severe bone loss, after decortication of the corresponding articular surfaces of the DRUJ, sculpt the resected segment of the ulna to fit into the space between the ulnar head and sigmoid notch as a corticocancellous bone graft.

**Fixation**
- Cannulated self-tapping screws are preferable to K-wires for fixation of the arthrodesis site.
- K-wires can irritate cutaneous nerves when buried or can cause wound problems when placed percutaneously.
- There is usually no need to remove hardware when screws are used, and rehabilitation can begin sooner because of secure fixation.
- Cannulated screws over guidewires allow accurate screw placement and facilitate the alignment of the cortices of the distal ulna and radius.
- Establish ulnar neutral variance by moving the ulnar head proximally or distally to bring its distal surface parallel with the distal radius surface; confirm correct placement fluoroscopically.
- Do this while holding the forearm in neutral rotation with the patient’s elbow resting on the operating table while supporting the forearm perpendicular to the table in neutral rotation.
- Temporarily fix the ulnar head to the sigmoid notch of the distal part of the radius with a single K-wire, and ensure proper position with fluoroscopy.
- While maintaining neutral forearm rotation, drill two guidewires across the DRUJ to stabilize the ulnar head in proper position.
- Place one wire a few millimeters proximal to the subchondral bone of the distal ulna, and position the second wire proximal enough to allow for seat-
BA TECH FIG 4 • A. Placement of the two K-wires to stabilize the ulna head. B. Drill over the K-wires, measure, and put in the screws.

- Confirm correct placement of the guidewires with fluoroscopy.
- Advance the distal wire into the far (radial) cortex of the radius and measure for screw length.
- The proximal screw provides rotational control and needs only tricortical fixation. It can be 5 mm shorter than the distal screw.
- After the screw lengths are measured, advance the wires through the skin to the radial side of the forearm with a mallet and grasp them with a clamp to avoid having the wire come out during drilling and screw placement.
- With a mallet, the chances of injuring a branch of the radial sensory nerve branch are less than those with a power driver.
- Drill over the guidewires with a cannulated drill bit (TECH FIG 4B).
- Pack additional cancellous bone harvested from the excised ulnar segment into the DRUJ space.
- Insert the selected screws over the guidewires while manually compressing the ulnar head against the radius.
- Tighten the distal screw first to avoid compressing the radial and ulnar shafts together and levering the ulnar head out of position.
- Do not use lag-screw technique on the proximal screw, and avoid tilting the head of the ulna; it must remain parallel to the long axis of the ulnar shaft.

TECH FIG 5 • Modification of the Sauvé-Kapandji procedure with ECU tenodesis as described by Minami et al. After the Sauvé-Kapandji procedure, a 3.5-mm hole was drilled from the dorsoulnar aspect of the ulnar shaft into the intramedullary cavity. The ECU tendon was then split in the central sulcus and the radial half released at the ulnocarpal level. It was then reflected proximally, leaving it attached at the musculotendinous junction. This proximally based strip was then passed into the medullary canal through the drill hole, retrieved at the distal stump of the ulna, and then sutured back on itself in an interlacing fashion.

- Split the ECU tendon in the central sulcus and release the radial half at the ulnocarpal level.
- Reflect this half of the ECU proximally, leaving it attached at the musculotendinous junction.
- Pass this proximally based strip, approximately 6 to 8 cm long, into the medullary canal through the drill hole, and retrieve it at the distal stump of the ulna, pulling it distally under moderate tension, and then suture it back onto itself in an interlacing fashion (TECH FIG 5).

Flexor Carpi Ulnaris Stabilization of the Proximal Ulna Stump

- Over a distance of 8 to 10 cm through the volar aspect of the incision, isolate a distally based slip of FCU tendon (measuring about half the width of the tendon) attached to the pisiform.
- Drill a 4- to 4.5-mm hole on the volar cortex, 1 cm proximal to the end of the osteotomized surface of the proximal ulnar segment.
- This is facilitated by inserting the drill bit obliquely through the medullary cavity in a dorsal to volar direction.
- Pass the slip of FCU tendon deep to the FCU muscle through the distal end of the ulnar stump, and loop it back on itself, securing it with nonabsorbable suture (TECH FIG 6).
- Suture the tendon under moderate tension, keeping the forearm in neutral rotation and the wrist in neutral flexion-extension and neutral radioulnar deviation.

Extensor Carpi Ulnaris Stabilization of the Proximal Ulna Stump

- After fixation of the DRUJ, drill a 3.5-mm hole from the dorsoulnar aspect of the ulnar shaft proximal stump into its intramedullary cavity.
Pull the pronator quadratus muscle into the gap in the ulna and suture it to the volar aspect of the tendon sheath of the ECU.

Reattach the sixth dorsal compartment within the groove on the ulnar head and close the wound.

**Wound Closure**

- Make sure that there is a gap of 10 to 12 mm between the proximal and distal ulnar segments.
- Suture the fascia of the underlying pronator quadratus into the gap to prevent reossification across the pseudarthrosis site and stabilize the stump of the ulnar shaft (TECH FIG 7A).
- Repair the retinacular compartments (TECH FIG 7B) and close the skin in routine fashion.

**TECH FIG 6** • Modification of the Sauvé-Kapandji procedure with FCU tenodesis as described by Lamey and Fernandez.12 Lateral aspect of the wrist, showing stabilization of the proximal ulnar segment with use of a distally based slip of the FCU tendon.

**TECH FIG 7** • A. Suturing the pronator quadratus into the gap. B. Closure of the retinaculum.

**TECHNIQUE FOR CASES CHARACTERIZED BY POOR BONE QUALITY (FUJITA TECHNIQUE8,9)**

- Make a 7-cm longitudinal skin incision on the dorsal aspect of the wrist centered on the ulna head (TECH FIG 8A).
- Open the fourth dorsal compartment. Divide the septum between the fourth and fifth compartments and reflect the retinaculum ulnarly to preserve a single common retinacular flap.
- Retract the extensor digitorum communis and extensor digiti minimi tendons radially and perform a neurectomy of the terminal branch of the posterior interosseous nerve.
- Incise the capsule of the DRUJ and dissect the distal part of the ulna subperiosteally.
- Perform an oblique osteotomy with an oscillating saw 30 mm proximal to the distal end of the ulna and excise the ulna head (TECH FIG 8B).
- Perform a synovectomy of the DRUJ and remove the periosteum of the resected portion of the ulna. Interpose the pronator quadratus muscle at the osteotomy site.
- Drill a hole 10 mm in diameter at the sigmoid notch of the radius while viewing the distal articular surface of the radius through the TFC, which is usually ruptured. Do not penetrate the subchondral bone (TECH FIG 8C).
- Remove all soft tissue from the resected portion of the ulna and then rotate it 90 degrees and insert the cut end of the ulnar graft into the hole in the radius, creating a shelf 12 to 15 mm long.
- Impact the ulnar graft into the subchondral and cancellous bone of the distal part of the radius without penetrating the radial cortex, and fix it in the drill hole with a cancellous bone screw (TECH FIG 8D). Do not overtighten the screw.
- Cover the graft with the joint capsule contiguous with a periosteal flap.
- Mobilize and relocate the ECU tendon by dissecting the septum between the fifth and sixth compartments.
- If subluxation of the ECU tendon is evident during rotation of the forearm, reflect the distal portion of the periosteal flap ulnarly beneath the ECU tendon to act as a sling, and suture it to the adjacent soft tissue to restrain the ECU in a dorsal and radial position over the graft.
- Close in the fashion previously outlined.
TECH FIG 8 • Modification of the Sauvé-Kapandji procedure with the distal ulna used as a bone peg as described by Fujita et al.\textsuperscript{9} \textbf{A.} Make a 7-cm longitudinal skin incision on the dorsal aspect of the wrist centered on the ulna head. \textbf{B.} Perform an oblique osteotomy with an oscillating saw 30 mm proximal to the distal end of the ulna and excise the ulna head. \textbf{C.} Drill a hole 10 mm in diameter at the sigmoid notch of the radius while viewing the distal articular surface of the radius through the TFC, which is usually ruptured. Do not penetrate the subchondral bone. \textbf{D.} Remove all soft tissue from the resected portion of the ulna and then rotate it 90 degrees and insert the cut end of the ulnar graft into the hole in the radius, creating a shelf 12 to 15 mm long. Impact the ulnar graft into the subchondral and cancellous bone of the distal part of the radius without penetrating the radial cortex, and fix it in the drill hole with a cancellous bone screw.

<td>▪ In patients with rheumatoid arthritis, DRUJ symptoms should be distinguished clinically, not radiographically, from radiocarpal symptoms. Many patients can be treated with the Sauvé-Kapandji procedure successfully despite radiocarpal changes on radiographs.</td>
<td></td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

▪ Rehabilitation after the Sauvé-Kapandji procedure follows guidelines published by Skirven.\textsuperscript{16}

▪ Postoperatively, a bulky dressing with plaster splints extending above the elbow, maintaining the forearm in neutral position, is applied for 7 to 10 days.

▪ Sutures are then removed and the patient is given a removable, lightweight splint to support the wrist.

▪ Hand therapy is initiated with an emphasis on gentle active wrist, digit, and forearm rotation exercises.

▪ Except for exercise sessions and bathing, the splint is worn at all times.

▪ In the postoperative period, the goal is to allow adequate healing by supporting and protecting the arthrodesis site from stress, followed by gradual restoration of functional mobility without sacrificing the stability of the ulnar shaft or the arthrodesis.

▪ The arthrodesis is protected from loading forces for 4 to 6 weeks.

▪ When the arthrodesis appears healed radiographically, usually 8 weeks postoperatively, light strengthening exercises are initiated. Heavy lifting and forearm torque are avoided until 3 months postoperatively.

▪ For conservative management of postoperative instability of the ulnar shaft, Skirven has recommended a small, cuff-style splint to support the pseudarthrosis site and help stabilize the ulnar shaft.\textsuperscript{16}

▪ The splint, which is made of thermoplastic material, extends from the distal radius ulnarly to a few centimeters proximal to the pseudarthrosis site.

▪ An adjustable strap allows the patient to set the tension on the splint to provide comfort and the level of stability required for specific activities.
OUTCOMES

- There is a broad international experience with this operation on many patients.
- Zimmermann in Austria retrospectively reported on 43 patients’ clinical results and DASH questionnaires 8 years (range 5 to 12 years) after a Sauvé-Kapandji operation. Forearm rotation improved in all patients. Ulnar wrist pain was diminished in 97% of the patients, and 9% had mild pain at the proximal ulnar stump. Grip strength compared to the contralateral side improved from a preoperative mean of 38% to a postoperative mean of 55%. The mean DASH score was 28 points (range 0 to 53 points). In all cases the arthrodesis fused within 8 weeks.
- In Australia, Millroy reported on 81 procedures in 71 patients and found that “almost all patients were pain free during normal activity, although 7 experienced discomfort with overuse.”
- In Belgium, De Smet conducted a prospective survey on 84 patients treated for posttraumatic arthritis of the DRUJ with the procedure. According to the Mayo wrist score, there were 20 excellent, 34 good, 18 fair, and 12 poor results, with an overall satisfaction rate of 74%.
- In Denmark, Jacobsen found that 15 of 17 employed patients returned to work.
- In England, Carter found that 86% of his patients would have the operation again.
- In Germany, Daecke looked at the functional outcomes of 56 patients with the DASH and Mayo wrist scores as well as clinical results. Although only 50% of patients were free of symptoms during heavy labor, 95% had excellent results. The postoperative DASH score was 24.2 ± 22.5 and the Mayo wrist score was 76.1 ± 17.6.
- In Switzerland, Lamey reported on 18 patients who underwent the Sauvé-Kapandji procedure with the FCU tenodesis of the ulna stump. There were 6 excellent, 7 good, 4 fair, and 1 poor Mayo wrist scores. Eight of the patients who had performed heavy manual labor before the injury were able to return to work full-time without restrictions.
- Many other studies report similar outcomes, confirming the utility and broad appeal of this operation.

COMPLICATIONS

- The main source of complications from the Sauvé-Kapandji procedure is the distal stump of the ulna.
- Pain, ulnar impingement syndrome, and a feeling of instability of the ulnar shaft have been reported, but these symptoms are usually transient and resolve by 3 months postoperatively.
- Significant instability of the ulnar shaft is more commonly reported after the Darrach procedure, but it can also occur if too much bone is resected during the described procedure.
- To prevent instability, the surgeon should carefully stabilize the ulnar stump with pronator quadratus fascia advancement, should place the osteotomies as far distally as possible, and should not resect too much bone.
- The surgeon should also avoid excessive stripping of the interosseous membrane. A soft tissue tube should surround the pseudarthrosis site to connect and stabilize the proximal and distal ulnar segments.
- Despite these precautions, painful instability of the distal ulnar stump can occur. In this scenario, the stump can be stabilized by using a strip of the ECU or FCU tendon based on its distal attachment.
- Another complication from the Sauvé-Kapandji procedure is ossification of the pseudarthrosis site.
- The pronator quadratus should be interposed in the ulnar gap after the osteotomy is complete and the ulnar segment should be removed extraperiosteally to minimize the occurrence of this complication.
- If ossification does occur, the bone may be resected when mature. The patient should then immediately begin forearm rotation exercises.
- Injury of the dorsal cutaneous branch of the ulnar nerve is a potential problem and can be avoided with careful dissection.
- Wada and Ishii reported closed rupture of a finger extensor tendon after the Sauvé-Kapandji procedure. They postulated that this was due to the ulnar shaft stump’s being left distal to the edge of the extensor retinaculum, causing attritional rupture of the tendon trapped between the bone edge and the retinaculum.
- This could be avoided by contouring the ulnar shaft edge to a smooth edge and covering the stump with the interposed pronator quadratus.
- Painful neuromas of the dorsal sensory branch of the ulna nerve have also been reported.
- Lamey and Fernandez noted that this may be more common when harvesting a distally based slip of the FCU from one incision. They recommend this be done from a second incision.
- Some patients develop hardware pain from palpable screw heads. These screws can be removed.

REFERENCES

DEFINITION
- As with any synovial joint, the distal radioulnar joint (DRUJ) can degenerate due to osteoarthritis, inflammatory arthritis, chronic instability, infection, and trauma.
- Standard treatments such as partial (“matched resection”) or complete (Darrach procedure) distal ulnar resection have the potential to destabilize the forearm axis and cause painful forearm rotation.
  - The normal compressive muscle forces acting between the radius and ulna help stabilize the DRUJ.
  - When the distal ulna has been resected and the forearm is rotated under such a compressive load, a palpable grinding between the ulnar stump and the radius may develop; this is referred to as ulnar impingement. This may progress from minor irritation to painful erosion of the radius. These patients present with pain on stress loading of the upper extremity, weakness in grip strength, decreased forearm rotation, and difficulty with lifting.1
- Ulnar head implant arthroplasty is designed to maintain the DRUJ, thereby avoiding ulnar impingement. An adequate soft tissue envelope repaired over the implant provides stability.
  - The first prosthesis used was a silicone cap designed to provide a soft end to the ulnar stump. These prostheses understandably failed under loading.
  - Newer designs aim to restore the ulnar head using a metallic prosthesis to articulate with the sigmoid notch.

ANATOMY

PATHOGENESIS

NATURAL HISTORY

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients who have had an ulnar head resection complain of painful forearm rotation, often associated with instability of the forearm axis, decreased strength, and joint grinding.
- In addition to recording the range and fluidity of DRUJ motion, the examiner must determine the stability of the joint and the contribution of ulnar impingement to the patient’s pain.
- Radioulnar compression creates radioulnar impingement by external passive compression.
  - The examiner should encircle the patient’s distal forearm with his or her hands and apply firm compression.
  - A positive sign is reproduction of the patient’s pain.
  - Active radioulnar impingement is reproduced by active muscle contraction, specifically the brachialis.
- The patient has pain lifting a load of 2 lbs with the forearm in neutral position.
- Ulnar stump instability results from compromised soft tissue stabilizers of the distal stump, which tends to fall away from the radius as the forearm is rotated.
- The patient is asked to actively rotate the forearm. Dorsal and palmar subluxation of the ulnar stump is visible.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard posteroanterior, lateral, and oblique radiographs of the wrist
  - These x-rays demonstrate scalloping of the ulnar cortex of the radial metaphysis and some corresponding pencilling of the distal ulnar stump.
- Posteroanterior stress-loaded radiographs
  - May demonstrate impingement between the radius and ulna
  - The patient stands with the involved forearm facing the x-ray tube. The wrist is stress-loaded by asking the patient to hold a 2.2-kg lead cylinder with the shoulder adducted, the elbow flexed to 90 degrees, and the forearm in the position of neutral rotation.
  - The forearm rests on the x-ray cassette and the radiograph is then taken with the beam aligned in the coronal plane, creating a posteroanterior view of the neutral forearm.
  - Radiographs are obtained before and after stress-loading.
- CT scanning
  - In patients with osteoarthritis of the DRUJ, axial scans are essential for evaluation of the extent of degenerative changes in the ulnar head and the need for total or partial replacement.
  - CT scanning is also essential for evaluation of the sigmoid notch for osteophytes and erosion in patients with painful ulnar head replacement.
  - CT scanning with forearm in pronation and supination is also useful in detecting radioulnar instability if clinical examination is equivocal.

DIFFERENTIAL DIAGNOSIS
- In addition to radioulnar impingement, a patient who has pain at the DRUJ after resection of the ulnar head may have pain due to the following conditions:
  - Ulnar neuropathy
  - Painful surgical scar due to sensory nerve injury or scarring
  - Radiocarpal or midcarpal arthritis

NONOPERATIVE MANAGEMENT
- Activity modification to minimize forearm rotatory movements will diminish pain.
- A Russe splint is partially helpful for patients with instability of the distal ulna stump but is of no help in preventing radioulnar impingement pain.
SURGICAL MANAGEMENT

- The most common indication for distal ulnar implant arthroplasty is to relieve impingement symptoms in patients who have undergone previous ulnar head resection.
- Other less common indications include:
  - Treatment of patients with primary degenerative arthritis of the DRUJ who have failed to respond to splinting and steroid injections
  - Reconstruction of the ulna after excision of a tumor involving the ulnar head
  - After unreconstructable fractures of the ulnar head as either a primary or delayed procedure
  - Relative indication: patients with well-controlled inflammatory arthritis but well-preserved bone stock
- The amount of the DRUJ that is replaced may vary for any given case.
  - Partial ulnar head replacement
  - Unconstrained replacement of the entire distal ulna with or without sigmoid notch resurfacing
  - Constrained total DRUJ replacement, including the sigmoid fossa of the distal radius
- Partial ulnar head replacement preserves the styloid process and the attachment of the triangular fibrocartilage.
  - This procedure is indicated when the disease process, typically arthritis, is limited to the distal ulnar articular surface.
  - Contraindications include instability of the distal ulna, excessive ulnar positive variance, and degeneration at the sigmoid notch.
  - Two types of implants are available: a one-piece stemmed metal prosthesis and a two-piece prosthesis with a titanium stem and an articulating pyrolytic carbon disc that replaces the head (FIG 1).
  - The long-term results of partial ulnar head replacement are not known. The articulating two-piece prosthesis has the theoretical advantage of less radius erosion from articulation with the pyrocarbon head.
  - Unconstrained complete ulnar head replacement is indicated for reconstruction of ulnar impingement after resection or replacement of an arthritic DRUJ associated with instability of the distal ulna. With mild instability, repair of the soft tissue envelope is adequate to restore stability. In cases with more obvious instability, an additional soft tissue procedure is indicated along with ulnar head replacement.
  - Ulnar head prostheses are generally spherical and made of metal or ceramic. An eccentric-shaped metallic head has been designed to more closely approximate the shape of the normal head. However, biomechanical studies have demonstrated normal tracking patterns of the distal ulna around the radius, closely simulating the normal joint, even with the use of spherical heads.
  - Ulnar head prostheses may articulate with a metal-backed polyethylene resurfacing of the sigmoid notch in an unconstrained manner (FIG 2).
  - An adequate soft tissue envelope is essential to prevent subluxation of a complete ulnar head replacement. The triangular fibrocartilage complex (TFCC) is no longer attached to the distal ulna, making the prosthesis prone to dislocation. Thus, an essential part of the surgical technique is reconstructing the capsuloligamentous envelope surrounding the ulnar prosthesis.
  - Other contraindications include previous open fracture, infection in or around the joint, skeletal immaturity, and known sensitivity to the implant materials.
  - In cases of marked instability, with lack of an adequate soft tissue stabilizing envelope and ablation of the DRUJ after trauma or tumor resection, a constrained total DRUJ replacement should be used (FIG 3).
  - The radial component consists of a plate with a polyethylene-lined metal sphere affixed to the interosseous surface of the radius.
  - The ulnar stem has a protruding peg that is captured and rotates within the polyethylene liner. The stem has limited
freedom of proximodistal and limited dorsopalmar motion, simulating normal DRUJ mechanics.

Preoperative Planning
- Preoperative radiographs of both sides are used for templating (FIG 4).
  - Normal anatomy and ulnar variance are reproduced to the extent possible.
  - The appropriate implant size is chosen.

Positioning
- Standard positioning and tourniquet application are used.

PARTIAL ULNAR HEAD REPLACEMENT ARTHROPLASTY
- Make a longitudinal incision in line with the fourth metacarpal.
- Divide the extensor retinaculum over the fourth compartment and reflect it ulnarly.
- Retract the two slips of the extensor digiti minimi tendon and elevate a large ulnar-based triquetral flap of capsule.
  - The flap includes the dorsal radiotriquetral ligament distally.
  - The TFCC should be repaired back to bone if foveal detachment is detected.
- Leave in place the ECU subsheath and ECU tendon.
- Resect the articular portion of the ulnar head using a customized jig specific to the implant system to be used.
- Ream the ulnar medullary canal and place a trial prosthesis of the appropriate size. Obtain intraoperative radiographs to confirm correct sizing of head and ulnar variance.
- Ascertain range of motion and stability and insert a definitive prosthesis. Restore the capsular flap and imbri cate it if necessary for stability (TECH FIG 1).

ULNAR HEAD HEMIARTHROPLASTY (WITHOUT SIGMOID NOTCH RESURFACING)
- Make a longitudinal skin incision on the ulnar border of the distal forearm (TECH FIG 2A).
- Incise the extensor retinaculum along the medial border of the distal ulna between the ECU and FCU.
- Identify and protect the dorsal cutaneous branch of the ulnar nerve as it crosses from volar to dorsal across the most distal part of the incision.
- Elevate the ECU tendon subsheath subperiosteally off the distal ulna along with the TFCC and ulnar collateral ligament distally.
- Determine the resection level of the distal ulna using a template and mark it with a pen or osteotome (TECH FIG 2B).
The aim is to create ulnar neutral variance after the implant is in place.

When the distal ulna has been previously excised, use the distal end of the sigmoid fossa of the distal radius as a landmark to determine the ulnar osteotomy level.

With soft tissue retractors in place, use an oscillating saw to osteotomize the distal ulna (TECH FIG 2C).

Take care to ensure that the cut is perpendicular to the long axis of the ulna.

Remove and size the ulnar head.

To allow for easy identification for soft tissue repair, place a tagging suture into the TFCC attachment in the fovea before releasing it from the ulna.

Inspect the sigmoid notch of the distal radius for incongruity. Remove osteophytes.

Define the intramedullary canal of the distal ulna using an awl or sharp broach. Gently enlarge the canal to the appropriate stem size using broaches of increasing diameter (TECH FIG 2D).

Gently impact the appropriate trial stem into the shaft of the distal ulna (TECH FIG 2E). The collar should seat firmly against the resected surface of the distal ulna.

In cases with previous excessive ulnar resection, a prosthesis with an extended collar may be indicated.

To ascertain the need for an extended collar, place a trial spacer on the neck of the trial stem before placing the trial head.

Place the trial head of the appropriate size onto the neck of the trial stem and reduce the DRUJ.

Supination and pronation should be full and smooth, with no instability at the articulation.

Obtain intraoperative radiographs to evaluate the size of the ulnar head and the ulnar variance.

If the prosthesis is too distal, resection of more distal ulna is necessary.

Remove the trial implant by gently applying anteriorly directed pressure on the distal ulna to dislodge the ulnar head from the sigmoid notch.

If a firm fit is obtained with the trial, a press-fit technique may be used with the final implant. In patients with osteopenia or previous wrist fusion, use cement to secure the ulnar stem.

Prepare the appropriately sized head for soft tissue stabilization before the stem is fully impacted. Pass two 3-0 nonabsorbable sutures with curved double needles through each row of holes in the prosthesis head. Pass the needles from the deeper suture through the TFCC at its previous foveal insertion, and insert the needles from the superficial suture into the ECU subsheath. Leave the sutures untied (TECH FIG 2F).

Insert and impact the final stem (with or without cement) using the stem impactor.

---

**TECH FIG 2**

A. A longitudinal incision is made between the flexor and extensor carpi ulnaris tendons on the ulnar border of the distal forearm and wrist. B. The cutting guide helps determine the level of resection of the ulnar head. The distal notches are for use with the three head sizes and standard stem, and the proximal notches are for use with a collared stem in cases of previous resection or resorption of the distal ulna. C. An oscillating saw is used to resect the ulnar head at the determined level. D. The ulnar medullary cavity is reamed using broaches. (continued)
Align the head of the prosthesis such that the two rows of suture holes are along the subcutaneous border of the ulna (TECH FIG 2G). Then place it onto the tapered neck of the stem and gently impact it.

Advance the soft tissues ulnarly over the head of the prosthesis as it is reduced into the sigmoid notch. With the forearm in midrotation, tie down the sutures placed in the head, closing the ECU subsheath over the top of the prosthesis.

Because the head does not freely rotate on the stem, it is essential to align the head before impaction onto the stem. The holes on the head are lined up with the subcutaneous border of the ulna. After the pull-through sutures of the prosthesis are tied down, the remaining soft tissue envelope deep to the extensor retinaculum is approximated with the forearm in neutral position. Preoperative radiographs of an unstable and incongruous ulnar head after comminuted fracture of the distal radius and ulna. Ulnar head replacement and soft tissue imbrication restored congruity and stability to the articulation.
CONSTRANDED DISTAL RADIOULNAR JOINT ARTHROPLASTY

- Make an 8-cm longitudinal incision in the shape of a hockey stick along the ulnar border of the distal forearm between the fifth and sixth dorsal extensor compartments (TECH FIG 3A).
- Create a rectangular ulnarily based fascia flap (TECH FIG 3B). Use the flap to create a barrier between the prosthesis and the ECU at closure.
  - The width of the flap should cover the head of the implant and may include the most proximal part of the extensor retinaculum.
- Expose the distal ulna through the floor of the fifth extensor compartment and mobilize the tendons of the extensor digiti minimi proximally for a distance of 8 cm.
- Divide the sensory branch of the posterior interosseous nerve to avoid avulsion of the nerve from the thumb extensors when placing an elevator between the extensor mass and the radius.
- Incise the ECU sheath to its insertion at the base of the fifth metacarpal.
  - This is to avoid pressure against the distal end of the implant.
- Excise the remaining head of the ulna at a level just proximal to the cartilage, or where the DRUJ would have been.
- Leave the radial attachment of the TFCC undisturbed to provide a barrier between the prosthesis and the carpal bones.
- Displace the ulnar shaft in a volar direction to expose the radius and sigmoid notch (TECH FIG 3C).
- Elevate the interosseous membrane along the distal 8 cm of the radius.

TECH FIG 3 • A. Intraoperative photograph of implantation with the Aptis system. The dorsoulnar skin incision is placed between the fifth and sixth extensor compartments. B. A large ulnar-based flap of retinaculum is raised for later interposition between the extensor carpi ulnaris tendon and the implant. C. The ulna is displaced volarly with retractors to expose the interosseous surface of the radius and the sigmoid notch. D. The radial plate template is positioned and temporarily fixed to the radius. The plate’s position is checked with radiographs (inset). E. Operative photograph demonstrating completion of fixation of the radial component. Radiographs confirm correct placement of implant and screw length (inset). F. A sizer with an attached ball is used to determine the level of ulnar resection. This ensures that the ulnar implant with seated polyethylene ball will be level with the radial socket. (continued)
Chapter 93  ULNAR HEAD IMPLANT ARTHROPLASTY 2855

TECHNIQUES

TECH FIG 3  (continued)  G. Medullary broaches are used to enlarge the medullary canal of the distal ulna.  H, I, J. Steps for final assembly of the system. After the ulnar stem is inserted, the polyethylene ball is placed over the peg. The ball is then aligned with the radial socket and the cap is placed over it and secured with two screws.  K. Final radiographs demonstrate correct placement of the implant.  L. The previously raised retinacular flap (marked by asterisks) is then placed over the prosthesis and beneath the extensor carpi ulnaris tendon.

- Place the radial trial plate over the interosseous crest of the radius with the volar border aligned with the volar surface of the radius (TECH FIG 3D).
  - The plate should lie at least 3 mm proximal to the distal end of the sigmoid notch of the radius to avoid impaction with the carpus.
- Use a burr to contour the distal radius as necessary to accommodate the plate. Position the plate and hold it temporarily with Kirschner wires passed through the plate.
- Use intraoperative imaging to check the position of the plate.
- After drilling the hole for the radial peg, remove the trial and gently impact the final radial component in place. Insert fixation screws into the radius to secure the implant and take radiographs (TECH FIG 3E). Remove the Kirschner wires.
- With the forearm fully pronated, seat a sizer with attached ball into the hemi-socket of the radius and align it with the ulna (TECH FIG 3F). Determine the level of ulnar resection.
- After resecting the distal ulna, insert a 1.6-mm guidewire into the medullary canal and use a cannulated drill to ream the canal.
- Insert a medullary broach of the appropriate size into the canal to bevel the distal ulna and plane its distal end (TECH FIG 3G).
- Irrigate the medullary canal and insert the stem of the ulnar component (TECH FIG 3H). Place the ultra-high-molecular-weight polyethylene ball over the distal peg and position the ulnar component within the hemi-socket of the radial component (TECH FIG 3I).
- Position the cover of the socket over the ball and secure it with two small screws (TECH FIG 3J).
- Obtain radiographs to confirm satisfactory positioning of the prosthesis (TECH FIG 3K).
- Position the fascia and retinacular flap between the prosthesis and the ECU tendon and suture them to the radius before doing a layered closure (TECH FIG 3L).

POSTOPERATIVE CARE

- The forearm is immobilized in neutral rotation and held in a supportive long-arm or Muenster-type splint or cast for 3 weeks.
- Active range of motion of the wrist and forearm is initiated at 3 weeks.
  - A removable splint is required between therapy sessions for 3 weeks.
- Therapy is advanced as tolerated after 6 weeks, with strengthening starting only after functional wrist and forearm motion has been obtained.
- For a patient with rheumatoid arthritis, poor-quality soft tissue coverage, or mild instability intraoperatively, immobilization in supination for up to 6 weeks must be considered.
- Postoperative radiographs should be obtained at 6 weeks, 6 months, and then yearly.

OUTCOMES

- Outcomes vary with the indication and type of prosthesis used.
- The pain of radioulnar impingement is relieved in patients with previous excision arthroplasty and stability is restored.
- The range of motion of the forearm after prosthetic replacement remains largely unchanged, as it depends on previous scarring.
- Grip strength recovered depends on the underlying problem, but in patients with severe pain and weakness preoperatively, final grip averages about 60% of the opposite side.
- The long-term results and the incidence of prosthetic loosening, failure, and radius erosion are not known.

COMPLICATIONS

- Immediate or short-term complications
  - Fracture of the distal ulna during reaming or impaction of the prosthesis
  - Dislocation of the prosthesis from the DRUJ postoperatively
  - Long-term complications
    - Progressive degeneration of the sigmoid notch
    - Implant loosening
    - Tenosynovitis of the ECU tendon
    - Erosion of the radius sigmoid notch with pain
    - Ectopic bone formation around the distal ulna
    - Stress shielding and resorption of distal ulna
    - Prosthetic fracture
  - Infection and wound breakdown, especially in revision cases with poor soft tissue cover
  - Injury to the dorsal sensory branch of the ulnar nerve, leading to tender neuroma

REFERENCES

DEFINITION
- A tear of the triangular fibrocartilage complex (TFCC) is one of the most common causes of ulnar wrist pain. The treatment of TFCC tears and the associated synovitis is one of the primary indications for operative wrist arthroscopy.
- Ulnar-sided wrist pain associated with a TFCC tear in the presence of ulnar-neutral or ulnar-plus variance constitutes ulnar abutment syndrome. Successful treatment of an ulnar abutment syndrome requires not only the débridement of the TFCC tear but also shortening of the ulna.
- Patients with Palmer type IA* TFCC tears are prime candidates for TFCC débridement.
- Patients with Palmer type II (degenerative central tears) can also benefit from TFCC débridement. For the more advanced degenerative tears associated with lunatotriquetral ligament tears (Palmer type IID and E), other procedures such as an ulnar shortening osteotomy must be considered.

ANATOMY
- The triangular fibrocartilage is the primary stabilizer of the distal radioulnar joint. It attaches radially on the distal lip of the sigmoid notch (FIG 1). Ulnarly, the triangular fibrocartilage inserts at the base of the ulnar styloid via a continuation of the dorsal and palmar radioulnar ligaments and the fibers of the ligamentum subcruentum.4

PATHOGENESIS
- Tears of the triangular fibrocartilage are typically the result of a fall on the outstretched upper extremity. The ulna is driven distally and compresses the TFCC between itself and the lunate, producing a central or radial tear of the articular disc. This same mechanism can result in lunatotriquetral tears and peripheral TFCC tears (reviewed elsewhere).
- Forceful ulnar deviation, such as noted in racquet sports and golf, can lead to TFCC tears. Gymnastics, with its significant axial loading of the wrist, can also lead to a TFCC tear.
- The combination of ulnar axial load and torque noted during these sports can be sufficient to tear the triangular fibrocartilage.
- At least 50% of intra-articular distal radius fractures are associated with tears of the triangular fibrocartilage.1 Many of these tears remain asymptomatic and require no surgical treatment.
- An ulnar abutment (impaction) syndrome can develop as a result of shortening after a distal radius fracture (FIG 2). Radial collapse of the articular platform leads to a relative lengthening of the ulna.
- Palmer et al9 have demonstrated an increase in the ulnocarpal load with increasing ulnar variance.
- Repetitive axial loading of the wrist in a patient with an ulnar-zero or ulnar-plus variance can lead to an attritional tear of the triangular fibrocartilage and ulnar abutment syndrome.

NATURAL HISTORY
- The natural history of TFCC tears is not well established. Many asymptomatic TFCC tears are noted on routine wrist arthroscopy. If left untreated one could assume that a TFCC...
A tear could lead to chondromalacia of the lunate, triquetrum, and distal ulnar head. This in turn could lead to painful ulnocarpal synovitis.

- The increase in the force transmitted through the ulnocarpal joint noted in an ulnar abutment syndrome can lead to a degenerative tear of the triangular fibrocartilage, chondromalacia of the lunate, triquetrum, and distal ulna, and a triquetrolunate ligament tear.

**PATIENT HISTORY AND PHYSICAL EXAMINATION**

- Physical examination includes the following:
  - Ulnocarpal compression test: Pain at the ulnocarpal joint with or without popping and grinding is suggestive of a TFCC tear and possible ulnar abutment syndrome.
  - Lester press test: Pain at the ulnocarpal joint is suggestive of a TFCC tear and possible ulnar abutment syndrome.
  - Ulnocarpal palpation: Pain at the ulnocarpal joint suggests the presence of TFCC pathology as well as ulnocarpal synovitis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- The radiographic evaluation of a patient with an ulnar abutment should include a standard wrist series and a Palmer 90°/90 neutral rotation view.
  - The Palmer 90°/90 view places the forearm in neutral rotation while the elbow is flexed to 90 degrees and the shoulder is abducted to 90 degrees. The ulnar variance is calculated from this view (Fig 3A). Ulnar abutment is suspected in a patient with an ulnar-zero or ulnar-plus variance.
  - The ulnar aspect of the lunate should be carefully examined for subchondral cysts.
  - An MRI should be considered when evaluating the patient for ulnar abutment syndrome. The MRI will demonstrate increased signal in the lunate on the T2 images (Fig 3B,C). This corresponds to either a cyst or intraosseous edema.
  - The triangular fibrocartilage can also be evaluated on the MR images. Whether an MR arthrogram is needed is a function of the MR resolution. The accuracy of lower-resolution MR is increased with the addition of an intra-articular gadolinium injection.

**DIFFERENTIAL DIAGNOSIS**

- TFCC tear
- Distal radioulnar ligament injury
- Distal radioulnar joint instability
- Ulnocarpal ligament injury
- Lunotriquetral joint instability
- Ulnocarpal synovitis
- Lunate chondromalacia
- Triquetral chondromalacia
- Distal ulnar chondromalacia
- Kienböck disease

**NONOPERATIVE TREATMENT**

- Immobilization of the involved wrist with either a Munster splint or long-arm cast for 4 weeks, combined with a course of nonsteroidal anti-inflammatory medications, activity modification, and therapy) can be helpful in patients who present acutely.
- A TFCC tear that is exacerbated by specific activities can occasionally respond to activity modification.

**SURGICAL MANAGEMENT**

- The failure of nonoperative treatment (splinting, rest, nonsteroidal anti-inflammatory medications, activity modification, and therapy) leads the surgeon to choose surgical débridement of a TFCC tear.
- Mechanical débridement of the triangular fibrocartilage has been successful. This can be challenging, particularly in regard to the débridement of the ulnar and dorsal aspects of the triangular fibrocartilage tear.
  - There are two potential problems with mechanical TFCC débridement:
    - Passage of the instruments across the radiocarpal joint places those joints at risk of scuffing.

---

**FIG 3**

- A. Ulnar-plus variance noted on 90°/90 neutral rotation view.
- B, C. T1- and T2-weighted MRIs of a wrist with an ulnar abutment demonstrating the change in signal at the ulnar proximal lunate.
The proximity of the scope to the operative site (TFCC) can distort the operator’s perception of the ulnocarpal joint.

Radiofrequency devices have become increasingly popular for TFCC débridement because of the small probe size and relatively low cost. Monopolar and bipolar radiofrequency devices are currently in use. The instrument settings vary with the device.

Arthroscopic ulnar shortening is indicated in patients with a TFCC tear who have longstanding or acute exacerbation of ulnar abutment syndrome and who do not respond to nonoperative treatment.

It is generally thought that an arthroscopically assisted ulnar shortening is indicated if the ulnar-plus variance is less than 4 mm.

The goal of the surgery is to create an ulnar-minus variance of 2 mm.

**Preoperative Planning**

- **TFCC débridement:** Preoperative evaluation should include wrist radiographs: a “wrist series” and a “90°/90°” view described by Palmer. An MRI with or without an arthrogram can also be helpful.
- **Arthroscopic ulnar shortening**
  - The patient must be informed that an arthroscopically assisted ulnar shortening may not be possible should there be laxity of the ulnocarpal ligaments, a peripheral TFCC tear, or lunatotriquetral laxity.
  - The amount of shortening should be calculated preoperatively.
  - The surgeon should verify that the operating room is equipped with a mini C-arm to permit intraoperative assessment of the amount of ulna resected.

**Positioning**

- The patient is placed in the supine position.
- A pneumatic tourniquet is placed on the proximal arm.
- The involved extremity is prepared and draped in the usual fashion.
- The wrist is distracted using a commercially available wrist traction device.

---

**MECHANICAL TFCC DÉBRIDEMENT**

**Portals and Arthroscopic Examination**

- The standard dorsal 3-4 and 4-5 or 6R wrist arthroscopy portals are used for TFCC débridement (TECH FIG 1). These portals should be wide enough to permit the easy passage of instruments.
- Before débriding the TFCC, perform a thorough and systematic arthroscopic examination of the radiocarpal, ulnocarpal, and midcarpal joints because associated intrinsic and extrinsic ligament injury and articular and synovial pathology could affect the treatment plan.
- Perform ulnocarpal synovectomy to ensure clear visualization of that joint.

**Radial and Palmar Débridement**

- The initial débridement of the radial and palmar and a portion of the dorsal aspects of the TFCC tear is accomplished with a scope in the 3-4 portal while the instruments enter through the 4-5 portal.
- Use small joint punches (straight and angled), graspers, mini-banana blades, and mini-hook knives to débride the TFCC. The suction punch is particularly useful.
- Take care not to injure the underlying ulnar head and overhanging lunate and triquetrum (TECH FIG 2).

**Ulnar Débridement**

- Once the radial and palmar aspects of the TFCC have been débrided, move the arthroscope to the 4-5 portal.

---

**TECH FIG 1** • Wrist arthroscopy portals.

**TECH FIG 2** • Mechanical débridement of the TFCC. The arthroscope is in the 3-4 portal looking ulnar, while the suction punch enters through the 4-5 portal to débride the palmar aspect of the TFCC.
Débride the ulnar aspect of the triangular fibrocartilage by passing the instruments through the 3-4 portal.

Keep three points in mind while débriding the ulnar aspect of the TFCC:

- Avoid injuring the attachment of the triangular fibrocartilage at its insertion at the base of the ulnar styloid.
- Avoid injuring the dorsal or palmar radioulnar ligaments. If the ulnar attachment of the TFCC is transected, or if the dorsal and palmar radioulnar ligaments are injured, distal radioulnar joint instability will result.
- Avoid scuffing the articular surfaces while passing the cutting and grasping instruments from the 3-4 portal across the radiocarpal joint into the ulnocarpal joint.

Dorsal Débridement

- The dorsal aspect of the TFCC tear can usually be débrided using the 3-4 and 4-5 portals. Occasionally, however, the instruments need to be passed through the 6U portal while the scope is placed in the 3-4 portal.
- Injury to the dorsal sensory branch of the ulnar nerve is avoided when establishing the 6U portal by using a longitudinal portal incision and blunt dissection to reach the ulnocarpal joint capsule.

Completion

- Once the TFCC has been débrided with the punches and knives, smooth the rough edges of the débrided TFCC using a full radius cutter.
- The 2.0-mm cutters are small but relatively ineffective, while the 2.9-mm cutters are effective but must be controlled so as to avoid collateral damage to the adjacent articular surfaces (TECH FIG 3A).
- The end point of the TFCC débridement is reached when the ulnar head is visible through the TFCC and a stable TFCC perimeter is created (TECH FIG 3B).
- Typically, a central defect measuring at least 1 cm in diameter is created.
- Before declaring the surgery complete, remove the instruments from the wrist, release the traction, and ulnarily deviate, axially load, and repeatedly supinate and pronate the wrist.
- The presence of popping or clicking is a sign that further débridement might be needed or that some other pathology is causing the popping and clicking.
- One source of such post-débridement popping is thickened synovium in the distal radioulnar joint just proximal to the TFCC.
- Close wounds using subcuticular sutures of 4-0 Prolene and apply a volar splint.

TECH FIG 3 • A. The arthroscope is in the 3-4 portal and the full radius cutter is passed through the 4-5 portal to smooth the edges of the débrided central TFCC tear. B. The débridement of the TFCC is complete. The ulnar head is clearly visible and ready for shortening.

LASER- OR RADIOFREQUENCY-ASSISTED TFCC DÉBRIDEMENT

- The technique of laser-assisted TFCC débridement is similar to that of mechanical débridement, with the exception that the arthroscope can be left in the 3-4 portal while the laser probe is kept in the 4-5 portal.
- The laser is set to 1.4 to 1.6 joules at a frequency of 15 pulses per second. With the help of a side-firing 70-degree laser tip, the triangular fibrocartilage can be rapidly and precisely débrided.
- The 70-degree laser tip permits ablation of not only the radial and palmar portions of the TFCC tear but also the ulnar and dorsal components.
- There is no need to bring the laser probe in through the 3-4 portal.
- During the débridement, take care not to injure the ulnar head. This is avoided by firing the laser tangentially to the head of the ulna or passing the probe beneath the triangular fibrocartilage and firing distally (TECH FIG 4).

TECH FIG 4 • Laser-assisted débridement of a TFCC tear. The laser probe is placed 1 mm from the TFCC.
The goal of the surgery is to create an ulnar-minus variance of 2 mm without any irregularities of the remaining distal ulna. Small irregularities, however, tend to flatten out with the passage of time.

Arthroscopic ulnar shortening is accomplished by placing the scope in the 3-4 portal and introducing the instruments through the 4-5 portal. Occasionally the 6U portal can be used, as can the distal distal radioulnar joint portal.

While the holmium:YAG laser is useful for ulnar shortening, the barrel abrader can also be used alone or in combination with the laser. If the holmium:YAG laser is used, it is introduced through the 4-5 portal and the cartilage and subchondral bone of the ulnar seat of the distal ulna are rapidly vaporized (TECH FIG 5A,B).

The laser becomes less efficient once the trabeculae of the distal ulna are visible (TECH FIG 5C). At that point, the 2.9-mm barrel abrader is brought in to finish the shortening (TECH FIG 5D).

It is important to avoid injury to the sigmoid notch, and frequent fluoroscopic monitoring of the amount of bone resected is mandatory.

Take care to fully supinate and pronate the wrist to adequately débride the ulnar head.

Remove all instruments at the end of the procedure, and ulnarily deviate, axially load, and supinate and pronate the wrist to be sure no clicking or popping is noted. If any clicking or popping is noted and it appears to be emanating from the area of the surgery, further ulnar leveling may be required.

Close wounds using subcuticular sutures of 4-0 Prolene and apply a volar splint.

**TECH FIG 5**  
A. The 70-degree side-firing laser probe easily vaporizes the hyaline cartilage and subchondral bone of the ulnar head.  
B. The laser has cleared the ulnar head of its cartilage and subchondral plate.  
C. The spacing of the bony trabeculae of the ulnar head decreases the laser’s efficiency. The final leveling of the ulnar head is achieved with the small joint burr.  
D. The small joint burr is brought in through the 4-5 or 6R portal to finish the ulnar shortening.
**POSTOPERATIVE CARE**

- Postoperative care includes early range of motion and suture removal at 2 weeks.
  - Early range of motion is critical as it leads to a more supple scar and a better range of motion.
  - Strengthening exercises are initiated at 6 weeks if needed.
  - Premature resumption of heavy lifting or repetitive activities will lead to ulnocarpal synovitis.
  - Some patients are pain-free after as little as 2 weeks, and the surgeon must temper the patient’s desire to return to full activity.
  - The patient is instructed to avoid heavy lifting for 3 months.
  - Typically patients are able to return to unrestricted activities in 12 weeks, although they may experience some discomfort for 6 to 12 months.
  - Patients who undergo a simple TFCC débridement will recover more rapidly than those who undergo an arthroscopic ulnar shortening.

**OUTCOMES**

- The results of arthroscopic débridement of traumatic triangular fibrocartilage tears have been very good.²,³
  - Minami et al¹ noted, however, that degenerative tears (Palmer type II) have a less favorable prognosis due to the associated ulnar wrist pathology noted in these patients.
  - Our results¹¹ and those reported by Osterman⁰ and Palmer⁸ suggest that arthroscopically assisted ulnar shortening in properly selected patients provides excellent and good results in over 80% of patients (FIG 4).

**COMPLICATIONS**

- TFCC débridement
  - Infection and injury to the dorsal branch of the ulnar nerve are rare.

- Excessive débridement of the TFCC (dorsal and palmar radioulnar ligaments, attachment in the ulnar fovea) can lead to instability.
- Formation of portal site cysts (very rare)
- Arthroscopic ulnar shortening
  - Inadequate bony resection can lead to a nonresolution of the patient’s symptoms.
  - Uneven resection of the distal ulna can lead to catching of any significant residual bony prominence on the overlying triangular fibrocartilage.
  - We have seen one patient reconstitute his triangular fibrocartilage and require repeat débridement. This phenomenon has been anecdotally reported by others.
  - The surgeon must remain vigilant and avoid injury to the sigmoid notch.
  - The surgeon must avoid excessive ulnar débridement, which could lead to the detachment of the triangular fibrocartilage from the fovea.

---

**PEARLS AND PITFALLS**

**TFCC débridement**

- The 4-5 and 6R portals should be placed just distal to the distal surface of the TFCC.
- Inappropriate distal placement of the portals can lead to scuffing of the lunate and triquetrum.

**Nerve injury**

- The dorsal branch of the ulnar nerve is at risk during the creation of all ulnar portals.
- All portals should be made by incising the skin with a no. 15 blade (avoid plunging a no. 11 blade into the joint). Once the skin is cut, a Hartmann hemostat should be used to bluntly dissect through the subcutaneous tissue and penetrate the wrist joint capsule.

**Débridement**

- Avoid injury to the peripheral attachments of the TFCC and the dorsal and palmar radioulnar ligaments.

**Incision orientation**

- Small transverse incisions in Langer lines closed with a subcuticular Prolene produce a superior cosmetic result.

**Scope**

- The 1.9-mm arthroscopes are less likely to scuff the wrist joint articular surfaces.

**Rehabilitation**

- Avoid early (before 4 weeks) heavy loading of the wrist.

**Arthroscopic ulnar shortening**

- Arthroscopically assisted ulnar shortening should not be combined with other procedures that require postoperative wrist immobilization.

**Excision of ulnar head**

- A systematic approach to the excision of the ulnar head is critical. The assistant must take the wrist from full supination to full pronation while the operator maintains the arthroscope in the 3-4 portal and the instruments in the ulnar portals. The ulnar head is débrided as it is presented to the surgeon by the assistant during the rotation of the distal radioulnar joint.

---

**FIG 4**

Six-month postoperative radiograph after arthroscopic ulnar shortening in patient in Techniques Figure 5.
REFERENCES

DEFINITION
- Ulnar impaction syndrome (ulnocarpal abutment) results from a chronic compressive overloading of the ulnocarpal articulation secondary to static or dynamic ulnar-positive variance.
- Ulnar variance defines the relationship of the length of the ulna to that of the radius.
- Ulnar-positive variance can be the result of a congenital anomaly; traumatic radial shortening from a distal radius, Essex-Lopresti, or Galeazzi fracture; injury to the distal radius physis; or a variant of normal anatomy.
- An ulnar shortening osteotomy is designed to decompress the ulnocarpal joint while simultaneously tightening the ulnocarpal and radioulnar marginal ligaments of the triangular fibrocartilage complex (TFCC).14

ANATOMY
- The distal radius has three articular surfaces: the scaphoid fossa, the lunate fossa, and the sigmoid notch.
- The radius articulates with and rotates around the ulnar head via the sigmoid notch. The sigmoid notch has well-defined dorsal, palmar, and distal margins, while the proximal margin is indistinct.
- The distal radioulnar joint (DRUJ) and ulnocarpal relationships are maintained by numerous ligamentous structures (FIG 1A).
- The interosseous membrane is a complex structure with a thickened central portion. It almost completely spans the radius and ulna, acting as a hinge for forearm rotation.
- The diaphysis of the distal half of the ulna is supplied by small segmental branches from the anterior and posterior interosseous arteries. These enter the ulna in 1- to 3-cm intervals from the direction of the interosseous membrane and must be protected during the surgical approach.22
- The dorsal capsule of the DRUJ contains two ligaments: the proximal metaphyseal arcuate ligament and the distal radioulnar ligament. The palmar capsule is composed of a single radioulnar ligament.1
- The TFCC spans the ulnocarpal joint and connects the distal radius to the distal ulna (FIG 1B). The TFCC functions to cover the distal ulna, to partially dampen and transmit a portion of the axial load of the wrist through the ulna, to stabilize the DRUJ, and to provide support for the ulnar side of the carpus.
- The TFCC contains a central avascular articular disc composed of types I and II collagen. It is of variable thickness

FIG 1 • A. The soft tissue structures encompassing the triangular fibrocartilage complex (TFC) of the wrist stabilizing the radioulnocarpal unit. The TFC proper originates from the radius medially and attaches to the base of the ulnar styloid. Fibers originating from the subsheath of the extensor carpi ulnaris dorsally cross path with fibers originating from the ulnocarpal ligaments volarly and blend with the TFC proper. B. Distal radioulnar joint (DRUJ) ligaments. (The disc component of the TFCC has been removed to show the deep limbs of the radioulnar ligaments.) The volar and dorsal radioulnar ligaments are the major soft tissue stabilizers of the DRUJ and insert onto the base of the ulnar styloid.
The articular disc is connected to the peripheral palmar and dorsal radioulnar (marginal) ligaments, which originate on the medial border of the distal radius and insert into the base of the ulnar styloid at the fovea. These ligaments are composed of linear type I collagen and are stabilizers of the DRUJ.

The ulnolunate and ulnotriquetral ligaments originate from the ulnar fovea and pass palmar to the palmar radioulnar ligament. They traverse the palmar surface of the TFCC to insert on their respective carpal bones. These ulnocarpal ligaments stabilize the ulnar side of the carpus relative to the ulna and resist carpal supination.

The periphery of the TFCC is supplied by dorsal and palmar branches of the anterior interosseous artery and the ulnar artery. Because of this vascular distribution, injuries to the periphery of the TFCC are capable of healing and are often amenable to repair. Injuries to the central avascular portion of the articular disc do not heal in a predictable manner and are often treated with debridement.

**PATHOGENESIS**

Normal ulnar variance ranges from neutral to plus or minus 2 mm. The average axial load transmitted across the TFCC and subsequently the ulna is 20% if ulnar variance is neutral. An ulnar-positive variance of 2.5 mm increases the load across the distal ulna 42.7%, while an ulnar variance of −2.5 mm decreases the ulnar load to 3.1% (Table 1).

Congenital or acquired ulnar-positive variance (FIG 2) can lead to degenerative wear of the TFCC and surrounding structures.

The Palmer classification divides TFCC lesions into traumatic (type I) or degenerative (type II). Type II lesions are associated with ulnocarpal impaction and are further subdivided based on the severity and the other structures involved. Type II TFCC tears are generally not amenable to direct repair.

- Type IIA: TFCC wear
- Type IIB: TFCC wear plus lunate or ulnar head chondromalacia
- Type IIC: TFCC perforation plus lunate or ulnar head chondromalacia
- Type IID: TFCC perforation plus lunate or ulnar head chondromalacia plus lunotriquetral ligament perforation
- Type IIE: TFCC perforation plus lunate or ulnar head chondromalacia plus lunotriquetral ligament perforation plus ulnocarpal arthritis

**NATURAL HISTORY**

Defining the natural history of ulnocarpal impaction syndrome is at best challenging.

The Palmer classification provides an accurate anatomic description of the degenerative changes seen in the ulnocarpal structures, but it does not dictate treatment, suggest prognosis, or indicate timing of progression.

Deterioration of the ulnocarpal structures is very common regardless of ulnar variance. Numerous cadaveric studies have found TFCC perforations and chondromalacia of the ulnar head, lunate, and triquetrum in up to 70% of “normal specimens.”

Ulnar-positive variance and persistent heavy demand across the ulnocarpal joint can hasten the development of the disease.

An individual’s ability to unload the ulnar side of the wrist with conservative measures and change of lifestyle may slow or even prevent progression.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

The patient history must be detailed and must include:

- Medical history
- Description of previous surgical procedures involving not only the wrist but also the elbow
- Analysis of whether the pain was caused by an acute injury or brought on by repetitive motion activities
  - A distal radius or radial head fracture can lead to ulnocarpal impaction, as can a chronic distal radius physeal injury (ie, the gymnast’s wrist).
- Characterization of the pain
  - Description of the location, duration, and radiation of the pain as well as any associated swelling, burning or tingling sensations, or sounds (clicks, etc.)
- Aggravating and alleviating factors
- The physical examination should always begin with inspection.

*Removal of two thirds or more of the horizontal portion of the triangular fibrocartilage complex statistically decreased the percentage of force through the nine ulnas tested. (Adapted from Palmer AK, Werner FW. The triangular fibrocartilage complex of the wrist: anatomy and function. J Hand Surg Am 1981;6A:153–162.)
The wrist and elbow should be examined for surgical scars.

Prominence of the ulna either palmarly or dorsally may indicate instability of the DRUJ. A palmar sag and a supination posture of the wrist may indicate the capsuloligamentous instability that occurs in rheumatoid arthritis.

Swelling, bruising, perforations of the skin, or obvious dislocations may indicate trauma.

Intrinsic atrophy and clawing may indicate ulnar nerve pathology.

Splinter hemorrhages beneath the nails and decreased turgor in the volar digital pads suggests vascular insufficiency.

Single-finger palpation should proceed in a systematic fashion by isolating anatomic structures. The examination should be performed with the patient’s elbow resting on a table, the hand pointing toward the ceiling, and the forearm in a neutral position.

Tenderness over any anatomic structure suggests a specific clinical diagnosis.

Active and passive range-of-motion (ROM) maneuvers may illicit pain, suggesting pathology. Limitations of ROM may be the result of swelling or obstruction (blocking). The examiner should listen for sounds of pathology throughout ROM.

Specific provocative tests should be performed in an attempt to further define the injured structure(s).

Piano key test: A positive result is characterized by painful laxity in the affected wrist compared with the contralateral wrist, suggesting DRUJ synovitis.

Ulnar compression test: A positive test is exacerbation of pain, which suggests arthritis or instability; dorsal or palmar subluxation may be noted.

Lunotriquetral ballottement test: Used to elicit laxity associated with pain and crepitus in the presence of lunotriquetral instability.

Reagan shuck test: Positive if pain and clicking at the lunotriquetral joint is present, suggesting lunotriquetral ligament perforation or disruption.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Plain radiographic views should include neutral rotation posteroanterior and lateral projections of both wrists. These are obtained with the patient seated and the elbow flexed at 90 degrees and the shoulder abducted at 90 degrees.

The contralateral wrist films may be used as a template for reconstruction.

Radiographic assessment of ulnar variance has used a neutral rotation radiographic view of the wrist that provides an image of the radioulnar length with the wrist unloaded. Such views may underestimate variance in wrists in which power grip and pronation result in significant proximal migration of the radius. Tomaino found that ulnar variance increased an average of 2.5 mm using the pronated grip view and ranged from an increase of 1 to 4 mm (FIG 3A).

Other plain views may be obtained based on clinical suspicion.

The carpal tunnel (FIG 3B) view visualizes the hook of the hamate and the pisotriquetral joint.

An oblique view in 30 degrees of pronation (FIG 3C) allows evaluation of the dorsal ulnar wrist.

The reverse oblique view (30 degrees of supination) (FIG 3D) allows evaluation of the palmar ulnar wrist with a profile of the pisotriquetral joint.

An ulnar deviation posteroanterior view (FIG 3E) may reveal lunotriquetral instability or evidence of ulnocarpal abutment. If ulnocarpal abutment is suspected, it is often useful to obtain a posteroanterior radiograph with the forearm in pronation and the fist clenched (Fig 3A), which increases ulnar variance.

Videofluoroscopy is useful for evaluating dynamic ligament instabilities. The wrist should be examined through an entire active and passive ROM as well as with provocative maneuvers in an attempt to demonstrate pathology while reproducing symptoms.

Arthrography may demonstrate a TFCC defect or interosseous ligament disruption if contrast material injected into one compartment leaks into an adjacent space.

MRI can aid in the detection of soft tissue and osseous lesions, including interosseous and extrinsic ligament tears, TFCC defects, tumors, avascular necrosis, and occult fractures (FIG 3F).

Sensitivity of the MRI increases if it is combined with arthrography. The ability to show marrow changes in the
ulnar portion of the lunate and simultaneous central TFCC pathology is very helpful in confirming a diagnosis of ulnocarpal impaction.

- Arthroscopy can confirm a diagnosis suggested by findings from other diagnostic modalities.
  - This is the most sensitive tool for diagnosis of chondral and ligamentous pathology.
  - It has therapeutic applications in the management of ulnar abutment, TFCC defects, interosseous ligament tears, chondral defects, loose bodies, synovitis, and degenerative arthritis.
- Bone scan, ultrasonography, and computed tomography serve a very limited role in the diagnosis of ulnar impaction syndrome.

Differential Diagnosis

- Extensor carpi ulnaris (ECU) subluxation or tenosynovitis
- DRUJ arthritis (degenerative or inflammatory), incongruity, intra-articular pathology, instability
- Ulnar styloid fracture nonunion
- Isolated TFCC tears
- Lunate and triquetrum lesions: chondromalacia, cyst, or interosseous ganglion (lunate/capitate), intraosseous pathology (enchondroma, osteoid osteoma)
- Kienböck disease
- Lunotriquetral instability (trauma or impaction)
- Midcarpal joint arthritis or chondromalacia
- Hamate hook, triquetral, or pisiform fractures
- Flexor carpi ulnaris tendinitis
- Pisotriquetral arthritis
- Guyon canal pathology: ganglion, tunnel syndrome, ulnar artery thrombosis
- Ulnar neuritis

Nonoperative Management

- Rest and avoidance of any aggravating maneuvers are the mainstay of nonoperative management for ulnar impaction syndrome.
- The success of this treatment lies with the patient’s ability to change the way he or she does any number of routine tasks and may involve a change of employment.
- Ice and elevation may help to reduce any swelling associated with overuse or aggravation of a previous injury.
- Nonsteroidal anti-inflammatory medications will also reduce swelling and provide some analgesia.
- Neutral splinting provides support for the wrist and may help to prevent aggravating maneuvers.
- Injection of a steroid and local anesthetic mixture into the wrist may provide some temporary relief of symptoms and decrease swelling.
- An intra-articular injection may also help differentiate intra- and extra-articular disorders.
- A combination of hand therapy modalities (ie, ultrasound, iontophoresis) and patient education may alleviate some symptoms.

Surgical Management

- Surgical treatment of ulnar impaction syndrome is indicated for patients who fail to respond to conservative modalities or those who cannot avoid aggravating maneuvers.
- Patients undergoing ulnar shortening osteotomy must be good surgical candidates, with a high likelihood of healing the osteotomy site.
- Otherwise, an alternative surgical procedure, such as a wafer resection osteotomy, should be considered.
- Wrist arthroscopy is frequently used to document physical findings consistent with ulna impaction syndrome before performing a shortening osteotomy, especially in cases of diagnostic uncertainty even after nonoperative management and injections discussed above.

Commercial Devices for Ulnar Shortening Osteotomy

- Plates and jigs to assist with ulnar osteotomy are commercially available. These offer features such as low-profile plate design, locking screws, simplicity of use, decreased surgical time, and improved accuracy of the osteotomy cuts.
The surgeon must consider whether the potential advantages of these systems justify the additional expense.\textsuperscript{18}

**Preoperative Planning**

- Neutral rotation posteroanterior and lateral radiographs of both wrists demonstrate ulnar variance and the morphology of the DRUJ, helping to determine the degree of shortening required to unload the joint and still provide a congruent articulation.
- In principle, a long ulna should be shortened to neutral or 1 mm of negative variance. If there is ulnar-neutral variance as a baseline, 2 mm of bone should be removed.\textsuperscript{7}
- Care must be taken to prevent excessive shortening of the ulna, as this has the potential to increase pressures across the DRUJ articular surface\textsuperscript{11} and can lead to limitation of forearm rotation.
- The absolute amount of shortening possible is limited by the marginal ligaments of an intact TFCC.
- This is reportedly 15 mm in the setting of posttraumatic ulna impaction syndrome.\textsuperscript{8}
- DRUJ anomalies, congenital disorders, or arthritis should be ruled out.
- DRUJ stability is best assessed with examination under anesthesia.

**Positioning**

- Preoperative antibiotics with a coverage spectrum for skin flora are given intravenously about 30 minutes before the skin incision.
- The patient is positioned supine on the operating table with the upper extremity on an armboard.

### AUTHORS’ PREFERRED TECHNIQUE FOR ULNAR SHORTENING OSTEOTOMY

**Exposure**

- Make an 8- to 10-cm incision over the subcutaneous border of the ulna as previously described (TECH FIG 1A).
- Elevate the ECU muscle–tendon from the distal, dorsal aspect of the ulna to allow sufficient room for a six- or seven-hole AO dynamic compression plate (Synthes LC-DCP, Synthes USA, Paoli, PA) (TECH FIG 1B).
- Take care to avoid disrupting the ECU subsheath distally.

**Osteotomy**

- Position the LC-DCP plate along the distal dorsal ulnar shaft to ensure fit, and prebend it into a very slightly concave configuration to ensure compression of the volar cortex with plate application.
- A 3.5-mm plate is appropriate for most individuals, although a 2.7-mm plate may be used for smaller patients.
- Draw the proposed oblique osteotomy site beneath the third (for a six-hole plate) or fourth (for a seven-hole plate) hole in the plate.
Chapter 95  Ulnar Shortening Osteotomy

The osteotomy is made obliquely in a dorsal to palmar direction so that the osteotomy site can later be secured with an interfragmentary screw applied through the dorsal plate.

The oblique osteotomy angle is about 45 to 60 degrees, and it is typically 5 to 6 cm proximal to the ulnar styloid (TECH FIG 2A).

The orientation of the osteotomy (either distal dorsal to proximal palmar or vice versa) is designed such that the acute angle (point) of the cut bone is adjacent to the plate on the side of the fragment to be compressed. This technique compresses the bone to the plate, avoiding displacement of the osteotomy.

Secure the Synthes small distractor–compressor apparatus over the proposed osteotomy site (along the ulnar border) with four 2.5-mm threaded Kirschner wires (TECH FIG 2B).

Place the pins into the ulna in a region that will later be spanned by the plate to avoid creating unprotected stress risers after removal.

Avoid interfering with the osteotomy when placing the pins by referring to the line drawn at the proposed osteotomy site.

Place the pins palmar enough to allow the plate to be securely seated over the dorsal surface of the ulna.

Kerf thickness varies based on the specific blade used and can be obtained from the manufacturer.8

Make the second parallel osteotomy cut proximal to the first, using a freehand technique, and remove the wafer of bone.

Distract the osteotomy site and inspect it to ensure that there are no bony excrescences or residual uncut bone margins, which could interfere with apposition of the fragments.

**Alternative Osteotomy Technique**

Perform a single osteotomy cut using stacked saw blades. This theoretically removes some of the “human element” and provides a more precise cut with improved apposition of the fragments.

Using a single cut technique, reproducible ulnar shortening with precision within 0.2 mm of the exact desired ulnar variance has been reported.

A relatively steep angled cut (60 degrees) using stacked blades with a kerf thickness of 4.45 mm can allow for up to 9 mm of shortening with a single cut.

Cuts may be made at lesser angles and with lesser kerf thicknesses to allow for lesser degrees of shortening.8

**Ulna Osteotomy**

Remove the plate from the operative field and complete the first osteotomy cut using a precise oscillating blade (TECH FIG 3).

It may be helpful to complete the distal cut first to avoid removing too much distal bone, forcing distal placement of the plate and poor fixation.

Take care to continuously irrigate the bone edges while sawing to avoid thermal necrosis of the bone and periosteum.

The kerf (amount of bone resected by the saw blade itself) must be taken into account when planning the site of the second osteotomy cut to determine accurately the total amount of bone removed.
Reduction and Stabilization

- Dial down the small distractor apparatus to achieve compression at the osteotomy site and bone-to-bone abutment (TECH FIG 4A).
  - A reduction clamp is valuable in guiding and then securing the fragments as compression is applied.
- Examine the radioulnar relationship under fluoroscopy to ensure adequate correction of ulnar variance and DRUJ congruence.
  - Additional bone resection followed by repeat reduction and compression can be easily achieved if necessary.
- Again place the Synthes nonlocking LC-DCP plate on the dorsum of the ulna, and drill screw holes using a compression or neutral drill guide.
  - With the exception of the interfragmentary lag screw hole, directly over the osteotomy site, all screw holes in the plate are drilled using a 2.5-mm drill followed by a 3.5-mm tap (unless self-tapping screws are used).
- First secure the plate with static screws to the fragment with the acute angle (point) on the side away from the plate (palmar in this case, using a dorsal plate).
- Reduce and secure the osteotomy, and then place compression screws in the other fragment, the one with the acute angle (point) adjacent to the plate.
  - Place the first compression screw in the second hole away from the osteotomy.
  - Fill the remaining more proximal holes with either compression or static screws.
- As a final step, insert an interfragmentary lag screw through the osteotomy via the hole in the plate directly over the osteotomy (TECH FIG 4B).
  - Pass a 3.5-mm drill only through the near cortex, followed by a 2.5-mm drill through the far cortex. Tap this hole and fill it with a 3.5-mm bone screw.
  - Once proximal and distal stabilization has been achieved, it may be necessary to remove the 2.5-mm pins to fill the remaining screw holes.

Completion

- Again examine the bone under fluoroscopy to ensure good plate-to-bone and osteotomy site apposition and to assess screw lengths. Make a final assessment of the radioulnar relationship using standard posteroanterior and lateral neutral rotation views (TECH FIG 5).
- Irrigate the wound with normal saline. Close the deep subcutaneous layer with 3-0 Vicryl and approximate the skin edges with interrupted horizontal mattress 4-0 nylon.
- Apply a palmar, forearm-based plaster wrist splint after the tourniquet is deflated and sterile dressings have been applied.
  - The arm is protected in a cast or splint until bony union has occurred.
ULNAR SHORTENING OSTEOTOMY USING AN AO COMPRESSION DEVICE

- Expose the ulna in the manner previously described and plan the osteotomy about 5 to 6 cm proximal to the ulnar styloid.
- Place a five- or six-hole 3.5-mm LC-DCP plate on the flat surface of the distal ulna, centered about the planned osteotomy site, with two or three holes distal, one hole across, and two or three holes proximal to the osteotomy.
- Although the plate may be placed dorsal or volar, palmar positioning of the plate may be preferable to avoid subcutaneous prominences of the hardware after surgery.
- Contour the plate in the manner described above.
- Fix the plate distally with two or three 3.5-mm cortical screws placed in a static mode.
- For a dorsal plate, draw the planned osteotomy on the bone with a marking pen at an angle of about 45 degrees distal dorsal to proximal palmar so that the proximal fragment will compress into the plate (TECH FIG 6).
- Fix the standard AO compression device to the ulna proximally with one unicortical screw and engage the mobile arm in the most proximal plate hole.
- Place the unicortical screw far enough proximal that adequate compression can be obtained. This distance will vary based on the amount of bone to be removed.
- Once shortening is complete and the compression device removed, the empty screw hole must not be too close to the proximal margin of the plate in order to avoid a stress riser.
- Remove the compression device and one distal screw, and loosen the most distal screw slightly, allowing the plate to be rotated away.
- Using a water-cooled oscillating saw, make the distal cut first using the freehand technique.
- Interrupt the osteotomy cut after it is two thirds complete.
- The saw blade may be left in this initial cut to act as a planar guide for the second parallel and proximal osteotomy cut.
- Place a new blade into the saw and make the proximal cut two thirds of the way through the bone.
- Complete the initial distal cut, followed by the proximal cut, and remove the perfectly round wafer of bone.
- Replace the previously removed distal screw and tighten both screws.
- Reapply the compression device and compress the osteotomy.
- Place the screw just proximal to the interfragmentary compression hole in a compression mode using the compression guide.
- Place the interfragmentary compression screw by first drilling a gliding hole through the near cortex with a 3.5-mm drill bit.
- Then, using a drill guide (“top hat”), drill the far cortex with a 2.5-mm drill bit. Measure the hole, tap the far cortex with a 3.5-mm tap, and place the interfragmentary compression screw.
- Remove the compression device and fill the remaining proximal screw hole(s) using the static drill guide.
- Irrigate and close the wound and apply a splint as previously described.

OSTEOCHONDRAL SHORTENING OSTEOTOMY

- Wrist arthroscopy is performed to both stage and treat any ulnocarpal arthritis or TFCC tear that may require débridement or repair.
- After arthroscopy, make a longitudinal incision over the fifth dorsal compartment.
  - Take care to identify and protect the dorsal sensory branch of the ulnar nerve.
  - Incise the fifth extensor compartment, retract the extensor digiti quinti tendon, and create a capsulotomy through the floor of this fifth compartment.
  - Complete the capsulotomy in an L-shaped fashion by extending the incision transversely just proximal to the dorsal radioulnar ligament of the TFCC, thus preserving its stabilizing function for the DRUJ.
- Based on preoperative determinations, resect a 3- to 5-mm wafer of bone using a microsagittal saw at the level of the proximal margin of the DRUJ.
- Leave the distal ulna articular surface and the TFCC foveal attachments intact (TECH FIG 7A–C).
- Reduce and compress the osteotomy with a hemostat and a Kirschner wire placed for temporary stabilization.
- Intraoperative fluoroscopy is used to confirm the adequacy of resection and osteotomy reduction.
- More bone can be removed if necessary, up to 5 mm total.
- Excessive bony resection could lead to DRUJ instability or impingement.
Thread a cannulated headless compression screw over the previously inserted Kirschner wire while manual compression is maintained (TECH FIG 7D,E).
- Remove the Kirschner wire and irrigate the wounds.
- Repair the dorsal capsule with interrupted nonabsorbable sutures.
- Transpose the extensor digiti quinti tendon out of the fifth compartment as the capsule is repaired.
- Close the skin incision with a nonabsorbable monofilament suture, and inject all incisions, as well as the wrist, with a local anesthetic.
- Place the wrist in a bulky dressing with a volar splint.

PEARLS AND PITFALLS
- In very osteopenic bone, the surgeon should consider using a longer plate or locking hardware to achieve better bony purchase (FIG 4).
- Smokers, malnourished patients, and patients with poorly controlled diabetes or vascular compromise have a higher risk of osteotomy nonunion. The surgeon should consider a procedure that does not require bone healing (Darrach or wafer osteotomy).
Ulnar shortening osteotomy should be avoided in patients with DRUJ arthritis. The surgeon should consider unloading the ulnocarpal axis with a Sauvé-Kapandji or Darrach procedure.

The dorsal sensory branch of the ulnar nerve should be protected during the surgical exposure. It runs medial to the ulnar head with the forearm supinated and more palmar with the forearm pronated.\(^2\)

The surgeon should avoid circumferential exposure of the ulna to avoid injury to the segmental blood supply to the ulnar diaphysis, which typically enters the bone from the region of the interosseous membrane.\(^22\)

The ECU subsheath should not be disrupted during the surgical approach.

In smaller patients, the surgeon should consider using a 2.7-mm AO dynamic compression plate.

The Kirschner wires used in the Synthes distractor apparatus should be inserted far enough away from the osteotomy site such that they will not interfere with the osteotomy cuts. They should be biased palmarly in the ulna if dorsal plating is planned. The four pins should be inserted in the region that will be spanned by the plate to prevent creation of an unprotected stress riser. The surgeon should avoid passing the distal pins through the ulna into the radius, as this will prevent shortening of the ulna.

Making the distal cut first may help to avoid placing the plate too distally on the ulna.

The osteotomy site should be continuously irrigated while the bone is being cut to avoid thermal necrosis of the bone and periosteum.

The surgeon should avoid overshortening the ulna, as this can lead to DRUJ instability, loss of forearm rotation, and increased DRUJ contact pressures. Failure to consider the kerf thickness when planning the osteotomy can lead to excessive shortening.

After the cuts are made, the surgeon should distract the osteotomy and inspect for bony excrescences or residual uncut bone margins, which can interfere with apposition of the proximal and distal fragments.

Although the plate may be placed on the dorsal or palmar surface of the ulna, palmar positioning of the plate may be preferable to avoid a subcutaneous prominence of the hardware after surgery in thin or smaller patients.

### POSTOPERATIVE CARE

- Short-arm below-elbow splint immediately postoperatively
- Ice and elevation to assist with swelling control
- Elbow and finger range of motion is encouraged immediately.
- Sutures are removed at 10 to 14 days.
- A removable splint is applied and protected range of motion is started at 6 to 8 weeks, depending on the radiographic appearance of healing.
- More aggressive range-of-motion exercises are started with hand therapy after 8 to 10 weeks if necessary.

### OUTCOMES

Chun and Palmer\(^6\) reviewed their series of 30 wrists in 27 patients with an average follow-up of 51 months. Wrist s were graded preoperatively and postoperatively according to the Gartland and Werley wrist system. Preoperative wrists graded as poor (28) and fair (2) improved to excellent (24), good (4), fair (1), and poor (1) after ulnar shortening osteotomy. They reported no ulnar nonunions, and complications were rare.

Loh et al\(^10\) evaluated 23 wrists at a mean follow-up of 33 months. A statistically significant reduction in pain intensity by visual analogue scale assessment was seen in 77% of patients. Preoperative versus postoperative change in range of motion was not statistically significant, and postoperative wrist function and grip strength also failed to show a statistically significant improvement. Sixty-eight percent of patients complained of local irritation secondary to prominent hardware and 32% eventually had the implant removed.

We do not think that the use of specialized equipment is necessary to achieve accurate cuts and stable fixation for an ulnar shortening osteotomy.

Sunil et al\(^20\) reported no significant differences in duration of surgery, relief of pain, return to work, postoperative complications, time elapsed between surgery and return to work, or osteotomy union in patients undergoing ulnar shortening osteotomy using the Rayhack device versus those undergoing freehand osteotomies.

Braun\(^3\) reported a $650 increase in cost with use of the Rayhack device compared to performing the technique freehand.

Our preferred technique is simple, it does not require specialized equipment (Synthes Small External Fixation and Small Fragment Bone Fixation Systems), it provides for rotational control of the distal segment, it provides compression of the osteotomy site, and it uses only one size of drill bit, tap, and screw except for the single interfragmentary hole at the osteotomy site.

### COMPLICATIONS

- Wound infection and osteomyelitis (rare)
- Hardware fracture (rare with 3.5-mm plate)
- Hardware failure with very osteopenic bone
- Delayed union rates in smokers (7.1 months for smokers versus 4.1 months for nonsmokers)\(^4\)
- Painful, prominent hardware: It is generally not necessary to remove hardware, but 3.5-mm compression plates seem to be removable at 6 to 9 months in symptomatic patients with a low risk for refracture when sequential sets of radiographs confirm healing of the osteotomy site.\(^17\)

### REFERENCES

DEFINITION

- Acute compartment syndrome is a condition in which increased tissue pressure compromises the circulation within the enclosed space of fascial compartments. As a result of this elevated interstitial pressure, the blood supply to the soft tissues is impaired. If left untreated, elevated pressures can cause irreversible muscle and nerve damage resulting in fibrosis and contracture.

ANATOMY

- Compartment syndrome is most common in the forearm and hand but can occur in the arm and in the finger.
- The arm is divided into two fascial compartments, the forearm into three compartments, the hand into ten compartments, and the finger into two compartments.
- The two arm compartments are the anterior and posterior, separated by the medial and lateral intermuscular septa (FIG 1A).

- The anterior arm compartment contains the biceps brachii, brachialis, and coracobrachialis.
- The posterior arm compartment contains the triceps brachii.
- The forearm consists of three compartments: the volar, the dorsal, and the mobile wad of three (FIG 1B).
- The contents of the volar compartment include the flexor muscles and can be subdivided into superficial and deep components. The superficial muscles are the flexor carpi ulnaris, palmaris longus, pronator teres, and flexor carpi radialis. The deep muscles are the flexor digitorum superficialis and profundus, and the flexor pollicis longus.
- The dorsal compartment of the forearm contains the extensor muscles. The superficial extensors include the extensor digitorum communis, extensor digiti minimi, and extensor carpi ulnaris. The deep layer includes the supinator, abductor pollicis longus, extensor pollicis longus, extensor pollicis brevis, and extensor indicis.

FIG 1 • A. Compartments of the arm. (continued)
The mobile wad of three is a distinct muscle compartment that contains the brachioradialis, extensor carpi radialis longus, and extensor carpi radialis brevis.

The wrist has one significant closed space, the carpal tunnel. Although not a compartment in the strictest sense, increased pressure in this tunnel can be detrimental to the median nerve.

The hand contains ten distinct compartments (FIG 1C).

- There are seven compartments for the interossei. Each of the four dorsal and three palmar interossei has a separate compartment.
- The adductor compartment contains the adductor pollicis.
- The thenar compartment contains the abductor pollicis brevis, the opponens pollicis, and the flexor pollicis brevis.
- The hypothenar compartment contains the abductor digiti minimi, flexor digiti minimi, and opponens digiti minimi.
- Compartment syndrome can also occur in the finger due to the limited skin compliance from the multiple fascial attachments.

PATHOGENESIS

- Increased pressure within a compartment decreases the blood supply to the soft tissues and can result in tissue ischemia and ultimately necrosis. The blood flow to a compartment is determined by several factors, including venous pressure, arterial pressure, and local interstitial pressure. Increased capillary permeability results from muscle ischemia. This increased permeability leads to intramuscular edema, increases the tissue pressure, decreases blood flow and oxygen transport, and leads to more tissue damage. It is easy to appreciate the vicious cycle that escalates the pathophysiology of the compartment syndrome.

- Many conditions are associated with compartment syndrome. These can be divided into two major categories:
  - Conditions that decrease compartment volume (tight casts or dressings, burn eschar, limb lengthening or application of traction, increased external pressure on limb from prolonged weight [lying on limb or entrapment under a weight])
  - Conditions that increase compartment contents (bleeding—arterial or venous injury, anticoagulation, trauma, reperfusion injury, edema, infiltrated infusion, snakebite, infection, high-pressure injection)

NATURAL HISTORY

- Compartment syndrome results in hypoxic cell damage and ultimately anoxic cell death. Functional changes occur in muscle after 2 to 4 hours of total ischemia. Hypoxia to nerves causes paresthesia and hypoesthesia within 30 minutes of ischemia, but irreversible nerve damage may not occur until 12 hours or more of total ischemia.
An untreated compartment syndrome can result in permanent neural deficit, tissue necrosis, growth arrest, Volkmann contracture, and even wet gangrene.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- It is important to elicit a detailed history and evaluate the possible causes of compartment syndrome (discussed above).
- Pain out of proportion to physical findings is the most important finding. For patients with this finding, one must have a high clinical suspicion regardless of the presumed severity of the inciting event.
- Most commonly, patients will present with a history of trauma or a crushing injury; however, other causes must not be overlooked.
- Compartment syndrome may involve single or multiple compartments in the extremity.
- Physical examination findings include:
  - A tense, swollen, and tender compartment (FIG 2)
  - Pain with passive stretch of the muscles within the compartment
  - Paresthesias or sensory disturbances in the nerve distribution of the compressed nerve are intermediate findings. This can be accompanied by motor weakness. Motor paralysis is a later finding.
  - Pallor and pulselessness are late findings.
- The findings of pain out of proportion to physical examination, a tense compartment, and pain with passive stretch are sufficient to warrant intracompartmental pressure measurements. One should not delay definitive diagnosis and treatment until later findings are present.

In obtunded or sedated patients, a tense, swollen compartment is sufficient to warrant intracompartmental pressure measurements.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Clinical examination is the cornerstone of the diagnosis, and it is important to have a high degree of suspicion for compartment syndrome.
- Immediate fasciotomy is indicated in patients with unequivocal symptoms and signs of compartment syndrome. Direct measurement of compartment pressures is indicated in all cases when the patient’s symptoms and physical examination signs are indicative of compartment syndrome, and it is especially important in patients who are obtunded or sedated.
- Diagnosis of compartment syndrome of the finger is made clinically and not through the use of pressure measurement.
- Pressure measurement in the arm is made in both anterior and posterior compartments. Anteriorly, the pressure is measured over the biceps muscle, and posteriorly over the triceps muscle.
  - The physician must be careful not to injure the radial nerve when measuring the arm compartment pressure. The nerve courses deep to the triceps in the spiral groove of the humerus. Ten centimeters proximal to the lateral epicondyle, it passes through the lateral intermuscular septum to the anterior compartment.
- In the forearm, the pressure is measured over the palmar, mobile wad, and dorsal compartments.
  - The median and ulnar nerves are at risk during measurement of the palmar compartment. The ulnar nerve courses deep to the flexor carpi ulnaris in the ulnar forearm; the median nerve is between the flexor digitorum superficialis and profundus muscles.
  - When measuring the mobile wad, the superficial branch of the radial nerve is deep to the brachioradialis in the forearm but emerges between the brachioradialis and extensor carpi radialis longus tendons about 8 cm proximal to the radial styloid.
  - The posterior interosseous nerve courses around the radial neck in the proximal radial forearm and should be avoided when measuring the mobile wad and dorsal compartments.
- In the hand, pressure measurements should be made in the affected compartments; measurements are generally made in the area of the planned incisions.
  - There is not an absolute increased compartment pressure that warrants fasciotomy. When the pressure approaches 30 to 45 mm Hg, or 30 mm Hg less than the diastolic pressure, with concordant physical examination findings, decompressive fasciotomy should be performed. In the hand, lower pressures (15 to 20 mm Hg) may indicate compartment syndrome.
  - Plain radiographs should be performed to evaluate any underlying bony abnormality. Fractures and dislocations should be reduced as anatomically as possible.
  - Arterial injury can lead to ischemia and can present similarly. Arteriography is indicated if the history may be significant for arterial injury (fracture, avulsion, or laceration).

**DIFFERENTIAL DIAGNOSIS**

- Arterial injury
- Nerve injury

---

**FIG 2** Diffuse, tense swelling of the hand. A. Palmar view with loss of palmar concavity. B. Radial view.
NONOPERATIVE MANAGEMENT

- There is no role for nonoperative management of an acute compartment syndrome. In acute cases of compartment syndrome with elevated compartment pressure, prompt decompressive fasciotomies are required to relieve tissue ischemia.
- In patients with early symptoms and signs of compartment syndrome, but without elevated compartment pressures, removal of all compressive dressings and casts, and elevation of the affected extremity to the level of the heart is indicated.
- Frequent close monitoring by physical examination and repeated pressure measurements as necessary are critical.
- In patients presenting late with aseptic muscle necrosis, acute fasciotomy and débridement may not be indicated.

SURGICAL MANAGEMENT

Preoperative Planning

- The surgeon should review radiographs and plan for surgical stabilization as necessary.

Positioning

- The patient is positioned supine on the operating table with the upper extremity on an armboard.

SURGICAL MANAGEMENT

Preoperative Planning

- The surgeon should review radiographs and plan for surgical stabilization as necessary.

Positioning

- The patient is positioned supine on the operating table with the upper extremity on an armboard.

Tourniquets are not routinely used during decompressive fasciotomy.
- If the arm is affected, the shoulder and axilla are included in the sterile field to allow exposure to the entire extremity.

Approach

- Skin is considered a significant compressive structure, and it is important to create a skin incision of sufficient length to allow complete decompression. Cosmesis is not a concern.
- Incisions are planned to afford complete and rapid decompression of the compartments while maintaining coverage of vital structures and avoiding joint contractures due to scarring.
- The viability of muscles is determined by muscle tone and color, contractility, and bleeding.
- If the viability is still unclear, the muscle should be left alone and re-inspected in 24 to 48 hours.
- The skin is left open and the wounds are copiously irrigated and covered with wet saline dressings. Occasionally, a wound vacuum dressing can be applied to facilitate care and reduce edema and pain associated with frequent dressing changes.
- Once the wound is considered to be stable and clean, the skin can be closed if under no tension. If tension is present, split-thickness skin grafts are usually applied.

DECOMPRESSION OF THE ARM

- Compartment syndrome of the arm is rare. It can be approached from the lateral, posterior, or anteromedial approach.
- The choice of incision may be based on the need for fracture fixation.\(^1,2\)
- The lateral approach begins at the deltoid insertion and extends to the lateral epicondyle. The fascia overlying the biceps anteriorly and triceps posteriorly is split through the incision (TECH FIG 1A).
- The anteromedial approach extends from the medial epicondyle toward the axilla, and the fascia overlying the biceps and triceps is split (TECH FIG 1B). This incision can be continued from the forearm skin incisions.
- The ulnar nerve must be protected in this approach.
- For isolated posterior compartment syndrome, a posterior incision can be made from 8 cm distal to the acromion to the olecranon\(^5\) (TECH FIG 1C). The triceps fascia is directly exposed and incised.
- The radial nerve runs between the long and lateral heads of the triceps and is at risk during muscle débridement.

TECH FIG 1 • A. Lateral approach to the arm. B. Anteromedial approach to the arm. C. Posterior approach to the arm.
DECOMPRESSION OF THE Volar Forearm

- Design a curvilinear incision from the carpal tunnel to the antecubital fossa. A complete carpal tunnel release is indicated if symptoms of median nerve compression are present (TECH FIG 2).
- Start the incision distally between the thenar and hypothenar eminences in line with the radial border of the ring finger. Release the skin, palmar fascia, and transverse carpal ligament.
- Continue the incision proximally to the distal wrist crease, then curve it ulnarly to the pisiform and extend it proximally along the ulnar side of the distal forearm.
  - This prevents exposure of the flexor tendons and median nerve and protects the palmar cutaneous branch of the median nerve.
- Curve the incision radially in the mid-forearm and then just anterior to the medial epicondyle at the elbow.
  - Creation of this flap provides coverage of the median nerve.
- At the antecubital fossa, curve the incision slightly anteriorly to meet the incision of the arm, if necessary.
  - This prevents a linear incision at the level of the elbow and provides coverage for the brachial artery.
- Release the fascia covering the superficial and deep compartment of the forearm, as well as the mobile wad, through this incision. Release the lacertus fibrosis at the elbow. Release individual muscle fascia if release of the compartment fascia does not relieve the pressure within each muscle.
- Loosely close the wound over the carpal tunnel; it is generally left open over the forearm.
  - If the swelling is mild, the fascia may be left open and the skin closed, or the skin edges may be approximated with a vessel loop-stapling technique.
  - If the wound is left open, it is covered with a sterile nonocclusive dressing. Alternatively, a VAC dressing may be applied.
- An alternative incision uses the Henry approach between the brachioradialis and the flexor carpi radialis, connecting to the carpal tunnel distally and proximally crossing the antecubital fossa obliquely from radial to ulnar.
  - If this approach is used, take care not to injure the palmar cutaneous branch of the median nerve at the wrist.

TECH FIG 2 • Incision for decompression of the palmar forearm. Note the incision in the hand used here for release of the thenar compartment.

DECOMPRESSION OF THE DORSAL FOREARM

- In the forearm, release of the volar compartment and mobile wad may decrease the pressure in the dorsal compartment. Once the palmar fasciotomy has been performed, the dorsal compartment should be re-evaluated for the need for fasciotomy.
- Make a longitudinal dorsal incision just ulnar to the tubercle of Lister and extending proximally toward the lateral epicondyle. Release the fascia over the dorsal compartment (TECH FIG 3).
- Release individual muscle fascia if necessary.
- If posterior interosseous nerve involvement is suspected, separate the extensor carpi ulnaris and extensor digitorum communis muscles to expose and release the fascia overlying the supinator.
- The wound is managed in a similar way to that described for the volar forearm fasciotomy.

TECH FIG 3 • Incision for approach to the dorsal forearm.

DECOMPRESSION OF THE HAND COMPARTMENTS

- To release the four dorsal and three palmar interosseous compartments and the adductor compartment, make two dorsal longitudinal incisions over the second and fourth metacarpals (TECH FIG 4A).
- Take the incisions to the level of the extensor tendons. Avoid the sensory branches of the radial and ulnar nerves, and preserve dorsal veins to minimize postoperative edema.
Retract the extensor tendons and the dorsal surface of the metacarpal. Release the dorsal compartments on each side of the metacarpal (the first and second dorsal compartments are reached on either side of the second metacarpal, and the third and fourth dorsal compartments are found on either side of the fourth metacarpal). Continue blunt dissection palmarly through the dorsal interosseous to release the three palmar interosseous compartments.

Release the adductor compartment through the incision over the second metacarpal.

Release the thenar compartment through a longitudinal incision along the radial border of the thumb metacarpal, and release the hypothenar compartment through an incision along the ulnar border of the fifth metacarpal (TECH FIG 4B). Split the underlying fascia longitudinally.

The wounds are left open (TECH FIG 4C) and the hand is placed in a bulky splint in intrinsic-plus position (metacarpophalangeal joints flexed 70 degrees and interphalangeal joints extended).

DECOMPRESSION OF THE FINGER

Make longitudinal midaxial incisions along the finger. These incisions are made by connecting the most dorsal portions of the joint flexion creases (TECH FIG 5A). These are more easily seen with the finger in flexion.

Avoid making a more palmar, midlateral incision to prevent postoperative flexion contracture.

Carefully divide the transverse retinacular ligament and Cleland’s ligament to release the neurovascular bundles on both radial and ulnar sides (TECH FIG 5B).

If possible, loosely approximate the skin.

TECH FIG 5 • A. Incision for the release of the finger. Dots are placed at the apex of each flexion crease, and connecting the dots provides the midaxial line. B. Division of the transverse retinacular ligament and Cleland’s ligament.
POSTOPERATIVE CARE

A second look is planned 48 to 72 hours after the index procedure.
- Additional débridement of devitalized tissue is performed. Serial débridements are performed until no devitalized tissue remains.
- Delayed primary closure of the skin (not fascia) may be possible. More frequently, split-thickness skin grafting is performed to cover the wounds (FIG 3). If significant soft tissue has been lost with exposed tendon, nerve, or bone, flap coverage is planned.
- Wound coverage should be performed as soon as possible to minimize complications such as infection, desiccation, and amputation.
- The upper extremity should be elevated and splinted in an intrinsic-plus position. Gentle active and active assisted range of motion of the hand, wrist, and elbow should be initiated as soon as swelling begins to subside, generally within 2 to 3 days after wound closure. Placement of a flap or skin graft may preclude motion at certain joints, but unaffected joints should be ranged.

OUTCOMES

- The outcome after compartment release depends both on the severity of the initial injury and the time elapsed before release.
- Patients with prompt diagnosis and treatment and limited devitalized tissues generally have favorable outcomes.
- Patients with severe initial injuries, delayed treatment, or extensive tissue necrosis have a more guarded prognosis for functional recovery of the upper extremity.

COMPLICATIONS

- Volkmann ischemic contracture is the result of untreated acute compartment syndrome.
- Necrosis and fibrosis of the muscle occur, with a resultant claw hand deformity. This deformity is due to extrinsic flexor and extensor contracture with concomitant intrinsic muscle dysfunction.
- Nerve dysfunction results either from the initial ischemic injury or from subsequent compressive neuropathy due to the dense scarring of the tissues surrounding the nerves.
- The deeper compartments are more severely compromised, with the flexor digitorum profundus alone affected in milder cases, and fibrosis of all muscles in the most severe.

REFERENCES

DEFINITION
- Since the beginning of the Industrial Revolution and the advent of industrial machinery, high-pressure injuries have been reported in the literature.
- The force needed to break the skin is 100 pounds per square inch (psi). In general, high-pressure injuries are forced into the tissues at a pressure of 141 to 703 kg/cm² (2000 to 12,000 psi)\(^8\) (FIG 1).
- The substances typically injected include grease, paint, paint thinners, diesel fuel, oil, water, and cement. Cases involving molten metal,\(^4\) dry cleaning solvents,\(^10\) and veterinary vaccines\(^6\) also have been documented.

ANATOMY
- The site of injection and pressure helps to determine the extent of injury.
  - Kaufman\(^{14,15}\) found that fingers that were injected with wax experienced tissue injury until a point of resistance was encountered. In the digits, the limiting factors to the extent of injury are the pulleys. He noted that the cruciate pulleys are pliable and thin, whereas the annular pulleys are rigid.
  - If the injection occurs at the level of the proximal or distal interphalangeal joints (PIP or DIP joints), the substance injected will dissect through the tendon sheath.\(^{14}\)
  - The synovial sheaths of the index, long, and ring fingers extend to the metacarpophalangeal joint; the synovial sheaths of the thumb and little finger extend into the proximal palm at the radial and ulnar bursae.\(^9\)
  - Any injections that occur over the middle segments of the fingers, away from the joints, will be diverted around the digit and spread laterally in the superficial tissues.\(^{14}\)
  - Based on this information, the proximal spread of material can be predicted.
  - Injections into the palm, thenar, and hypothenar eminences are generally contained in those myofascial spaces and lead to less permanent impairment.\(^{18}\)
  - The morbidity is determined by the volume, pressure, viscosity, resistance of the tissues, location of injection, anatomy of the compartment, and toxicity of the material injected.

PATHOGENESIS
- High-pressure injuries are divided into three stages.
  - The acute stage occurs immediately.
    - The injection causes compression and spasm of the vessels, leading to compromised blood flow. This is manifested by white, mottled tissue; numbness; severe pain; or a combination of these findings.
    - Any initial paresthesias that occur are due to local compression or chemical irritation of the digital nerves.
    - During this stage, the site of injection is key in determining where the material has spread. Very high pressures can overcome tissue resistance.
    - The volume of material injected also determines the degree of tissue distention and impairment in blood flow.
    - In several studies by Gelberman,\(^8\) Schoo,\(^{25}\) and Hayes,\(^{12}\) patients with hands that had higher-volume injections and longer time to decompression had higher morbidity rates.
  - During the intermediate stage, a foreign body reaction induces oleogranuloma formation and fibrosis.
    - The inflammation that occurs is determined by the volume and type of substance.
    - The injection of paint solvent has a significantly higher morbidity due to its low viscosity, allowing diffusion through the soft tissues. Its corrosive effects cause severe tissue necrosis.\(^9\)
    - Patients with grease injections have more chronic inflammatory reactions, leading to prolonged sequelae (foreign body granulomas).\(^{12,26}\)
    - Schoo\(^{25}\) reported that amputation rates associated with various injection injuries were as follows: paint thinner, 80%; paint (soya alkyl base), 58%; automotive grease, 23%; and hydraulic fluid, 14%.
  - The late stage of injury occurs when the granulomas break open, resulting in draining sinuses and cutaneous lesions.
    - Chronic sinuses may degenerate into malignancies (squamous epithelioma).\(^{7,25}\)
    - Secondary infections may occur in this stage; these may be due to Staphylococcus aureus, Streptococcus epidermidis, Pseudomonas spp., or a variety of polymicrobial flora.\(^{23,24}\)

FIG 1 • An innocuous-appearing puncture of the volar radial surface of the right small finger. This may be the only visible point of injury in a high-pressure injection injury.
NATURAL HISTORY
- Most patients with high-pressure injection injuries are young men. These injuries occur more commonly among manual laborers (FIG 2).
- Previously it was thought that most of these injuries occurred to people who had been on the job for less than 6 months, but more recent studies show that the mean time on the job was 11 years.\(^1\)\(^1\),\(^3\)\(^1\)
- The nondominant hand (58%–76%)\(^7\),\(^1\)\(^1\) is injured more often than the dominant hand.
- The index finger, thumb, palm, and small finger are affected in descending order.
- Controversy continues as to what induces the inflammatory response in these injuries.
- Some authors have suggested that the injury overwhelms the patient, leading to morbidity, whereas others believe that the injury induces a significant inflammatory response.
- Most agree that surgery should be done within the first 3 hours after injury to decrease the morbidity.\(^2\)\(^7\),\(^2\)\(^8\)

PATIENT HISTORY AND PHYSICAL FINDINGS
- Important factors to discover include the patient’s hand dominance and occupation; the sequence of events post-injury; and the type of injector and pressure, as well as the substance injected.
- Comorbidities, including vascular disease, diabetes, and smoking history, are relevant risk factors that influence healing and post-treatment function.\(^1\)\(^8\)
- If possible, the material safety data sheet (MSDS) for the substance injected should be obtained from the company.
- Physical examination should include:
  - Determining the location of the puncture site to determine the spread of the injectate. It is not uncommon for the site of injury to be small and difficult to find.
  - Observing range of motion when the patient attempts to form a fist
  - Palpation of the digit, hand, and arm to help determine the extent of débridement that will be required

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs of the hand and forearm are helpful in evaluating the extent of injury.
- Although not all injected substances are radiopaque, air may be present in the compartments of the hand and forearm, which may help in determining how far the substance has traveled.\(^2\)\(^0\),\(^2\)\(^3\),\(^3\)\(^0\)
- It may be necessary to obtain radiographs of the arm and chest. Extension into the arm, chest wall, and mediastinum from injuries to the hand has been reported.\(^2\)\(^9\)
- Imaging studies also document pre-existing pathology.

DIFFERENTIAL DIAGNOSIS
- Snake bite
- Spider bite
- Crush injury
- Suppurative tenosynovitis
- Black thorn tenosynovitis
- Mycobacterium marina infection (chronic)

NONOPERATIVE MANAGEMENT
- Most injuries require surgical débridement, and there are only few case reports of nonoperative management for such injuries.
- Cases that are managed without surgery include air injection into the hand, which leads to subcutaneous emphysema that resolves within hours to days\(^1\)\(^7\) or, occasionally, water injection that is managed conservatively.\(^1\)\(^6\)

SURGICAL MANAGEMENT
- Early and aggressive decompression and débridement of all tissues is the cornerstone of treatment.
- The time from injury to surgery is the major determinant of morbidity and prognosis in high-pressure injection injuries.\(^2\)\(^7\),\(^2\)\(^8\)

Preoperative Planning
- Radiographic studies should be reviewed.
- Attention should be paid to radiopaque areas of the hand and forearm.
- Air in the soft tissue should be evaluated.
- The bones should be evaluated for any possible fractures or pre-existing lesions.
- Any intravenous lines should be placed in the patient’s non-injured extremity, and manipulation of the injured extremity should be limited.

Positioning
- The patient should be placed supine with the arm abducted.
- The arm should not be exsanguinated with an Esmarch bandage, to avoid proximal spread of the injected material and further trauma to the tissues.
- Regional anesthesia can be used to avoid general anesthesia, if necessary, but local blocks and injections should not be performed.
- If the IV regional (Bier) block is selected, gravity exsanguination is performed without a compression wrap but with 4 minutes of elevation.

Approach
- Two basic techniques are used to approach high-pressure injection injuries. Both are based on the idea of wide débridement, limited by scar formation over joint areas.
BRUNER’S INCISIONS

- The hand is prepped and exsanguinated by elevation.
- For longitudinal exposure of the digits, it is important to avoid crossing the joint creases in a straight line. This is accomplished by creating Bruner zigzag incisions at the joint creases.
  - The digit is incised to avoid crossing the flexion creases so that no longitudinal incisions are made through the crease itself (TECH FIG 1A).
  - The injectate is removed, avoiding the neurovascular bundles located on the volar radial and volar ulnar surfaces of the digits.
  - The incision is extended to the palm, if necessary. The palmar incisions also are placed in such a manner as to avoid postoperative contracture of the crease (TECH FIG 1B).
  - If extension is necessary proximal to the wrist crease, the incision should be angled with the point toward the ulnar surface to avoid injury of the palmar sensory branch of the median nerve (TECH FIG 1C).
  - Extension onto the forearm may be longitudinal or in an S curve, if compartment decompression is necessary\(^1\) (TECH FIG 1D).

### TECH FIG 1

- Bruner’s incision of the right index finger. A. The incision was made for adequate exposure to remove grease debris in the finger while avoiding crossing the joint creases. B. The incision is extended to the palm to allow for visualization of affected tissues and further débridement. C. Incision across the wrist crease. Crossing the crease is avoided by creating a Bruner’s incision or a curvilinear incision at the wrist crease. D. Longitudinal extension of the incision into the forearm. High-pressure injectate was pushed into the forearm tissues.

MIDAXIAL INCISIONS

- Longitudinal midaxial incisions are made on the digit, radially and ulnarily.
  - These incisions are made dorsal to the neurovascular bundles (TECH FIG. 2).

### TECH FIG 2

- Midaxial incision of the finger. This will sacrifice the dorsal branches of the neurovascular bundle, but the digital nerve and artery are protected in the volar tissues.

- The incision is continued across the palm, if necessary. If extension onto the palm is necessary, then it may be necessary to cross the web space, including the neurovascular bundles, but it must not be divided.
- Incision across the palm continues as described for Bruner’s incision.\(^3\)
MODIFIED BRUNER’S INCISION

- The digit is incised with a Bruner’s incision distal to the flexion crease, extending to the lateral aspect of the skin on the volar digital skin (TECH FIG 3A).
- At the flexion crease, a transverse incision is made through the flexion crease, and the next interphalangeal incision is another oblique Bruner’s incision (TECH FIG 3B).
- This is continued along the length of the digit onto the palm.

TECH FIG 3 • **A.** Modified Bruner’s incision with transverse extensions at the interphalangeal flexion creases allows for a widened visual field and more complete débridement. **B.** Modified Bruner’s incision at the metacarpophalangeal joint crease allows for visualization of the A1 pulley system, the neurovascular bundles, and the surrounding soft tissues.

PEARLS AND PITFALLS

- Understand that the underlying pathology usually will be worse than the external wound.
- Comorbidities are critically important in management of patients with injection injuries.
- Obtain the Material Safety Data Sheet (MSDS) to understand the toxic effects of the injected material.
- Exploration should extend to clearly healthy tissue. Avoid “minimally invasive” treatment.
- Leave the wound open or very loosely closed.

POSTOPERATIVE CARE

- The wound should be left open and packed, or very loosely closed. The hand should then be splinted in the “safe” position (FIG 3A,B).
- Any additional débridement should be performed at 48-hour intervals, as necessary, until the wound can be primarily closed or covered (FIG 3C).
  - Less involved injuries often are allowed to heal by secondary intention, especially if critical structures are covered.
  - Occasionally, free tissue transfer may be necessary for coverage.5,22
- Parenteral corticosteroids have been advocated to decrease the inflammatory response postoperatively.
- The possibility of increasing the infection rate with corticosteroids does exist, although neither animal data nor human clinical findings show such an increase.
- Animal studies have suggested that corticosteroids may be beneficial for patients sustaining injections of organic solvents.
- No convincing human data have been published that show that corticosteroids are effective in limiting tissue loss, and they should be used cautiously.13,21

OUTCOMES

- Outcomes of high-pressure injection injuries are based on the volume, pressure, viscosity, resistance of the tissues, location of injection, anatomy of the compartment, and toxicity of the material.
- Morbidity includes cold intolerance, hypersensitivity, paresthesias, constant pain, impairment of the activities of daily living, infection, oleoma formation (FIG 4A), squamous degeneration,25 and amputation.
- Amputation rates ranging from 14% to 88% have been reported in the literature.12,19,25
- The highest amputation rates are associated with organic solvent injection into the fingers.13
- In this subset of patients, the time to débridement also had a significant impact on the amputation rate.
  - If surgery occurs within 6 hours of injury, the amputation rate is 40%.
  - If the surgery is delayed for more than 6 hours, the amputation rate increases to 57%.
  - If débridement is delayed to more than 1 week after injury the amputation rate is 88%.13
- Metacarpophalangeal range of motion decreases an average of 8.1%, proximal interphalangeal range of motion decreases...
23.9%, and distal interphalangeal range of motion decreases by 29.7%.
- Maximum grip strength diminishes by 12%, and pinch strength decreases by 35%.
- Two-point discrimination increases by 49%31 (FIG 4B,C).
- Permanent partial impairment of the injured hand depends on the mechanism of injury and the time to treatment.

- The average impairment for injuries caused by spray guns is 15%, by pneumatic hoses less than 2%, and by hydraulic fluid 6%.30
- If treatment is delayed more than 6 hours after injury, then the permanent impairment rate is approximately 17%; however, if treatment is obtained in under 6 hours, that rate is only 4%.30
- Loss of work related to these injuries also varies, from 6 to 26 weeks, with about 92% of patients returning to their previous jobs.12
COMPLICATIONS

- Infection
- Cold intolerance
- Hypersensitivity
- Oleoma formation
- Malignant degeneration
- Decreased range of motion and function
- Paresthesias
- Diminished two-point discrimination
- Amputation

REFERENCES

Replantation is the reattachment of a completely amputated body part.
Revascularization is the restoration of circulation and repair of all injured structures in an incompletely amputated, dysvascular body part. Revascularization always includes repair of the arteries to re-establish blood flow to the part.
Revision amputation is the procedure performed at the site of amputation to gain soft tissue coverage and to address concomitant injuries to the digit.
The decision of whether to perform replantation or revascularization and revision amputation of a digit is multifactorial. The relative indications and contraindications for each are discussed later in the chapter.

ANATOMY
An understanding of the anatomy over the complete length of the digit is essential for successful replantation. The anatomy of the thumb is different from that of the four fingers.
Palmar and dorsal cutaneous ligaments maintain the position of the neurovascular bundle during range of motion of the digit.
Grayson’s ligament is palmar to the neurovascular bundle, originates from the flexor tendon sheath, and inserts on the skin.
Cleland’s ligament travels dorsal to the neurovascular bundle from the phalanx to the overlying skin.
A radial and ulnar proper digital artery supplies each digit. Each vessel travels with a respective radial and ulnar proper digital nerve. At the level of the digit, the artery lies dorsal to the nerve.
The ulnar digital artery is typically larger in the thumb and index finger. The radial digital artery usually is larger in the small finger.
Three major palmar arches arise from the digital arteries. The proximal, middle, and distal arches are consistently located at the level of the C1 pulley, C3 pulley, and just distal to the flexor digitorum profundus (FDP) insertion, respectively.
Four palmar and four dorsal branches usually extend from each digital artery.
Injection studies have demonstrated that the venous system of the digit consists of a series of arcades on the dorsal and palmar surfaces, with connecting oblique and transverse anastomotic veins. The dorsal veins have a larger caliber than the palmar veins, which do not consistently travel with the digital artery and nerve.
A radial and ulnar proper digital nerve travels with each proper digital artery. The digital nerve is sensory only and typically contains one to three fascicles. It trifurcates at the level of the distal interphalangeal (DIP) joint.
Each finger has two flexor tendons within the flexor tendon sheath.
The FDP tendon inserts at the proximal base of the distal phalanx.
The flexor digitorum superficialis (FDS) tendon inserts as two slips into the midportion of the middle phalanx. The FDS tendon splits into two slips, and its relative position to the FDP tendon switches from palmar to dorsal at Camper’s chiasm. This allows the deeper FDP tendon to continue to its more distal insertion.
There are a series of five annular and three cruciform pulleys, which are discrete thickenings of the fibro-osseous sheath. The annular pulleys prevent bowstringing of the flexor tendons during flexion, whereas the cruciate pulleys are collapsible, accommodating flexion.
The odd-numbered annular pulleys are located over the joints of the finger, and the even-numbered annular pulleys are over the proximal and middle phalanx, respectively.
The A2 and A4 pulleys are most important in preventing bowstringing and should be preserved if possible.
Each lesser digit receives a tendon from the extensor digitorum communis (EDC). The index and small fingers each have a second extensor tendon, the extensor indicis proprius (EIP) and extensor digiti minimi (EDM), respectively. Both of these tendons are ulnar to the EDC tendons.

PATHOGENESIS
The mechanism of injury has a considerable effect on the potential for replantation.
Sharp amputations are ideal for replantation because of the narrow zone of injury.
The degree of tissue injury increases substantially with crush and avulsion mechanisms and may prohibit successful replantation (FIG 1).
Most digit amputations occur as an isolated injury. When amputations occur in the multiply injured patient, consideration of other systemic injuries and adherence to ATLS (Advanced Trauma Life Support) protocols may prevent replantation.

NATURAL HISTORY
Replantation of an amputated digit results in longer hospital stays and more prolonged rehabilitation than revision amputation. Patient satisfaction, however, usually is higher with replantation than with revision amputation or a prosthesis.
Functionally, the expected range of motion in a replanted digit is 50% of normal.
Secondary procedures, such as tenolysis, are common.
The literature reports rates of reoperation ranging from 3% to 93%. In a series of more than 1000 replants and revascularizations, 35% of patients required at least one secondary surgery. The incidence is higher for replantations than for revascularizations.
Expected survival rates of replanted digits are 80% or higher, with even higher survival rates in revascularized digits.
PATIENT HISTORY AND PHYSICAL FINDINGS

- The surgeon must evaluate the patient in the emergency room immediately on arrival. A complete history and physical examination are performed.
- The history should include specific details regarding the mechanism and timing of the injury. Identification of the specific machinery involved often reveals valuable information about potential contamination and the pattern of injury sustained by the amputated part.
- A history of mental instability is relevant, because rehabilitation protocols require significant patient compliance to maximize functional outcomes. Furthermore, self-inflicted amputations are unlikely to yield the same functional results after replantation as accidental amputations.
- A history of medical comorbidities should be thoroughly evaluated. Conditions such as diabetes, peripheral vascular disease, hypercoaguability, and tobacco use are not absolute contraindications to replantation but must be considered.
- Similarly, the surgeon must evaluate for medical conditions that prevent the patient from tolerating the blood volume changes associated with major limb replantation. Revision amputation may be the best choice if the patient has a history of previous trauma or arthritis in the amputated part.
- Ischemia time and method of transport should be evaluated for appropriateness. In the digits, a warm ischemia time of less than 6 hours is desired. In more proximal amputations containing muscle, ischemia time is more critical.
  - Cooling the amputated part reduces metabolic acidosis, bacterial growth, and muscle necrosis. Cold ischemia times of up to 12 hours are tolerated for replantation of digits. There are reports of successful replantation of digits with warm ischemia times of 42 hours and cold ischemia times of 96 hours.\(^1\,2\,4\)
  - Proper transportation of the amputated part is essential. Never place the part directly on ice. The part should be wrapped in a sterile gauze moistened with Ringer’s lactate or normal saline. The gauze is then placed in a leak-proof plastic bag and the bag is placed on ice (FIG 2). The goal temperature is 4°C.
  - Alternatively, the part may be immersed in Ringer’s lactate or normal saline in a plastic bag with the bag then placed on ice.
  - The surgeon examines the part and the injured extremity to evaluate suitability for replantation. The number of digits, level of injury, and type of injury are assessed.
  - Specifically, the surgeon evaluates the injured parts for the red-line sign and the ribbon sign.
    - The red-line sign refers to a red streak of ecchymosis along the lateral border of the digit, which is the result of hemorrhage from avulsed branches of the digital artery after a traction injury (FIG 3).
    - The ribbon sign also represents an avulsion injury. Coiling of the artery at the amputation site results from
disruption of the vessel wall layers from traction. If re-plantation is attempted, vein grafting is required.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- When the patient arrives in the emergency department, standard radiographs of the amputated parts and the injured limb are obtained (FIG 4).
- Laboratory evaluations should include a complete blood count, basic metabolic panel, coagulation panel, drug screen, and blood type and crossmatch. Other preoperative tests are ordered as indicated by the patient’s age and comorbidities.

NONOPERATIVE MANAGEMENT

- There is no role for nonoperative management of these injuries.
- Some surgeons advocate performing revision amputations in the emergency department under local anesthesia. It has been our experience that these procedures are best performed in the operating room with appropriate anesthesia, hemostasis, sterile conditions, lighting, and equipment.

SURGICAL MANAGEMENT

- The decision to replant a digit is predicated on the determination that the anticipated function after replantation will be better than that of a revision amputation. This determination is made after careful consideration of the factors influencing the predicted survival of the replanted digit, morbidity to the patient, and functional outcome.
- Specific factors related to the status of the amputated part and the status of the patient include:
  - Mechanism of injury (eg, sharp, crush, avulsion)
  - Level of amputation
  - Ischemia time (warm or cold)
  - Health of patient
  - Age of patient
  - Presence of segmental injury
  - Predicted rehabilitation
  - Vocation and hobbies
- Informed consent for replantation versus revision amputation must reference the postoperative care differences.
  - Patients undergoing revision amputation typically are discharged from the hospital much quicker and have much shorter, less intensive rehabilitation protocols.
  - Patients treated by replantation typically require a 5- to 7-day hospital course, avoidance of smoking and caffeine, possible blood transfusions, and prolonged rehabilitation. Furthermore, these patients must be advised about the likelihood of cold intolerance.
- The techniques we use for replantation of amputated digits are described in detail in the following sections. The same techniques and sequence of repair are followed for the revascularization of partially amputated parts.
  - In partial amputations, not all structures will be injured, so it may be that only some structures require repair. For example, if the dorsal skin and its veins remain intact, the procedure does not require venous anastomosis for outflow.
  - Each case should be examined individually, and all structures should be carefully evaluated for injury.

Preoperative Planning

- Broad-spectrum antibiotics and tetanus prophylaxis are administered on presentation in the emergency department.
- The patient, hand, and amputated parts are examined to confirm suitability for possible replantation.
- A urethral catheter should be placed for long procedures.
- Regional anesthesia is preferred due to the autonomic block, which yields increased peripheral vasodilation. Ideally, an indwelling catheter is placed to allow for continuous postoperative pain relief and sympathetic block. General anesthesia is required for children.
- If an attempt at replantation is determined to be appropriate and desired, the parts are brought to the operating room as soon as possible. Initial preparation of the parts can begin while the anesthesia team evaluates the patient.
- The operating room and patient must be kept warm to prevent peripheral vasoconstriction.
- The sequence of repair is as follows:
  1. Débridement and identification of structures
  2. Bone shortening and fixation

FIG 3 • The red-line sign, which represents an avulsion injury, is seen clinically as a red streak of ecchymosis along the lateral border of the digit. This ecchymosis is the result of hemorrhage from avulsed branches of the digital artery after a traction injury. The ribbon sign, which also represents an avulsion injury, refers to the corkscrew appearance of the digital artery resulting from disruption of the vessel wall layers. When these clinical signs are present, the zone of injury must be bypassed with vein grafts if replantation is attempted.

FIG 4 • A. Standard PA radiograph of the injured hand. B. A radiograph of the amputated parts is also obtained by placing the bag containing the parts directly on the x-ray cassette.
3. Extensor tendon repair
4. Flexor tendon repair
5. Arterial repair
6. Nerve repair
7. Vein repair
8. Skin closure/coverage

**Positioning**
- The patient is positioned supine on a standard operating room table with a hand table attachment. The table is rotated 90 degrees to allow access for the operating microscope and fluoroscopy.

**Approach**
- Slightly dorsal midaxial incisions are made on both the radial and ulnar sides of the digits. These incisions allow for rapid identification of both the neurovascular bundles and the dorsal veins. Both the palmar and dorsal flaps can be reflected as needed (**FIG 5**).

**PREPARATION OF THE AMPUTATED PART**
- A two-team approach is used. One team prepares the amputated part while the other team prepares the patient.
- The parts should continue to be kept cool until they are reattached. A sterile prep table and a sterile covered ice-filled basin are required for preparation of the parts (**TECH FIG 1**).
  - A sterile metal irrigation basin is filled with ice and covered with a sterile adhesive drape.
  - A moist sterile towel is placed over the drape as a working surface.
  - The basin should be filled such that the ice forms a mound above its rim.
  - The parts are brought to the operating room and cleaned on the sterile prep table with Hibiclens and sterile Ringer’s lactate.

**TECH FIG 1 • A,B.** The amputated parts are removed from the bag, and a sterile prep is performed on a separate table. 
**C.** A sterile metal irrigation basin is filled with ice and covered with a sterile adhesive drape. Use as much ice as can be placed without disruption of the sterile environment to maximize contact with the amputated parts. 
**D.** A sterile surgical towel is then placed over the drape and used as a working surface. 
**E.** Nylon sutures placed through the amputated parts are secured to the surgical towel. The amputated parts are now ready for débridement and preparation.
TECHNIQUES

PREPARATION OF THE STUMP

- A nylon suture is passed through the tip of each amputated part and secured to the towel with a small hemostat.
- Under loupe magnification, the contaminated skin edges and subcutaneous tissues are débrided.
- Slightly dorsal midlateral incisions are made on the radial and ulnar sides of the digit. Arteries, nerves, and veins are identified and tagged for later with small hemoclips. The hemoclips should be placed as close to the vessel and nerve ends as possible to avoid damaging the structures.
- The nerves and vessels are exposed for a length of 1.5 to 2 cm. The veins lie in the subdermal plane and can be identified by elevating the dorsal skin flap. If the veins are difficult to isolate, the surgeon may defer their identification until after the anastomosis of one artery when engorgement makes them more prominent.
- The flexor tendons are identified, and a 4-0 nonabsorbable braided suture is placed in each tendon in a Tajima fashion. The crossing limb of the Tajima suture should be placed 1.0 to 1.2 cm from the free end of the tendon.
- The bone is then shortened appropriately. Consideration of the level and geometry of amputation is required. It is necessary to reference the recipient site to match the orientation of the bone ends.
- In general, 4 to 10 mm of total digit shortening allows for appropriate débridement of nerves and vessels to healthy tissue and subsequent primary repair without tension. Shortening also eases skin coverage of the repair site. The amount of shortening depends partly on the mechanism of injury. Crush injuries typically require more resection than sharp injuries.
- Two 0.045-inch K-wires are placed longitudinally down the long axis of the bone in a retrograde fashion. The K-wires should exit through the tip of the digit just palmar to the nail. The K-wires are advanced until the tips are showing through the bone so that the amputated digit is now ready for immediate attachment.
- The parts should continue to be kept cool under ice packs until they are reattached.

Once a vein is located, continue the dissection in the same subdermal plane to identify others. If possible, two veins are repaired for each artery.

- Flexor tendons are identified, and a Tajima suture is placed in each (TECH FIG 2). If the tendons have retracted proximally, atraumatic retrieval is necessary to avoid inducing spasm or damaging the proximal vessels. If required, a separate proximal incision is made to retrieve the tendons safely.

**TECH FIG 2** • A. A Tajima-type suture repair is used so that the flexor tendons can be opposed and secured at the ideal time. B,C. The suture is placed in the proximal and distal ends of the tendon. D. The sutures are then tied in the repair site at the appropriate time.
Bone shortening has already been performed at the time of débridement. If shortening was limited by the proximity of joints, the use of vein grafts should be entertained at the time of vessel anastomosis. When shortening the bone in a thumb amputation, the resection should be maximized on the amputated part so that if the replant fails, thumb length is maintained.

Numerous methods of bone fixation are available, including longitudinal K-wires, crossed K-wires, intraosseous wiring, tension band, intramedullary screw, and plate and screws.

- Parallel longitudinal K-wires are quick, easy, and have low nonunion and complication rates. When possible, this is my preferred technique (TECH FIG 3A–D).
- Crossed K-wires are also relatively quick and easy to use. The drawback to crossed K-wires is potential risk to the neurovascular bundles, either directly or by tethering (TECH FIG 3E–H).
- Intraosseous wiring takes more time and exposure to perform, but allows for early range of motion. Drill holes accepting of a 24-gauge wire are placed in a dorsal-to-palmar and radial-to-ulnar orientation at each bone end. Two loops of 24-gauge wire are then passed perpendicular to each other through the analogous drill holes at each bone end and tightened in standard cerclage fashion.
- The tension band technique is a useful option for arthrodesis, because it allows the surgeon to set the desired amount of flexion. Two parallel 0.045-inch K-wires are placed across the fusion site, and a figure-8 loop of 24-gauge wire is used over the dorsum of the finger to complete the construct.

Any amputated parts that are not being replanted should not be discarded, because these are an excellent source for donor grafts.

**BONE FIXATION**

- Bone shortening has already been performed at the time of débridement. If shortening was limited by the proximity of joints, the use of vein grafts should be entertained at the time of vessel anastomosis. When shortening the bone in a thumb amputation, the resection should be maximized on the amputated part so that if the replant fails, thumb length is maintained.
- Numerous methods of bone fixation are available, including longitudinal K-wires, crossed K-wires, intraosseous wiring, tension band, intramedullary screw, and plate and screws.
  - Parallel longitudinal K-wires are quick, easy, and have low nonunion and complication rates. When possible, this is my preferred technique (TECH FIG 3A–D).
  - Crossed K-wires are also relatively quick and easy to use. The drawback to crossed K-wires is potential risk to the neurovascular bundles, either directly or by tethering (TECH FIG 3E–H).
  - Intraosseous wiring takes more time and exposure to perform, but allows for early range of motion. Drill holes accepting of a 24-gauge wire are placed in a dorsal-to-palmar and radial-to-ulnar orientation at each bone end. Two loops of 24-gauge wire are then passed perpendicular to each other through the analogous drill holes at each bone end and tightened in standard cerclage fashion.
  - The tension band technique is a useful option for arthrodesis, because it allows the surgeon to set the desired amount of flexion. Two parallel 0.045-inch K-wires are placed across the fusion site, and a figure-8 loop of 24-gauge wire is used over the dorsum of the finger to complete the construct.

Any amputated parts that are not being replanted should not be discarded, because these are an excellent source for donor grafts.
The intramedullary screw is most useful in thumb amputations at the metacarpal level. Removal of this hardware is difficult, so its use should be avoided in highly contaminated wounds where the risk of infection is high.

Lag screw fixation is appropriate to treat long oblique fractures. However, because most amputations do not result in this fracture pattern, this technique is seldom used in replantation surgery.

After bone stabilization, the extensor mechanism is repaired.

In the digit, the tendon is repaired with two horizontal mattress sutures using a 4-0 nonabsorbable suture. It is imperative to repair the entire extensor mechanism. If the amputation is through the proximal phalanx, repair of the lateral bands will optimize functional outcomes.

EXTENSOR TENDON REPAIR

- After bone stabilization, the extensor mechanism is repaired.
- In the digit, the tendon is repaired with two horizontal mattress sutures using a 4-0 nonabsorbable suture.

FLEXOR TENDON REPAIR

- Because the Tajima sutures have already been placed, they are now ready to be tied in the repair site. The two strands of the repair should be tied simultaneously to achieve a symmetric repair.
- In certain circumstances, the surgeon may choose to delay tying the sutures until after the microsurgical portion of the case. Specifically, in very proximal amputations, the ability to position the digit in slight hyperextension may facilitate the vessel and nerve repair.
- Both the FDS and FDP are repaired when feasible. If the amputation is in zone 2 and the tendons are not cleanly cut, repair of only the FDP tendon is reasonable.
- If the amputation level is distal to the FDS insertion, but proximal to the DIP joint, we typically do not repair the FDP or extensor tendon. We favor arthrodesis of the DIP joint with K-wires and direct rehabilitation toward early active and passive range of motion of the proximal interphalangeal (PIP) joint.

ARTERIAL REPAIR

- We have found that both digital arteries should be repaired, when feasible, to maximize survival rates.
- The operating microscope and microsurgical instrument set are used.
- The most important factor affecting survival is achieving a tension-free anastomosis of normal intima to normal intima (TECH FIG 4A–C).
- Débridement of damaged arteries is performed under the operating microscope. The surgeon must resect until normal intima is identified. The liberal use of vein grafts is advocated for resulting defects.
- The tourniquet is released to ensure good blood flow from the proximal stumps.

- Plate-and-screw fixation is generally not required in digit replantation because nonunion is rare. While it provides rigid fixation, the hardware is bulky, increases tendon adhesions, and requires more time and exposure.
- Regardless of the method of fixation, the surgeon must constantly evaluate alignment and rotation of the digit in both flexion and extension. The flexed fingertips should point toward the distal pole of the scaphoid.
Sharply trim the proximal stump with angled Potts scissors and dilate the lumen with jeweler’s forceps or a lacrimal duct dilator.

If adequate blood flow is not obtained, evaluate for all reversible causes of vasospasm, including hypotension, hypovolemia, acidosis, pain, or cold. Double check that the tourniquet was deflated.

Evaluate the proximal vessel for mechanical constriction.

Thoroughly irrigate the lumen with warm heparinized Ringer’s lactate through a 30-gauge blunt-tipped needle on a 10-ml syringe.

If vasospasm persists, irrigate the proximal vessel with papaverine solution (diluted 1:20 with sterile normal saline).

After appropriate blood flow is established, the proximal and distal stumps are placed within the vascular approximators. Several types of approximating devices are available. We favor two clamps on a sliding bar. The clamps should have less than 30 g of closing pressure and should be limited to no more than 30 minutes of application time due to the potential for vessel damage (TECH FIG 4D).

Place a microsurgical background deep to the repair site.

A bolus of 3000 to 5000 U of intravenous heparin is given just before the anastomosis. After the bolus, we typically initiate a heparin drip at 1000 U/hr.

Repeat inspection of the intima is performed proximally and distally to confirm its integrity. Verify that the anastomosis is tension-free and that no adventitia overhangs the lumen.

Appropriately sized monofilament nylon sutures (Table 1) are used, and initial sutures are placed 180 degrees apart.

The size of each “bite” should be about one to two times the thickness of the arterial wall.

Care must be taken to avoid damaging the intima of the vessel.

One limb each of the initial sutures should be cut long for use in manipulating the vessel without directly handling it.

Suture the front wall of the artery sequentially between stay sutures.

Irrigate the lumen after each suture is tied, and inspect the repair site to confirm that the back wall was not captured.

Flip the approximating clamp to expose the back wall and complete the anastomosis.

Remove the vessel from the approximating clips and repeat the procedure on the other digital artery.

If a tension-free repair is not possible, primary nerve grafting is performed. The medial antebrachial cutaneous nerve is the ideal caliber for digital nerves and can be obtained from the ipsilateral extremity. Similarly, any amputated digits that are not candidates for replantation provide an excellent source for grafts.
VEIN REPAIR

- Ideally, a minimum of two veins are repaired for each artery. The largest veins identified should be repaired.
- When performing the anastomosis, each “bite” should be about two to three times the thickness of the vein wall.
- Constant irrigation with heparinized Ringer’s lactate helps to “float” the lumen of the vein open.
- Due to the low pressure flow, the venous anastomosis can be performed with fewer sutures than are required for the arterial anastomosis (TECH FIG 6).
- Familiarity with alternatives to venous anastomosis is necessary in the event suitable veins cannot be located.

- Continuous venous oozing can be encouraged by removal of the nail with subsequent scraping of the matrix. This scraping is performed every 2 hours with a cotton-tipped applicator and is followed by the application of heparin-soaked pledgets.
- If proximal veins are present but distal veins are not, creation of either an arteriovenous or venous-cutaneous fistula may facilitate outflow to reduce congestion. This scenario is most common in very distal amputations just proximal to the nail. An arteriovenous fistula may be created possibly if one artery has been successfully repaired and back-bleeding is present from the other distal artery. This artery can be anastomosed to the proximal vein. Alternatively, a vein graft can be used to create a temporary shunt from the skin of the pulp to the proximal vein.
- Medicinal leeches (Hirudo medicinalis) can be placed on the engorged part if venous congestion occurs. They should be changed every few hours and should be used for a minimum of 7 days to allow for the establishment of collateral circulation. Although the leeches may fall off after engorgement, they secrete hirudin, a local anticoagulant that keeps the digit bleeding for 8 to 12 hours. While using leech therapy, the patient should be treated with a third-generation cephalosporin as prophylaxis against Aeromonas hydrophilia infection, a symbiotic gram-negative rod in the leech gut.

SKIN COVERAGE AND WOUND CLOSURE

- Before the wound is closed, meticulous hemostasis must be achieved. Even small postoperative hematomas can compress the vascular repairs and result in failure of the replant.
- Interrupted nylon sutures are used to close the wounds, avoiding constriction of underlying structures. The midlateral incisions can be left open without concern for healing difficulties. If the repaired dorsal veins lack local coverage, a split- or full-thickness graft should be applied.

- No part of the postoperative dressing should be circumferential. Small strips of petroleum-impregnated gauze are applied to the incisions. A bulky dressing is constructed with a plaster splint extending above the elbow. The tips of all digits must remain exposed, and a temperature probe is taped to the pulp of the replanted digit for monitoring.
- The limb is elevated in a foam pillow.
## POSTOPERATIVE CARE

- Usually, the hand is elevated, with the level of elevation adjusted for changes in vascular status. If arterial inflow becomes problematic, the hand is lowered. If venous congestion is present, the hand is raised.
- Color, warmth, turgor, and capillary refill are monitored by the surgeon. 
- The patient’s room should be kept warm, preferably above 22°C (72°F). The temperature probe is monitored by the nursing staff, and the surgeon is notified if the digital temperature is less than 30°C or if the temperature drops 2°C over 1 hour.
- The patient is maintained on bed rest for the first 2 or 3 days, and the room is kept dark with minimal stimulation. Visitors are limited to two at a time.
- The patient is restricted from nicotine and caffeine products.
- The intravenous heparin drip is continued at 1000 U/hr. The rate is adjusted for a goal activated partial thromboplastin time (aPTT) of 1.5 times normal. It is maintained for 5 days, then weaned by 100 U/hr until off.
- Dextran 40 is given as a 50-mL bolus and then maintained at a rate of 20 mL/hr while the patient is in the hospital.
- Enteric-coated aspirin (325 mg daily) and dipyridamole (50 mg tid) are initiated and maintained for 6 weeks postoperatively.
- Chlorpromazine (25 mg orally q 8 h) is useful as both an anxiolytic and a peripheral vasodilator. We generally use it for the duration of the patient’s hospital stay.
- Appropriate antibiotics are maintained for 7 days.
- We prefer to leave the operative dressing in place for 7 days to avoid causing vasospasm. Excessive bleeding with formation of a blood cast that would restrict venous outflow should prompt an earlier dressing change.
- Gentle active motion is started on postoperative day 3 within the confines of the splint. Formal hand therapy is initiated after the splint is removed.

### OUTCOMES

- A survival rate greater than 80% is expected for replantation surgery.
- Functional outcomes are greatest for replantation of the thumb, proximal hand, and single digit distal to the FDS insertion (Fig 6A–D).  
- Recovery of sensation is correlated with function. As in other peripheral nerve injuries, age is the most important factor influencing recovery.

### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Amputated parts</th>
<th>Take the amputated parts to the operating room to begin débridement and identification of structures as soon as the room is ready.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Heterotopic replantation</td>
<td>Prioritize the functional goals for replantation. If multiple digits are amputated, but not all parts are suitable for replantation, put the salvageable digits in the most functional position (eg, replant a finger in the thumb position if the thumb cannot be saved).</td>
</tr>
<tr>
<td>Vein grafts</td>
<td>If there is concern for intimal damage, resection and the liberal use of vein grafts saves time and frustration. Always reverse the vein graft in case valves are present in the segment. The volar aspect of the wrist contains numerous veins 1 to 2 mm in diameter.</td>
</tr>
<tr>
<td>Spare-parts surgery</td>
<td>Never discard any amputated parts until the conclusion of the case. Amputated parts that are not suitable for replantation are an ideal source of autologous grafts.</td>
</tr>
<tr>
<td>Vascular anastomosis</td>
<td>Never perform an anastomosis under tension. Either additional bone shortening or vein grafting should be performed.</td>
</tr>
<tr>
<td>Multiple digit replantations</td>
<td>The overall duration of surgery is decreased by performing a structure-by-structure repair instead of a digit-by-digit repair (ie, repair the same anatomic structure in all digits before repairing the next structure).</td>
</tr>
</tbody>
</table>

*FIG 6 • A–D. This patient sustained an amputated thumb, which was successfully replanted with good cosmetic and functional results. (continued)*
factor for recovery, with better results in younger patients. The average two-point discrimination in replanted thumbs is 11 mm and in fingers is 8 mm.7 These values represent the average recovery for sharp amputation. Crush and avulsion mechanisms result in poorer two-point discrimination.

- Range of motion is related to level of amputation. Active PIP joint motion in replantations proximal to the FDS insertion average 35 degrees, whereas replantations distal to the FDS insertion result in 82 degrees of PIP joint motion (FIG 6E–G).10

COMPLICATIONS

Immediate Complications
- Immediate complications affect the survival of the replanted digit and typically relate to the vascular status.
- Arterial insufficiency may result from unrecognized vessel injury away from the anastomosis, which causes thrombosis or vasospasm.
  - A check for reversible causes is initiated to ensure that the patient is warm, comfortable, hydrated, and calm.
  - Check the dressings to confirm that there is no mechanical constriction.
  - Confirm that the patient’s hematocrit is near normal and that all ordered medications are being given appropriately.
  - The hand should be lowered to increase inflow, and an intravenous bolus of heparin (3000–5000 U) is given. If the patient has not been anticoagulated or has not achieved therapeutic levels, a regional sympathetic block will aid peripheral vasodilation.
  - Vigilant re-examination of color, warmth, turgor, and capillary refill is necessary to decide whether exploration in the operating room is indicated. Revisions after 4 to 6 hours of reduced perfusion seldom result in digit salvage.10
  - If venous engorgement occurs postoperatively, elevate the hand and remove constrictive dressings (including sutures that are too tight).
  - Consideration for return to the operating room is based on intraoperative findings affecting the possibility of revising the venous anastomosis.
  - If this is not possible, leeches or nail removal are used to alleviate venous congestion. These methods typically are used to bridge the first 4 to 6 days until adequate outflow is established.

Long-term Complications
- Long-term complications include pin tract infections, cold intolerance, stiffness, malunion, and nonunion.
- Pin tract infections usually occur more than 4 weeks after surgery. They are easily treated by pin removal and a course of oral antibiotics.
- Cold intolerance is almost universal. (This also is a problem in revision amputations.) Cold intolerance is expected to improve over the first 2 years but it remains debatable whether it completely resolves.3,18
- Digital stiffness is common, because both the flexor and extensor tendons are repaired. Tenolysis should be delayed for at least 3 months post-replantation but has demonstrated good results.12
- Malunion usually results from malalignment at the time of bone fixation. Intraoperatively, rotational alignment is the most difficult to assess. Malunion is more common in proximal amputations, because even slight malalignment at the amputation level is greatly accentuated at the fingertip.
- Nonunion is not common after replantation of the digit. It has been reported in fewer than 10% of digit replantations and rarely requires reoperation.19,20

REFERENCES
DEFINITION
- Vasospastic and vaso-occlusive diseases of the hands include a wide range of disorders that cause decreased or limited blood flow to the digits, resulting in chronic ulcerations and even loss of digits.
- Vasospastic disorders result from constriction of the microvasculature, resulting in decreased blood flow.
  - The most common vasospastic disorder is Raynaud syndrome.
  - Raynaud syndrome may also have an obstructive component.
- Vaso-occlusive disorders produce disruption of blood flow due to a reduction in cross-sectional area of the vessel lumen.

ANATOMY
- The right common carotid artery and right subclavian artery originate from the brachiocephalic trunk, whereas the left subclavian artery branches directly from the aorta.
- The subclavian artery becomes the axillary artery at the distal edge of the first rib and ends at the distal edge of the teres major tendon.
- The brachial artery is a continuation of the axillary artery, beginning at the distal margin of the teres major.
- The hand is supplied by the radial and ulnar arteries, which originate from the brachial artery at the level of the antecubital fossa.
- The radial artery becomes the deep palmar arch; the ulnar artery becomes the superficial palmar arch (FIG 1).
  - The superficial palmar arch is the major arterial inflow to the fingers on the ulnar aspect of the hand, whereas the deep palmar arch supplies blood to the digits on the radial aspect of the hand.
  - The superficial palmar arch lies more distal in the palm than the deep palmar arch.
  - In about 80% of patients, the deep and superficial palmar arches are in continuity, a configuration described as a complete palmar arch.\(^3\)
  - In a small subset of patients, a persistent median artery also can contribute blood supply to the hand.
  - Sympathetic nerves exit the spinal cord along with the ventral roots of the second and third thoracic nerves, passing via the brachial plexus into the forearm and hand.
  - The sympathetic nerve fibers innervate the blood vessel walls, controlling the tone of the vascular smooth muscle.

PATHOGENESIS
- Raynaud’s syndrome, a vasospastic disorder, is characterized by significant structural narrowing of the arterial lumen due to intimal hyperplasia. Vasospasm can occur from increased sympathetic tone in response to temperature, vibratory stimuli, and sometimes emotional stress, causing further ischemia and the clinical manifestation of color changes.
- Vaso-occlusive disorders result in ischemia distal to the site of occlusion.

NATURAL HISTORY
- Clinical manifestations of vasospastic disorders range from episodic digital vasospasm and pain, to severe hand and digit ischemia, progressing to gangrene.
- The classic triphasic attack in Raynaud’s syndrome consists of sudden onset of digital pallor or blanching after cold exposure.
or emotional stress, followed by a period of cyanosis and then redness with rewarming, resulting in the classic white-blue-red sequence of color changes.1
  - The typical Raynaud’s attack lasts for 15 to 45 minutes.
  - Vaso-occlusive disorders follow a more predictable clinical course in that they usually result from fixed lesions that are progressive.
  - Cold intolerance and vasomotor color changes in the hand develop, forcing patients to seek treatment.

PATIENT HISTORY AND PHYSICAL FINDINGS
  - A complete history and physical examination must be done on each patient, focusing on evidence of connective tissue or cardiovascular disease.
  - Does the patient describe paresthesias, pallor, cold intolerance, pain, digit ulceration?
  - The entire upper extremity is examined for range of motion, skin color and turgor, capillary refill, radial and ulnar pulses, temperature, and presence of ulcerations.
  - The distal fingertips and nails of each finger are examined closely.
  - The radial and ulnar pulses are palpated and examined by Doppler probe if necessary.
  - The palmar arch is assessed with the Doppler probe as well as the radial and ulnar digital arteries to each finger.
  - Allen’s test is performed.
    - The radial and ulnar arteries are occluded at the level of the wrist.
    - The arterial flow is then re-established to the hand sequentially by releasing the radial and ulnar arteries, and capillary refill is assessed.
    - This test evaluates the patency of arterial inflow to the hand through the radial and ulnar arteries.
  - Any pulsatile masses are noted and evaluated.

IMAGING AND OTHER DIAGNOSTIC STUDIES
  - Posteroanterior (PA), lateral, and oblique radiographs to evaluate bone architecture and the presence of any calcification in the radial and ulnar arteries, palmar arches, or digital arteries
  - Doppler examination
  - Echocardiogram to evaluate potential sources of emboli
  - Digital photoplethysmography, which measures digital volume changes over time, can be used to differentiate vasospastic from vaso-occlusive disease.
  - Segmental arterial pressure measurements
  - Nielsen digital hypothermic challenge test
  - Ultrasonography
  - Angiography: remains the gold standard to evaluate blood flow to the hand
  - MR angiography
  - Laboratory tests: complete blood cell count (CBC) with platelet count, coagulation studies, markers for collagen vascular diseases

DIFFERENTIAL DIAGNOSIS
  - Raynaud’s disease
  - Hypothenar hammer syndrome
  - Malignancy
  - Trauma
  - Buerger disease (thromboangiitis obliterans): an inflammatory occlusive disease of the small and medium-sized vessels of the limbs
  - Arteritis: a group of disorders characterized by acute or chronic inflammation in the walls of small, medium, and large arteries. Patients with these conditions often present with concurrent fever, malaise, weight loss, cutaneous lesions, and arthralgias.
  - Diabetes
  - Peripheral vascular disease, atherosclerosis
  - Thoracic outlet syndrome
  - Connective tissue disorders (eg, scleroderma, systemic lupus erythematosus, rheumatoid arthritis)
  - Illicit drug use
  - Vascular tumors
  - Pseudoaneurysm
  - Iatrogenic injury

NONOPERATIVE MANAGEMENT
  - Pharmacologic therapy is the mainstay of treatment of vasospastic disorders of the hand.
  - Avoidance of smoking and exposure to cold temperatures may control vasospastic episodes.
  - Biofeedback
    - Patients are trained to control certain bodily processes that occur involuntarily.
    - Electrodes are attached to the skin of the patient and physiologic responses monitored.
    - The biofeedback therapist then leads the patient through exercises that bring about desired physical changes.
    - Occlusive dressings may be helpful both to protect areas from recurrent trauma and to promote healing of lesions.
    - Calcium channel blockers, eg, nifedipine
    - Pentoxifylline decreases blood viscosity and may result in relaxing vascular smooth muscle.
    - Prostacyclins
  - Nitrates
  - Local anesthetic blockade
  - Botulinum toxin A
  - Thrombolytic therapy

SURGICAL MANAGEMENT
  - The surgical management of vasospastic and vaso-occlusive diseases should proceed in a systematic fashion.
  - Indications for operative management are progressive symptoms (eg, Raynaud’s syndrome, ulcers, pain, cold intolerance) despite optimal medical management and with angiographically defined occlusion of one or both inflow arteries (ie, radial, ulnar).
  - Indications for a digital sympathectomy are progressive symptoms of Raynaud syndrome or ulcerations refractory to medical management with no evidence of major occlusion of the radial or ulnar arteries and with good visualization of three common digital arteries in the palm.
  - Cold challenges are very painful for patients with scleroderma and systemic lupus erythematosus and are used on a case-by-case basis.
  - The patient should be educated on the outcomes of the various procedures and realize the limitations of each one.

Preoperative Planning
  - The preoperative history and physical examination are reviewed.
The site of operative intervention is determined primarily by the preoperative imaging studies (eg, angiogram).

If vascular grafting is indicated, the donor vessels are identified and marked.

**Positioning**

- The patient is placed in the supine position on the operating room table with the extremity on an appropriately padded hand table.
- An upper arm tourniquet is placed, because a bloodless field is essential.
- If a vein graft is anticipated, another extremity (usually a leg) is prepped and a proximal tourniquet applied.

**Approach**

- Usually, the hand surgeon must access proximal arterial inflow vessels when treating either vasospastic or vaso-occlusive disorders of the hand.
- The brachial artery in the upper arm is approached via an incision on the medial aspect of the arm.
- The distal brachial artery and proximal radial and ulnar arteries are approached through a lazy S incision in the antecubital fossa.
- Care is taken to avoid making a straight line incision across the antecubital fossa.
- The radial and ulnar arteries in the forearm are approached through a longitudinal incision over the specific vessel.
- The palmar arches are accessed via Bruner incisions extending proximally from the proximal phalanges, using natural creases in the palm where possible, or through an inverted J-shaped incision in the palm.
- The digital arteries are approached through Bruner incisions on the palmar aspect of the finger or through a midlateral incision on the digit.

**FLATT DIGITAL SYMPATHECTOMY**

- Flatt digital sympathectomy is used for patients with vasospastic disorders such as Raynaud phenomenon.
- Proximal or cervical sympathectomy has largely fallen out of favor due to the high recurrence rates.
- Peripheral sympathectomy has gained popularity since Pick identified sympathetic nerve fibers innervating the arteries from the wrist to the fingers.
- Sympathectomy is performed at the level of the digital arteries.
- Make Bruner incisions in the distal palm and expose the digital arteries.
- Disrupt all connections between the digital nerves and digital arteries.
- Strip the adventitia from the digital arteries over a distance of 0.5 to 2.0 cm using the operating microscope (TECH FIG 1A,B).
- This must be performed very carefully to avoid damaging the digital arteries themselves.
- In cases of more widespread vasospasm, when more radical digital sympathectomy is required, strip the adventitia from the distal radial and ulnar arteries, the superficial palmar arch, and the common digital arteries in the palm (TECH FIG 1C,D).
**LERICHE SYMPATHECTOMY**

- If adequate collateral flow is present, consider excision of a segment of thrombosed or occluded artery.
- This is thought to reduce the sympathetic discharge from the diseased artery that is producing vasospasm in the more distal vessels.
- It also occasionally is used to treat a thrombosed or occluded ulnar artery in hypothenar hammer syndrome.

**MICROSURGICAL REVASCULARIZATION**

- Reconstruction of a thrombosed or occluded artery is considered if:
  - A discrete segment of artery can be resected and bypassed.
  - Adequate arterial inflow and patent distal arteries with adequate distal “run-off” are present.
- Resect the arterial segment and measure the defect.
- Reverse vein grafts (e.g., cephalic, saphenous) or arterial grafts (e.g., deep inferior epigastric artery, lateral circumflex artery, thoracodorsal artery) are harvested in the standard fashion.
- Draw an axial line down the length of the vessel to be harvested while it is still in situ.
- This helps prevent inadvertent “twisting” of the graft during the anastomoses.
- Perform standard microsurgical anastomoses using 9-0 or 10-0 nylon sutures and the operating microscope between the distal radial or ulnar arteries and the deep or superficial palmar arches respectively, or directly to one or more common digital arteries (TECH FIG 2).
- An end-to-side anastomosis of the graft to the inflow artery is preferable to maximize any remaining circulation to the hand, but end-to-end anastomoses are technically easier.
- The distal anastomosis usually is end-to-end to the superficial or deep palmar arches or end-to-side to the common digital arteries.
- After the anastomoses have been completed, the tourniquet is deflated, and vascular inflow through the other artery is occluded by manual compression for a few minutes to maximize flow across the anastomoses.
- Restoration of arterial flow into the hand is assessed either by using a pencil Doppler probe or by performing an Acland “adventitial strip test” distal to the distal anastomosis.

**TECH FIG 2**

- A. Microsurgical revascularization for thrombosis or occlusive disease of the distal ulnar artery and superficial palmar arch, using an interposition vein graft from the ulnar artery to the common digital arteries.
- B. Microvascular revascularization for thrombosis or occlusive disease of the distal radial artery and deep palmar arch, using an interposition vein graft from the radial artery to the princeps pollicis artery.
EMBOLECTOMY
- An acute embolus is treated by immediate heparinization to prevent propagation of the embolus more distally into the digits.
- Small Fogarty embolectomy catheters may be used selectively at the arm, elbow, forearm, and wrist levels, but use of embolectomy catheters in the hand and digits is difficult and can itself lead to vascular injury.
- After identification of the segment involved by the embolus, control the affected artery both proximal and distal to the embolus.
- Make a longitudinal arteriotomy proximally to access the vessel lumen.
  - A side branch may be chosen if available.
- Insert the Fogarty catheter into the artery, and pass it down the lumen beyond the area of occlusion; then inflate the balloon.
- Gently withdraw the catheter to retrieve any thrombus.
- This is repeated until the lumen is completely cleared of the embolus, as demonstrated by improved back-bleeding from the distal vessel.
- Suture the arteriotomy and release arterial inflow.
- Assess the restoration of arterial flow into the hand either by using a pencil Doppler probe on the artery more distally or by performing an Acland “adventitial strip test” distal to the site of embolism.

ARTERIALIZATION OF THE VENOUS SYSTEM
- Choose a suitable vein on the dorsum of the hand, that is, one that will lie in a straight line following anastomosis to the radial or ulnar artery near the palmar wrist.\(^ {16}\)
- Mobilize the vein and ligate the multiple side branches of the vein with small hemoclips to maximize flow to the fingers.
- Perform valvulotomies in the vein to prevent valvular obstruction.
- Ligate the vein proximally and perform an end-to-side microsurgical anastomosis between the vein and the radial or ulnar artery at the wrist.
- After the anastomosis has been performed, assess arterial flow through the distal vein.
- Any remaining obstruction due to a valve should be relieved by an open valvulotomy and excision of the valve leaflets, followed by microsurgical closure of the vein.
- Postoperative monitoring is performed using a pencil Doppler probe over the distal arterialized vein to the fingers.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>Embolectomy</th>
</tr>
</thead>
<tbody>
<tr>
<td>- A thorough history and physical examination must be performed.</td>
<td>- Identification of an embolus must be treated with heparinization immediately to prevent propagation of the clot.</td>
</tr>
<tr>
<td>- Preoperative studies must be reviewed before surgical intervention.</td>
<td>- The use of embolectomy catheters in the hand and digits should be done selectively and with caution.</td>
</tr>
</tbody>
</table>

Sympathectomy
- The adventitia of the artery must be stripped over a distance of 0.5 to 2.0 cm.

Microsurgical revascularization
- A discrete segment of thrombosed or occluded artery must be identified for this to be effective.
- Adequate arterial inflow and distal runoff is essential.

Embolectomy
- Generally used for unreconstructable vascular lesions
- Valvulotomies must be performed to prevent vascular obstruction when flow is established.
- All venous side branches should be ligated to maximize flow distally.

POSTOPERATIVE CARE
- The hand is immobilized in a lightweight splint to protect the operative site, with care taken to avoid any pressure on the underlying anastomoses or vulnerable mobilized arteries.
- The fingertips are observed for color and capillary refill, temperature using small temperature probes or oxygen saturation using a pulse oximeter.
- Microvascular reconstruction with interposition grafts can be monitored using a pencil Doppler probe.
- Relative anticoagulation can be achieved using a continuous infusion of dextran 40 or low-dose aspirin.

OUTCOMES
- Calcium channel blockers have been shown to be moderately effective in patients with Raynaud’s phenomenon, with 35% reporting improvement in severity of their symptoms.\(^ {19}\)
- The results of sympathectomy remain variable, although surgeons have reported improvements in pain, ulcer healing, cold intolerance, and quality of life.\(^ {8,11,18,20}\)
- Long-term patency rates for vascular bypass grafting secondary to occlusive disease have been reported to range between 53% and 94%.\(^ {2,8,10,13}\)
Combining sympathectomy with arterial reconstruction may offer improved outcomes versus sympathectomy alone.  

COMPLICATIONS
- Bleeding and hematoma
- Infection
- Thrombosis of the interposition graft
- Progression of the underlying systemic disease

REFERENCES
DEFINITION
- An *acute paronychia* is an infection of the soft tissue fold around the fingernail.
  - It is the most common soft tissue infection of the hand.
  - The most common infecting organism is *Staphylococcus aureus*, although these infections are commonly mixed infections.
- A *chronic paronychia* is characterized by repeated infection and inflammation of the eponychium.
  - The eponychium becomes thickened and rounded.
  - This problem often occurs in the setting of repeated and prolonged exposure to water.
  - The most commonly isolated organisms are *Candida albicans*, gram-positive cocci, gram-negative rods, and *Mycobacterium* spp.
- Herpetic whitlow is caused by an outbreak of herpes simplex virus in the skin of the finger and can be confused with acute paronychia or felon.
  - Herpetic whitlow is common in children and medical personnel who come into contact with oral secretions.
- A *felon* is a tense abscess of the distal pulp of the finger or thumb that involves multiple septal compartments (FIG 1).

ANATOMY
- The nail complex consists of the nail bed, nail plate, and perionychium (FIG 2).
  - The nail plate sits below the proximal nail fold.
  - The perionychium is the border tissue which surrounds the nail.
  - The eponychium is the tissue that attaches closely to the nail plate proximally, commonly referred to as the cuticle.
  - The nail folds consist of skin, which continues underneath the visible edges to form a protective barrier.
  - The pulp of each digit consists of multiple compartments separated by fibrous septa.
  - These vertical septa extend from the periosteum of the distal phalanx to the epidermis, lending structural support to the fingertip.

PATHOGENESIS
- Acute paronychia results from the introduction of bacteria into the space between the nail fold and the nail plate, either proximally or laterally.
  - This commonly occurs as a result of a hangnail, nail biting, or an overzealous manicure.
- Chronic paronychia results from colonization and infection by organisms that enter the space between the nail plate and the cuticle, eponychium, and nail fold.
  - This chronic infection and inflammation lead to fibrosis of the eponychium, which, in turn, leads to decreased vascularity of the dorsal nail fold.
  - This decreased vascularity predisposes to repeated bacterial insults, resulting in the characteristic clinical exacerbations.
- Felons often result from penetrating trauma, or from bacterial inoculation through the exocrine sweat glands contained within the pulp.
  - Cellulitis and local inflammation lead to local ischemia, which, in the setting of the closed spaces defined by septa, leads to increased pressure.
  - Fat necrosis and abscess formation result from the increased pressure, which, in turn, causes a further increase in pressure, and, in effect, a compartment syndrome.

NATURAL HISTORY
- If acute paronychia is left untreated, an early infection will turn into an abscess along the nail fold.
  - The abscess may then extend into the pulp space or into the eponychium and then to the opposite side of the nail.
  - Purulence at the base of the nail may cause ischemia of the germinal matrix, which then may lead to temporary or permanent nail growth arrest.
- Herpetic whitlow improves without any intervention in approximately 3 weeks.
  - Many cases of herpetic whitlow are misdiagnosed as acute paronychia or felon.
Subsequent incision and drainage may lead to secondary bacterial infection.

Chronic paronychia are characterized by induration of the eponychium punctuated by episodes of swelling and drainage.

A felon, if left untreated, may lead to osteomyelitis or septic flexor tenosynovitis.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- In acute paronychia, the patient will complain of swelling and pain immediately adjacent to the nail.
  - If an abscess has formed, there may be purulent drainage.
- In chronic paronychia, the patient will present with a chronically indurated and rounded eponychium characterized by repeated episodes of inflammation and drainage.
- Herpetic whitlow is characterized by pain and swelling followed by the appearance of multiple vesicular lesions.
  - The pain typically is out of proportion to the physical findings, and the fingertip is not tense (in contrast to a felon).
- A patient with a felon will present with severe throbbing pain, swelling, and a tense fingertip pad.
  - A felon will not extend proximal to the distal interphalangeal (DIP) joint flexion crease unless it is associated with septic flexor tenosynovitis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs are indicated to rule out osteomyelitis or if a foreign body is suspected.
- The diagnosis of herpetic whitlow is confirmed by Tzanck smear, which will show multinucleated giant cells.
- Patients suspected of having a systemic illness should have the appropriate laboratory workup.

**DIFFERENTIAL DIAGNOSIS**

- Acute paronychia
- Chronic paronychia
- Herpetic whitlow
- Felon
- Osteomyelitis
- Septic arthritis of the DIP joint

**NONOPERATIVE MANAGEMENT**

- Acute paronychia may be treated with warm soaks and oral antibiotics if infection is caught early and if no significant abscess is present.
- Herpetic whitlow is managed by keeping the hands clean to prevent bacterial superinfections; these lesions will resolve on their own.
  - Some recommend treatment with oral acyclovir, but multiple clinical trials have failed to show any definite benefit.
- Nonoperative treatment has no role in the treatment of chronic paronychia unless there is a concomitant fungal infection that may benefit from medical therapy.
- Given the rapid clinical progression of a felon, nonoperative treatment with antibiotics rarely will be successful, except in very early cases.

**SURGICAL MANAGEMENT**

- If the abscess is superficial, drainage may sometimes be performed without anesthesia.
- If the infection is more extensive or involves both sides of the nail, incision and drainage should be performed under digital nerve block.
  - Use lidocaine or a mixture of lidocaine and bupivacaine without epinephrine.
  - Instillation of the medication at the level of the distal metacarpal from dorsal to volar is the safest and best tolerated technique.
- Chronic paronychia usually are treated with eponychial marsupialization.
  - Chronic paronychia associated with underlying fungal infections may be amenable to more standard surgical treatments as performed for acute paronychia after the fungal infection has been successfully treated medically.
- Herpetic whitlow is treated with incision and drainage only if a bacterial superinfection has occurred.
Positioning
- The patient is placed in the supine position with a standard hand table and either digital or forearm tourniquet.

Approach
- The surgical approach is dictated by the location of the infection.
- Infection under the nail plate will require elevation of part of the nail.
- Infection under the eponychial fold will require elevation of the eponychium.
- Infection into the pulp will require incision deep into the pulp space.

**INCISION AND DRAINAGE OF AN ACUTE PARONYCHIA**

**Single Incision**
- Use a no. 15 scalpel to incise into the paronychial sulcus, keeping the blade directed away from the nail bed (TECH FIG 1A).
- If the abscess extends below the nail plate, then that portion of the nail is freed from the underlying bed, a longitudinal incision is made in the nail, and that section of the nail is removed in an atraumatic manner (TECH FIG 1B,C).
- Alternatively, if the purulence extends into the pulp space, the perionychium may be incised peripheral and parallel to the nail sulcus (TECH FIG 1D,E).
- If the abscess extends to the eponychium, the incision may be carried as far proximally as necessary; a portion of nail may then be removed if necessary.

**Parallel Incisions**
- If the abscess involves the eponychium and is not completely decompressed with a single incision, a parallel incision may be made on the opposite paronychial sulcus. The entire eponychial fold is elevated, and the proximal third of the nail is excised (TECH FIG 2).
- This is then irrigated and packed with gauze to prevent premature closure.
Chapter 100  SURGICAL TREATMENT OF ACUTE AND CHRONIC PARONYCHIA AND FELONS 2909

- Make a crescent-shaped incision 1 to 3 mm proximal to the eponychial fold, extending 3 to 5 mm proximally and extending to the edge of each nail fold (TECH FIG 3A,B).

- Excise this tissue, taking care not to damage the underlying germinal matrix (TECH FIG 3C).

- Irrigate and dress the wound appropriately.

- Allow the wound to heal by secondary intention.

EPONYCHIAL MARSUPIALIZATION FOR A CHRONIC PARONYCHIA

- Base the incision over the point of maximal tenderness. Be aware that an incision on the pulp can result in a tender scar.

- For a volarly oriented abscess, make an incision precisely in the midline distal to the DIP joint flexion crease (TECH FIG 4A,B).

- When the point of maximal tenderness is on the side of the finger pulp, make the incision longitudinally, dorsal to the tactile surface of the finger, not more than 3 mm from the edge of the nail. A more volar incision risks damage to the digital nerve branches (TECH FIG 4C).
PEARLS AND PITFALLS

**Misdiagnosis**
- Avoid misdiagnosis of herpetic whitlow as an acute paronychia with concomitant overtreatment of this problem resulting in a secondary bacterial infection and no improvement in the herpetic whitlow.
- Recognize underlying osteomyelitis in longstanding cases.
- Recognize any systemic illness that may hinder resolution of the infection.
- Chronic paronychia: avoid missing a cyst, tumor, or associated fungal infection.

**Technique**
- **Acute paronychia:** Determine whether purulence is present under the nail plate or extending into the pulp. Avoid incising into the sterile matrix by keeping the blade turned away from the nail bed.
- **Chronic paronychia:** Excise tissue superficial to the germinal matrix; avoid damaging the germinal matrix.
- **Felon:** Base the incision on the location of maximal tenderness. With a lateral incision, avoid damaging the digital nerve branches by remaining within 3 mm of the lateral edge of the nail. With a volar incision, do not cross the DIP joint flexion crease and avoid incising the flexor tendon sheath. Such incisions may lead to septic tenosynovitis.

**Postoperative care**
- **Acute paronychia and felon:** Treat with 10 days of oral antibiotics. Use of a removable splint over the distal digit is valuable early in recovery for patient comfort. Encourage early digital range of motion exercises during daily soaks.
- **Chronic paronychia:** Failure to modify environmental factors and treat systemic disease may lead to recurrence.

**POSTOPERATIVE CARE**
- Acute paronychia and felons
  - Oral antibiotics should be started postoperatively.
  - Soaks in a dilute solution of either chlorhexidine or povidone-iodine may be started on postoperative day 2 and continued until wound healing is completed. The packing is removed when the soaks begin.
  - Begin early range-of-motion exercises to avoid stiffness.
- Chronic paronychia
  - Oral antibiotics usually are not necessary.
  - Soaks in a dilute solution of either chlorhexidine or povidone-iodine may be started on postoperative day 2 and continued until wound healing is completed.

- Correction of environmental factors or systemic illness is critical.
- Begin early range-of-motion exercises to avoid stiffness.

**COMPLICATIONS**
- Recurrent infection (systemic spread of the infection)
- Incisional tenderness (pulp)
- Digital nerve injury
- Decreased sensation
- Neuroma
- Osteomyelitis
- Nail plate deformity
REFERENCES

DEFINITION

- Deep space infections occur in one of three anatomically defined potential spaces within the hand—the thenar, midpalmar, and hypothenar spaces—or in one forearm potential space, Parona’s space.
- Thenar space infections are the most common deep space infections. Midpalmar and hypothenar space infections are much more rare.
- Deep space infections usually result from direct penetrating trauma or spread from an adjacent infection such as a superficial abscess or a flexor tenosynovitis (in the case of thenar and midpalmar space infections).
- The single most common infecting organism is *Staphylococcus aureus*, although most of these infections are mixed.

ANATOMY

- The thenar space (FIG 1) is defined by the fascia of the adductor pollicis muscle dorsally and the tendon sheath of the index finger and palmar fascia volarly.
  - The radial border is defined by the insertion of the adductor pollicis tendon and fascia on the thumb proximal phalanx.
  - The ulnar border is the midpalmar (oblique) septum, which extends from the third metacarpal to the palmar fascia.
- The midpalmar space (see FIG 1) is bordered radially by the midpalmar septum and bordered ulnarly by the hypothenar septum, which extends from the fifth metacarpal to the palmar fascia.
  - The dorsal border of the midpalmar space is the fascia of the second and third palmar interosseous muscles, and the volar border is the flexor sheaths of the long, ring, and small fingers and the palmar fascia.
- The hypothenar space (FIG 1) is bordered radially by the hypothenar septum and dorsally by the periosteum of the fifth metacarpal. The fascia of the hypothenar muscles forms the ulnar and palmar borders.
- Parona’s space is a deep potential space in the distal forearm superficial to pronator quadratus and deep to the flexor digitorum profundus tendons. It is continuous with the midpalmar space.

PATHOGENESIS

- Thenar space infections may result from penetrating injury or local spread from adjacent flexor tenosynovitis or a subcutaneous abscess.
  - If not treated early, the infection may spread to the dorsal side of the hand after destroying the fascia of the adductor pollicis muscles and traveling between the transverse and oblique heads.
  - Midpalmar space infections usually result from direct penetrating trauma, but may also result from spread of an adjacent flexor tenosynovitis or superficial abscess.
  - Hypothenar space infections usually result from direct penetrating trauma, but may also result from spread of a superficial abscess.
  - Parona’s space infection may result from direct penetrating trauma, in which case the infection may be isolated to Parona’s space.
  - Infection involving Parona’s space may also result from contiguous spread from a ruptured radial or ulnar bursae (FIG 2). The end result will be involvement of the midpalmar space and a horseshoe abscess (FIG 3).
PATIENT HISTORY AND PHYSICAL FINDINGS
- The patient may recall a history of a penetrating injury in the vicinity of the involved deep space.
- In the case of a thenar space infection, the patient will present with swelling and tenderness in the thenar region.
  - The patient will hold the thumb in an abducted position to minimize the pressure for comfort.
  - If the infection has been present for some time, it may have spread dorsally, in which case swelling and tenderness will be found dorsally in the first web space.
- In the case of a midpalmar space infection there will be tenderness and swelling in the midpalm, although dorsal swelling may be more impressive due to the strength of the palmar aponeurosis.
  - The fingers will be held in a semiflexed posture.
  - This condition is distinguished from flexor tenosynovitis by relative lack of pain with passive motion of the fingers and with direct palpation of the flexor sheath along the digit.
  - Infection of Parona’s space is characterized by swelling in the distal volar forearm and pain with digital flexion.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs should be obtained in all cases to rule out the presence of foreign bodies.
- Radiographs also may reveal underlying osteomyelitis in the setting of more chronic infections.
- Patients suspected to have systemic illness should have an appropriate laboratory workup.

DIFFERENTIAL DIAGNOSIS
- Thenar space infection
- Midpalmar space infection
- Hypothenar space infection
- Flexor tenosynovitis
- Superficial abscess
- Osteomyelitis

NONOPERATIVE MANAGEMENT
- There is no role for nonoperative treatment in the setting of deep space infections.
- Antibiotics should be avoided until adequate cultures can be obtained, unless the patient is systemically ill and there will be a forced delay in operative treatment.

SURGICAL MANAGEMENT
- Drainage of deep space infections should be carried out in the operating room under general anesthesia.
- Gram stain and cultures for aerobes, anaerobes, mycobacteria, and fungi should be obtained intraoperatively just before IV antibiotics are administered.
- Thorough irrigation with 6 to 9 L of normal saline should be performed.
- All nonviable tissue must be débrided sharply.
- Surgical wounds may be closed very loosely over a drain if all necrotic tissue has been thoroughly débrided.
- If there is any doubt, the wound should be left open to heal by secondary intention using wet-to-dry dressing changes and soaks.
- In very severe cases, a second irrigation 48 to 72 hours later may be required.

Positioning
- The patient is positioned supine with a standard hand table and nonsterile tourniquet.

Approach
- Drainage of thenar space infections can be performed through a volar incision or a dorsal longitudinal incision (or, sometimes, both).
  - A volar incision involves risk to the recurrent motor branch of the median nerve, the digital nerves to the thumb and index finger, the princeps pollicis artery, and the proper digital arteries.
  - A volar incision also allows concomitant treatment of a thumb septic flexor tenosynovitis.
  - A dorsal longitudinal incision avoids the painful scar associated with a volar incision.
- Drainage of midpalmar space infections may be performed through a transverse skin incision in, or parallel to, the distal palmar crease over the third and fourth metacarpals.
  - Alternatively, a curved longitudinal incision may be used.
- Hypothenar space infections are approached through an incision in line with the ulnar border of the ring finger extending from 3 cm distal to the wrist crease to just proximal to the midpalmar crease.
- Parona’s space may be approached through a longitudinal incision just ulnar to the palmaris longus.
  - Alternatively, a trans–flexor carpi radialis approach may be used.
INCISION AND DRAINAGE OF THENAR SPACE INFECTIONS

- In the case of a volar approach, make an incision just adjacent and parallel to the thenar crease, beginning 1 cm proximal to the web space and extending 3 to 4 cm proximally (TECH FIG 1A).
- After blunt dissection through the palmar fascia, the digital nerves to the thumb and index finger, the princeps pollicis artery, the proper digital arteries, and the recurrent motor branch of the median nerve are encountered (TECH FIG 1B,C).
- The abscess will lie superficial to the adductor pollicis muscle.
- Dissection should then continue dorsally over the distal edge of the adductor muscle to decompress any dorsal extension of the abscess.
- Alternatively, a thenar space infection may be approached dorsally through a longitudinal incision (TECH FIG 1D).
- The dorsal incision may be straight or slightly curved and should bisect the space between the first and second metacarpals.
- Dissection should be carried down to the interval between the first dorsal interosseous muscle and adductor pollicis muscle, where the purulence will be encountered.
- Thoroughly débride all necrotic tissue, and irrigate copiously with sterile saline.
- Place a strip of packing strip gauze into the open wound to allow for drainage, and dress the wound appropriately.

INCISION AND DRAINAGE OF MIDPALMAR SPACE INFECTIONS

- Make a transverse incision parallel to or in the distal palmar crease over the third and fourth metacarpals (TECH FIG 2A).
- Alternatively, a curved longitudinal incision may be used (TECH FIG 2B).
- Bluntly dissect to either side of the flexor tendons to the ring or middle finger, where the abscess will be encountered.
- Protect the neurovascular bundles, which lie on either side of the tendons (TECH FIG 2C).
- Thoroughly débride all necrotic tissue, and irrigate copiously with sterile saline.
- Place a strip of packing strip gauze into the open wound to allow for drainage, and dress the wound appropriately.
INCISION AND DRAINAGE OF HYPOTHENAR SPACE INFECTIONS

- Make an incision in line with the ulnar border of the ring finger extending from just proximal to the midpalmar crease to 3 cm distal to the wrist crease (TECH FIG 3A).
- Incise the hypothenar fascia in line with the skin incision, and the purulence will be encountered (TECH FIG 3B).
- Thoroughly débride all necrotic tissue, and irrigate copiously with sterile saline.
- Place a strip of packing strip gauze into the open wound to allow for drainage, and dress the wound appropriately.

INCISION AND DRAINAGE OF PARONA’S SPACE INFECTIONS

- Approach Parona’s space with a longitudinal incision in the distal forearm just ulnar to the palmaris longus.
- If the infection is isolated to Parona’s space, keep the incision proximal to the wrist flexion crease.
- If the infection is contiguous with a midpalmar space abscess, the incision is carried across the wrist in Brunner fashion.
## PEARLS AND PITFALLS

| Misdiagnosis | • Recognize underlying osteomyelitis in longstanding cases.  
• Recognize any systemic illness that may hinder resolution of the infection. |
| Presurgical planning | • Always obtain radiographs to evaluate for osteomyelitis or a foreign body. |
| Technique | • When approaching the thenar space, protect the digital nerves to the thumb and index finger, the princeps pollicis artery, the proper digital arteries, and the recurrent motor branch of the median nerve.  
• In the midpalmar space, protect the superficial palmar arch and the digital nerves and arteries.  
• In the hypothenar space, protect the ulnar nerve and its branches, together with the ulnar artery.  
• Obtain Gram stain and cultures for anaerobes, aerobes, mycobacteria, and fungi.  
• Administer IV antibiotics intraoperatively once cultures have been obtained.  
• May close over Penrose drain if débridement is adequate.  
• If there is the possibility of remaining necrotic tissue, the wound should be left open to close by secondary intention. |
| Postoperative care | • Allow open wounds to heal by secondary intention with wet-to-dry dressing changes.  
• IV oral antibiotics for 7 to 14 days.  
• Infectious disease consultation, if necessary.  
• Maintain elevation.  
• Use of a removable splint will rest soft tissues and improve patient comfort.  
• Perform soaks in warm water three times per day.  
• Begin early digital range-of-motion exercises.  
• Be prepared to repeat irrigation and débridement if there is no clinical improvement after 48 hours. |

### POSTOPERATIVE CARE
- Intravenous antibiotics, initially given intraoperatively, are continued postoperatively.  
- The patient may be switched to oral antibiotics once cultures and sensitivities return from the microbiology laboratory and if he or she is responding to IV antibiotic therapy.  
- Let open wounds heal by secondary intention using wet-to-dry dressing changes and soaks or whirlpools.  
- Remove drains after 24 to 48 hours, depending on the condition of the wound and particulars associated with surgery.  
- Begin early range-of-motion exercises during soaks or whirlpool treatments to minimize digital stiffness.  
- Treatment of systemic illness is critical.

### COMPLICATIONS
- Persistent abscess formation if irrigation and débridement is inadequate or the wound is closed tightly and not allowed to drain.  
- Systemic spread of the infection if appropriate treatment is delayed.

### SUGGESTED READING
DEFINITION
- Septic arthritis is defined as an infection within the closed space of a joint.
- It is usually acute and purulent secondary to a pyogenic bacterial infection.
- It causes irreversible damage to articular cartilage and therefore warrants prompt treatment with adequate drainage and an appropriate antibiotic regimen.
- Delay in making the diagnosis and initiating treatment has serious implications for prognosis.

ANATOMY
- The interphalangeal (IP) and metacarpophalangeal (MP) joints of the hand are hinge joints (FIG 1).
- The IP joint space is maximized in slight flexion and the MP joint in extension.
- The wrist joint includes the radiocarpal, midcarpal, and radioulnar joints. Septic arthritis may be present in all of these wrist joint spaces, concomitantly or separately, if there are no intersseous ligament perforations, as is the case in younger patients (see FIG 1).

PATHOGENESIS
- Septic arthritis may affect any joint of the hand or wrist.
- Septic arthritis does not have a gender or race predilection, but it is more common in adults than in children.
- The inoculation of the joint is most likely due to a penetrating injury (ie, lacerations, puncture wounds, and bites). Other causes include hematogenous seeding or contiguous spread.¹⁰
- At the distal IP joint, septic arthritis is common from penetrating trauma as well as contiguous infection from a mucous cyst, felon, paronychia, or suppurative flexor tenosynovitis.
- At the proximal IP joint, contiguous infection is most commonly related to a suppurative flexor tenosynovitis.
- At the MP joint, septic arthritis is most common after direct inoculation from a clenched fist injury or fight bite.
- Hematogenous spread can result from any concomitant or preceding infection of the body, including oral, upper respiratory, gastrointestinal, and genitourinary infections.
- The synovium is highly vascular and contains no limiting basement membrane, promoting easy access of blood contents to the synovial space.³
- The presence of bacteria within the joint induces a cellular and immunologic response that is detrimental to the joint. Bacteria rapidly replicate, producing toxins. The presence of bacteria stimulates an immunogenic response, resulting in the arrival of leukocytes, which produce proteolytic enzymes. Both the bacterial toxins and leukocytic enzymes destroy the articular cartilage of the joint by degrading proteoglycans and eventually injuring the underlying chondrocytes.
- Multiple risk factors can predispose a patient to septic arthritis (Table 1).
- Any disorder that results in an immunocompromised state can predispose to septic arthritis.
- Rheumatoid arthritis, in particular, poses a high risk. This risk is related to a variety of factors including general debilitation, immunosuppressive medication, tumor necrosis factor blockers (eg, infliximab or etanercept) and chronic joint injury.

Table 1: Common Risk Factors Predisposing to Septic Arthritis

FIG 1 • Anatomy of the interphalangeal, metacarpophalangeal, and wrist joints.
In patients with rheumatoid arthritis, a diagnosis of septic arthritis may be delayed because of misinterpretation of a rheumatoid flare. A high index of suspicion must be maintained when evaluating for septic arthritis in patients with rheumatoid arthritis.5

Virtually any microbial pathogen is capable of causing pyogenic septic arthritis (Table 2).

- *Staphylococcus aureus* and *Streptococcus* spp. are the most common offending organisms.
- Gram-negative, anaerobic, and polymicrobial infections also are possible, especially in IV drug abusers and immunocompromised patients.
- Specific bacterial pathogens are related to certain circumstances, e.g., *Eikenella corrodens* in human bite wounds, *Pasteurella multocida* after domestic animal bites, *Neisseria gonorrhoeae* infections in sexually active young patients, and fungal and mycobacterial infections in immunocompromised patients.

**NATURAL HISTORY**

- The combination of the growing bacterial load and the ensuing inflammatory response results in a growing effusion that causes synovial ischemia, pressure necrosis of the cartilage, and infiltration of the bacteria into both the subchondral bone and overlying skin.
- Bacterial infiltration out of the joint can result in secondary osteomyelitis, suppurative flexor tenosynovitis, and skin breakdown with spontaneous drainage.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Patients will complain of pain and swelling.
- Systemic signs of joint infection may include fevers, chills, malaise, and tachycardia.
- The patient should be asked about a history of penetrating trauma; human, animal, or insect bites; recent joint aspirations; recent infections elsewhere; and the presence of an immunocompromising condition.
- On examination, patients will manifest a painful swollen joint, with overlying erythema and warmth.
- The most important physical examination finding is exquisite pain with motion, in contrast to a noninfectious effusion or overlying cellulitis.
- Medical professionals at the triage level may attempt to perform a regional block for pain relief. This must be prevented, because it will mask the condition.

- Attempted active digital motion will result in significant guarding, and passive flexion and extension should induce exquisite tenderness.
- Physical examination of the wrist often is less dramatic than that of the digits. The joint typically is held in a neutral position.
- Active wrist motion also will induce guarding and passive flexion, and extension should induce exquisite tenderness.
- Passive pronation and supination may help evaluate involvement of the distal radioulnar joint.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Laboratory studies should include white blood cell count (WBC), erythrocyte sedimentation rate, C-reactive protein, and blood cultures.
- The WBC usually is not elevated, but the erythrocyte sedimentation rate and C-reactive protein levels are consistently elevated (unless the patient is immunocompromised).
- Diagnosis of a septic arthritis is best accomplished by joint aspiration and analysis.
- If infection is present, increased fluid will be present in the joint.
- Joint aspirates should be sent for a cell count with differentiation, Gram stain, crystal analysis, glucose, and cultures (aerobic, anaerobic, fungal, and mycobacterial; Table 3).
- Diagnosis can be made most reliably with a joint fluid WBC count greater than 50,000 (and a differential of 75% or more segmented neutrophils); a Gram stain confirming the presence of bacteria; or positive cultures.3
- A low WBC count with a high percentage of neutrophils (>90%) may indicate an early septic arthritis.11
- A joint glucose of 40 mg/dL or less compared with the fasting blood glucose level also suggests a septic process.7
- Crystal analysis is necessary to rule out the presence of gout or pseudogout, because they also can present similarly, including an elevated WBC count in the aspirate.
- The role of imaging studies early in the course of the septic process is limited. Radiographs may reveal joint distension, presence of foreign bodies, osteomyelitis, air in the soft tissues, and chondrocalcinosis—characteristic of both gout and pseudogout (FIG 2A). Later radiographs will reveal joint destruction.
- MRI is effective in diagnosing early septic arthritis and in differentiating it from osteomyelitis or overlying tenosynovitis (FIG 2B).
Differential Diagnosis
- Rheumatoid arthritis
- Crystalline arthropathies: gout, pseudogout
- Seronegative arthropathies: systemic lupus erythematosus, psoriatic arthritis, Reiter syndrome, ankylosing spondylitis, rheumatic fever
- Lyme disease
- Cellulitis
- Osteomyelitis
- Suppurative flexor tenosynovitis

Nonoperative Management
- If septic arthritis is detected or suspected early enough, antibiotics alone have been suggested in the medical literature to be sufficient to eradicate the infection.\(^3\)
- In cases where comorbid conditions contraindicate surgery, serial aspiration of the involved joint can be done to decrease the bacterial load, decompress the joint, and allow medical management with antibiotics to treat the infection.
  - This technique has been shown to be less effective than open surgical drainage in large joints and, therefore, would be even less reliable in small joints.\(^4\)

Surgical Management
- Septic arthritis usually is considered a surgical pathology that warrants prompt treatment.
- Open and arthroscopic techniques are available for surgical drainage of the wrist.

Preoperative Planning
- Arrangements for instruments, irrigation fluid, drains, sutures, and assistants should be made in advance of surgery.

Positioning
- Approaches to the hand and wrist can be accomplished with the patient supine and the operative extremity extended on a hand table with the surgeon and assistants seated.
  - The hand table should be stable and well-secured, and should allow adequate space for both the operative limb and the surgeon’s elbow and forearm, to minimize surgeon fatigue and enhance stability.
  - Tourniquet use is advised to obtain a bloodless field and clear visualization of anatomic structures.
  - The limb usually is exsanguinated via gravity with elevation before inflating the tourniquet to avoid proximal spread of the bacteria.
  - A small-joint wrist arthroscopy tower should be used. This will provide positioning and application of traction during arthroscopy and also facilitate conversion to an open procedure if necessary. Additionally, small-joint arthroscopy equipment, including a 30-degree 2.7-mm camera, should be used.

Approach
- Multiple approaches to a joint are available. The choice of which approach to use should be based on ease of the approach while still allowing adequate joint exposure for débridement and minimizing contiguous spread of infection.
  - All surgical approaches of the hand and wrist warrant a sound understanding of surface anatomy, surgical anatomy, internervous planes, and surgical technique.

Aspiration of Interphalangeal or Metacarpophalangeal Joints
- Prepare the skin with an antiseptic wash, but avoid placing local anesthesia before the aspiration, because it may mask the location of the joint space.
- As large a needle as possible should be used, preferably 18- or 20-gauge.
- A syringe no larger than 3 or 5 mL should be used, because larger syringes cause too great a vacuum aspiration and collapse the joint, making them, therefore, less effective for aspiration.
  - The joint space can be identified just radial or ulnar to the extensor mechanism on the dorsal surface.
  - The needle should be inserted in a dorsal-to-volar direction with a 30- to 45-degree angle toward the midline.
  - A palpable “pop” or sensation of entering the joint should be felt, and the joint should be aspirated.
  - Distraction of the joint can sometimes aid entry.
  - If there is resistance to aspiration, the needle should be redirected while maintaining suction on the syringe.
SURGICAL DRAINAGE OF INTERPHALANGEAL OR METACARPOPHALANGEAL JOINTS

- For the MP joint, a dorsal longitudinal incision is made (TECH FIG 1A). The extensor mechanism is exposed and also incised longitudinally to expose the capsule.
- Alternatively, the capsule can be exposed by incising the ulnar sagittal band.
- The joint is exposed by incising the capsule dorsal to the collateral ligaments.
- For the proximal IP joint, a midaxial incision is preferred to avoid injury to the central slip and creation of a septic boutonniere deformity (TECH FIG 1B).
- The neurovascular bundle may be identified and retracted volarly. The dorsal sensory branches are at risk and should be retracted with the dorsal flap.
- The extensor mechanism, including the lateral bands, is identified and retracted dorsally, thereby exposing the capsule laterally. The accessory collaterals (volar to the proper collaterals) are released to allow entry into the joint.
- The distal IP joint can be approached through a midaxial incision or through a dorsal “H” incision and the terminal tendon retracted laterally, exposing the joint dorsal to the collateral ligaments.
- Injury to the terminal tendon can result in a mallet finger and possible late swan-neck deformity.
- Obtain cultures and thoroughly irrigate and débride the joint with gravity cystoscopy tubing or a bulb syringe.
- In-line traction on the digit will help expose the joint space.
- Inspect the joint surfaces for articular damage.
- Leave a small wick in the joint to prevent premature closure of the joint capsule, and reapproximate the extensor mechanism using a monofilament suture. Avoid using deep braided sutures in the face of an infection.
- Loosely close the skin around the wick with one or two 4-0 nylon sutures.
- Place the hand in a volar splint for comfort and emphasize that the patient should keep it elevated.

ASPIRATION OF THE WRIST

- Prepare the skin with an antiseptic wash but avoid placing local anesthesia pre-aspiration, because it may mask the location of the joint space.
- As large a needle as possible should be used, preferably 18-gauge.
- A syringe no larger than 5 or 10 mL should be used.
- Larger syringes cause too great a vacuum on aspiration and collapse the joint, and are, therefore, less effective for aspiration.
- The joint space can be identified just distal to Lister’s tubercle on the dorsum of the wrist. The needle should be angled approximately 10 degrees volar to accommodate for the normal volar tilt of the radius.
- Alternatively, the joint may be easily entered through the dorsal ulnocarpal space, just distal to the triangular fibrocartilage complex.
- A palpable pop or sensation of entering the joint should be felt and the joint should be aspirated. If there is resistance to aspiration then the needle should be redirected while maintaining suction on the syringe.
ARTHROSCOPIC DÉBRIDEMENT OF THE WRIST

- Secure the hand and wrist in a sterile small-joint arthroscopy tower. Apply 5 to 10 pounds of traction.
- Identify and mark the dorsal surface anatomy of the wrist. Specifically, palpate the dorsal and distal surface of the radius, ulna, distal radioulnar joint, and Lister’s tubercle. These landmarks will guide safe establishment of portals and maximize visualization (TECH FIG 2).
- The 3–4 portal is the main “viewing” portal and should be established first to visualize the radiocarpal joint. Begin by identifying the soft spot just distal to Lister’s tubercle. The portal is bordered by the third and fourth dorsal compartments.
  - An 18-gauge needle is directed just distal to Lister’s tubercle and should be angled about 10 degrees volar to accommodate for the normal volar tilt of the radius. The joint is then insufflated with 5 to 10 mL of normal saline.
- Create the portal with a 3-mm longitudinal skin incision using a no. 11 blade directed superiorly. Spread the soft tissue bluntly with a curved hemostat down to the joint, avoiding inadvertent penetration of the capsule.
- Direct a blunt-tipped cannula and trocar into the joint, again angling about 10 degrees volar just distal to Lister’s tubercle. Avoid plunging the cannula uncontrollably into the joint, because this may cause iatrogenic articular cartilage injury.
- Replace the trocar with the camera.
- Cultures can be taken through the cannula.
- Systematically explore the radioscapoid, radiolunate, and ulnocarpal joints for turbid fluid.
- In addition, evaluate the scapholunate ligament and triangular fibrocartilage complex for tears that may allow the infection to communicate with the midcarpal and distal radioulnar joints, respectively.
- Establish a second “working” portal. Arthroscopic equipment such as the shaver and probe will be used through this portal. A 25-gauge needle is directed into the proposed site under direct arthroscopic visualization before making the skin incision.
- The 4–5 portal is identified just ulnar to the fourth dorsal compartment and just distal to the distal radioulnar joint (see Tech Fig 2).
- Alternatively, a 6-R or 6-U portal can be used and can be identified just radial or ulnar, respectively, to the sixth dorsal compartment. Diligent blunt dissection with a curved hemostat must be performed before inserting the blunt cannula and trocar to avoid inadvertent injury to the dorsal ulnar sensory nerve.
- The joint can be both visualized and washed through the camera cannula in the viewing portal and drained through the working portal with a cannula. Drainage can be applied to gravity or suction.
- The joint can be further débrided with the aid of a shaver with suction placed through the working cannula.
- Devitalized tissues and synovial shavings can be taken through the shaver.
- Thorough arthroscopic débridement of the wrist should include visualization and irrigation of the midcarpal joint as well.
  - Palpate a soft spot about 1 cm distal to the 3–4 portal.
  - Place a 25-gauge needle first, and insufflate the joint with 5 mL of normal saline.
  - Direct a blunt cannula and trocar into the midcarpal joint just radial to the base of the capitate.
- After thorough visualization, irrigation, and débridement of the wrist, insert a small Hemovac drain through the working portal cannula.
- Remove the arthroscopic equipment. Close the portals with 4-0 nylon stitches.
- Place the wrist in a volar splint for comfort, and encourage limb elevation and active finger motion.

OPEN SURGICAL DRAINAGE OF THE WRIST

- A dorsal longitudinal incision should be placed just ulnar to Lister’s tubercle (TECH FIG 3A). The incision should be approximately 4 cm in length, with about two thirds distal to the tubercle.
- Alternatively, a transverse incision may be used. Although more cosmetic, it may not provide adequate exposure.
Once the extensor retinaculum is exposed with blunt dissection, the distal third is released perpendicular to the fibers and ulnar to the third dorsal compartment.

The interval between the third and fourth extensor compartments is bluntly dissected, and the joint capsule is exposed (TECH FIG 3B).

The joint capsule is incised longitudinally, and limited flaps are raised subperiosteally off the dorsal distal radius, like an inverted T (TECH FIG 3C).

Cultures are taken, and synovial tissue should be sent for culture and histology.

The joint should be thoroughly débrided and irrigated with gravity cystoscopy tubing or a bulb syringe.

Pulse lavage should be avoided due to its potential to cause additional soft tissue injury.

The joint should be ranged during irrigation to maximize the effect of the lavage.

The joint surfaces are inspected for articular damage.

Leave a small wick or drain in the joint and loosely close the skin around the wick.

Primary closure of the joint risks reaccumulation of pus.

Typically, two to three loosely placed 4-0 nylon sutures will be sufficient.

Place the wrist in a volar splint for comfort and encourage limb elevation.

Diagnosis
- Diagnosis is best accomplished by joint aspiration and analysis.

Antibiotics
- Obtain cultures before beginning antibiotics.
- Empiric antibiotics should be tailored to the most likely organism based on mechanism of injury and patient factors.

Aspiration
- Avoid using larger syringes, because the vacuum created can collapse the joint and may be less effective for aspiration.

Arthroscopic drainage
- Identify the surface landmarks of the joint and avoid inadvertent injury to the dorsal tendons and cutaneous nerve.
- Be prepared to convert to an open procedure if adequate exposure and débridement are not possible.

Open surgical drainage
- Be prepared to perform a second open surgical débridement if symptoms do not improve.

POSTOPERATIVE CARE
- Empiric IV antibiotics are initiated immediately after obtaining cultures and then later tailored to the results of laboratory cultures and sensitivities.
- IV antibiotics should be continued for 2 weeks or at least through symptom resolution, followed by oral antibiotics.\(^8\)
- The duration of antibiotics is the subject of some controversy. This should be determined on a case-by-case basis, with consideration of surgical findings, virulence of the offending bacterial pathogen, and the response to treatment.
- Early range of motion (active and active-assisted) in diluted povidone-iodine soaks is initiated three times daily to provide mechanical lavage of the joint and to prevent premature wound closure.
- The wick or drain is removed 1 or 2 days postoperatively.
As symptoms resolve, the soaks are discontinued to allow the wound to heal, and progressive range of motion exercises are initiated.

If symptoms do not improve within 2 days, then a repeat surgical drainage should be considered.

OUTCOMES

The results of surgical treatment of septic arthritis are not well-documented in the literature, and it is difficult to predict the outcome even during the course of treatment.

Functional outcome is most closely correlated to the duration of symptoms before treatment is initiated.10

Some loss of motion and joint stiffness are expected, even in cases treated with early surgical drainage and rehabilitation.1,10,12–14

Some joint space narrowing usually is seen following treatment, and significant arthrosis and ankylosis may occur in severe cases or when treatment has been delayed.

COMPLICATIONS

Joint stiffness, arthrosis, osteomyelitis, and secondary tendon adhesions

Salvage options for postseptic arthritis include arthrodesis, resection arthroplasty, or amputation.

Implant arthroplasty is controversial and is not generally recommended for a previously infected joint.

REFERENCES

DEFINITION
- Injury to the nail usually occurs in the traumatic setting. Because of its location at the distal end of the digits, the peri-onychium is the most frequently injured part of the hand.\(^9\)
  - Restoration of normal nail appearance is best achieved by acute treatment of the nail matrix.
  - Reconstructive techniques may be used to provide a more normal-appearing nail.
  - Excision of benign and malignant tumors involving the nail bed matrix may require techniques of nail bed repair and reconstruction also used in the traumatic setting.
  - Optimal treatment depends on thorough understanding of the components of the perionychium—skin, sterile matrix, germinal matrix, eponychial fold, and distal phalanx—and their anatomic relationship with each other.

ANATOMY
- The nail serves multiple functions: protecting the fingertip, regulating peripheral circulation, and contributing to sensory feedback of the fingertip.\(^9\)
- The perionychium includes the nail plate, nail bed, hyponychium, eponychium and fold, and paronychium (FIG 1).
- The proximal portion of the nail matrix is the germinal matrix, and the distal portion is the sterile matrix. The germinal matrix produces about 90% of the nail, while the sterile matrix produces the remaining 10% of the nail and produces the cells on the undersurface of the nail responsible for nail adherence.
- The hyponychium is the skin distal to the nail bed, the paronychium is the skin on each side of the nail, and the eponychium is the skin over the nail fold.
- The nail bed is adherent to the distal phalanx.

PATHOGENESIS
- The main causes of nail deformity are trauma and tumor.\(^13\)
- The middle finger is the most commonly injured finger.\(^1\)
- Inadequate treatment in the acute setting often leads to a nail deformity.
- There is an associated distal phalanx fracture in 50% of nail bed injuries. This type of injury should be considered an open fracture and treated as such, with irrigation and débridement, reduction of the fracture and fixation if necessary, and repair of the nail bed (FIG 2).\(^1,4\)
- Scarring can lead to a split nail deformity.
- Absence of nail matrix can lead to detachment of the nail.
- Lack of support from the distal phalanx leads to the hook nail deformity.
- Benign tumors (glomus tumor, distal interphalangeal joint ganglion), and malignant tumors (squamous cell carcinoma, melanoma) can affect nail appearance.

NATURAL HISTORY
- Repair in the acute period provides the best chance for normal appearance of the nail.
- The nail plate grows at about 0.1 mm per day or 2 to 3 mm per month. When the nail plate is removed for nail bed repair, new nail growth is delayed for 3 to 4 weeks.\(^9\)
- If placed back on after repair, the old nail will remain adherent for 1 to 3 months and then fall off as a new nail pushes out the old nail.\(^12\)
- After nail repair, it will take about 12 months for the nail to achieve its final appearance. Thickening of the nail proximal to the level of injury is seen for about 50 days (FIG 3).\(^9,12,13\)

PATIENT HISTORY AND PHYSICAL FINDINGS
- Traumatic injury to the perionychium is usually caused by a crush injury.\(^1,4\)
- In the acute setting, the status of the entire fingertip must be assessed: quality of the skin, presence of a subungual hematoma, quality of the nail matrix, capillary refill, sensory...
function, flexion and extension at the distal interphalangeal joint, presence of a distal phalanx fracture.

■ Features of acute nail bed injury
  ■ Subungual hematoma (FIG 4A,B): bleeding beneath the nail from laceration of the nail bed
  ■ Pain secondary to pressure in the space between the nail plate and the nail bed
  ■ Treated with evacuation of hematoma by trephination
  ■ Laceration of nail bed (FIG 4C,D)
    ■ Mechanism of injury usually is crush.
    ■ Concomitant injury to fingertip skin or distal phalanx fracture may be present.
    ■ Nail lacerations can be described in one of four ways: simple laceration, stellate laceration, severe crush, and avulsion.
    ■ Repair of nail bed laceration and Kirschner wire fixation of distal phalanx fracture if unstable
  ■ Nail bed avulsion (FIG 4E)
    ■ Quality of avulsed nail matrix and size of defect will determine treatment.
    ■ Treatment options include returning avulsed piece back on defect or harvesting a split nail graft from the adjacent matrix or from the great toe.
  ■ Posttraumatic nail deformities
    ■ Nail nonadherence or split nail (FIG 4F)
      ■ Usually due to injury to the sterile matrix, which produces the cells responsible for adherence

■ Excision of scar and primary closure or nail matrix reconstruction with a split graft from the great toe
■ Hook nail deformity (FIG 4G)
  ■ Due to excessive tension at junction of nail bed and hyponychial skin and loss of support of distal phalanx
  ■ Revision amputation or reconstruction of nail bed and bone graft to the distal tip of the distal phalanx
■ Nail remnant (FIG 4H)
  ■ Due to presence of residual germinal matrix not completely ablated at the time of initial repair or revision amputation
  ■ Complete nail matrix ablation or revision amputation
■ Pincer nail deformity (FIG 4I): characterized by excessive transverse curvature of the nail and progressive pinching off of the distal fingertip, causing pain and abnormal appearance
  ■ Partial or complete nail ablation
  ■ Reconstruction of nail bed with elevation of the lateral nail bed using dermal graft or AlloDerm

IMAGING AND OTHER DIAGNOSTIC STUDIES
■ AP and lateral radiographs of the distal phalanx are recommended to rule out a fracture.
  ■ Depending on the level of injury, the following fractures are seen: distal tuft fracture, comminuted fracture, and a transverse or oblique fracture of the midshaft.
  ■ Intra-articular fractures at the distal interphalangeal joint are rare with an associated nail bed injury.

DIFFERENTIAL DIAGNOSIS
■ Trauma
■ Benign tumor
  ■ Glomus tumor
  ■ Distal interphalangeal joint ganglion cyst
■ Malignant tumor
  ■ Squamous cell carcinoma
  ■ Melanoma

NONOPERATIVE MANAGEMENT
■ Left untreated, traumatic injury to the nail matrix may result in an abnormal appearance of the nail.
SURGICAL MANAGEMENT

- Repair in the acute period increases the chance of a normally appearing nail.
- Both surgeon and patient should be aware of the stages of nail growth and characteristic appearance at different points in the healing process as the nail grows out.
- Reconstruction of the nail matrix in a chronic injury should be approached with realistic expectations.
- Reconstruction of the nail matrix after tumor excision will depend on the amount of nail bed excised and the amount remaining.2,6–8

Preoperative Planning

- Management of malignant tumors involving the nail bed requires an understanding of the safe level of amputation (usually to the level of the more proximal joint) and the need for sentinel node biopsy.

Positioning

- To provide a bloodless field, use of a Penrose drain tourniquet at the base of the digit secured with a clamp is recommended (FIG 5).
- Use of a portion of a surgical glove as a tourniquet is discouraged because of the risk of leaving the tourniquet at the base of the digit after repair and placement of the dressing.

The dressing may then hide the tourniquet, and vascular compromise and subsequent necrosis of the finger is possible in the postoperative period.

Approach

- Sterile preparation and draping is done.
- A digital block with 1% plain lidocaine (maximum dose 7 mg/kg) is administered.
- Use of surgical loupes (2.5X magnification is sufficient) is recommended for the most accurate repair.
- A Kleinert elevator is used to separate the nail plate from the nail matrix.

FIG 5 • Use of Penrose drain tourniquet at base of digit.
The nail plate is cleaned and soaked in povidone-iodine (Betadine) as nail bed repair is done. If the nail plate is not available, a silicone sheet or nonadherent gauze can be used to maintain the eponychial fold after repair.

- Minimal débridement of the nail matrix is performed to preserve as much of the nail bed as possible.
- Incisions perpendicular to the eponychial fold may be necessary for adequate exposure of the germinal matrix (FIG 6).

**FIG 6** • Incisions made perpendicular to eponychial fold for exposure of the germinal matrix.

**DRAINAGE OF SUBUNGUAL HEMATOMA**

- A standard surgical preparation is performed to prevent introducing bacteria into the subungual space.
- Trephination of the nail can be accomplished using a heated paper clip, needle, or handheld battery-powered cautery (TECH FIG 1).
- Nail removal and repair is recommended if more than 50% of the nail is lifted up by the underlying hematoma or if the nail edges are not intact.

**TECH FIG 1** • Trephination of the nail to drain a subungual hematoma using a heated paper clip (A) or battery-powered cautery (B).

**REPAIR OF NAIL BED LACERATION**

- Use a digital block, standard surgical preparation, and a Penrose drain at the base of the digit to serve as tourniquet.
- Use the Kleinert elevator to separate the nail plate from the nail bed for adequate exposure (TECH FIG 2A).
- Repair the laceration under loupe magnification using simple sutures of 7-0 chromic (TECH FIG 2B).
- Avoid aggressive débridement of the nail bed.
- Clean the nail plate, soak it in Betadine, and rinse it with normal saline; then place it back into the proximal fold.

**TECH FIG 2** • Repair of nail bed laceration. A. Laceration with nail plate present. The nail plate is cleaned and will be used later as a splint to maintain the eponychial fold. B. Repair of nail bed and surrounding skin after débridement. (continued)
to maintain this space and to serve as a splint for a distal phalanx fracture (TECH FIG 2C).
- A figure 8 suture of 5-0 nylon or a simple stitch from nail to hyponychium can be used to hold the nail in place if desired (TECH FIG 2D).
- A silicone sheet may be used if the nail plate is not available.

- Repair of a nail bed avulsion and resultant proximal germinal matrix disruption may require incisions perpendicular to the curved portion of the eponychial fold for exposure.

### TREATMENT OF NAIL BED DEFECTS

- A defect amenable to reconstruction may be present after excision of scar (causing nonadherence or a split nail deformity) from prior injury to the nail bed (TECH FIG 3A).
- Small areas (less than 5 mm) can be left to heal by secondary intention but may result in recurrent scarring and nail deformity.
- Defects larger than 5 mm can be treated with split-thickness nail bed grafts from the adjacent noninjured nail bed, the nail bed from another digit, or the nail bed from a toe (TECH FIG 3B).²,⁶,⁹,¹³
- Prepare and drape the recipient and donor sites in standard surgical fashion and perform a digital block.
- Exsanguinate the digit and place a Penrose drain tourniquet at its base.
- Expose both nail beds and measure the defect.

- Harvest split-thickness nail bed graft from the sterile matrix of the donor digit using a no. 15 scalpel (TECH FIG 3C,D).
- To reduce the risk of donor-site nail deformity, the germinal matrix should not be used as a graft for a defect of the sterile matrix.
- Graft is carefully harvested by placing the blade parallel to the nail bed and taking it thin enough so that the blade can be seen through the graft.
- Suture the split-thickness nail bed graft in place using 7-0 chromic, as is done in a laceration repair (TECH FIG 3E).
- Reconstruction of the germinal matrix with subsequent nail growth on the recipient digit requires harvest of a full-thickness germinal matrix graft from a toe (preferably the second toe) (TECH FIG 3F).¹⁰

Chapter 103  NAIL MATRIX REPAIR, RECONSTRUCTION, AND ABLATION

NAIL MATRIX REPAIR, RECONSTRUCTION, AND ABLATION

A nail remnant may grow at the site of a previous nail ablation (TECH FIG 4A). It may grow in a dorsal direction, catching on clothes and requiring frequent clipping. This remnant may be a source of persistent pain, irritation, or infection.

- A cyst may form from a nail remnant after a revision amputation and become a source for a subcutaneous abscess (TECH FIG 4B).
- Complete excision of the residual germinal matrix is the goal of treatment.
- It is important to tell the patient that a nail will no longer grow at the fingertip.
- Re-enter the old incision, preserving skin to allow adequate primary closure.

Dissect to the proximal portion of the distal phalanx at the expected location of germinal matrix.

- The distal interphalangeal joint is used as a landmark to guide dissection to the level of the germinal matrix. It may be difficult to distinguish scar from residual germinal matrix after traumatic injury.
- Use a scalpel, curette, or rongeur (or some combination) to ablate the residual nail bed germinal matrix (TECH FIG 4C,D).
- To preserve length yet fully ablate the nail, a full-thickness skin graft can be used to cover the distal phalanx.
- The distal phalanx is a unique area where a skin graft may survive even after being placed directly on bone without the presence of periosteum.

Additional soft tissue bulk to the volar pad may be required to support the reconstructed nail.

- A thenar flap is available for reconstruction of the index or middle fingertips.
- Bone graft can be used for support, but there is a high rate of resorption.
- A favorable cosmetic result is often difficult to achieve.

TREATMENT OF PINCER NAIL DEFORMITY

- The goal of treatment is to flatten out the excessive curvature of the nail and correct the “pinched-in” appearance of the nail (TECH FIG 5A).
- Elevate the lateral margins of the nail bed from the distal phalanx using a Kleinert-Kutz elevator (TECH FIG 5B).
- Avoid injuring the paronychium as the nail bed is elevated.

Hook nail deformity can be caused by overaggressive débridement of the distal phalanx, resulting in lack of support, or by too much tension on the closure at the tip, creating an unnatural, curved appearance of the nail.

- If the germinal matrix is still present, the nail will continue to grow but will hook without adequate bony support.
- Three treatment options exist: doing nothing, reconstruction of the nail to produce a flatter nail with or without bone graft, and revision amputation.

Additional soft tissue bulk to the volar pad may be required to support the reconstructed nail.

- A thenar flap is available for reconstruction of the index or middle fingertips.
- Bone graft can be used for support, but there is a high rate of resorption.
- A favorable cosmetic result is often difficult to achieve.

TREATMENT OF PINCER NAIL DEFORMITY

Hook nail deformity can be caused by overaggressive débridement of the distal phalanx, resulting in lack of support, or by too much tension on the closure at the tip, creating an unnatural, curved appearance of the nail.

- If the germinal matrix is still present, the nail will continue to grow but will hook without adequate bony support.
- Three treatment options exist: doing nothing, reconstruction of the nail to produce a flatter nail with or without bone graft, and revision amputation.

Additional soft tissue bulk to the volar pad may be required to support the reconstructed nail.

- A thenar flap is available for reconstruction of the index or middle fingertips.
- Bone graft can be used for support, but there is a high rate of resorption.
- A favorable cosmetic result is often difficult to achieve.
- Make stab incisions on the ulnar and radial fingertip.
- Through these stab incisions, create subcutaneous tunnels to the radial and ulnar eponychium using the elevato. Make a second set of stab incisions at that proximal location (**TECH FIG 5C**).
- Cut dermal graft or AlloDerm to the appropriate length and place it through each tunnel.
- Pull the graft through the tunnel, distal to proximal, with the aid of a suture. This positions the graft in the desired location (**TECH FIG 5D**).
- Close the stab incisions with 6-0 nylon and replace the nail (**TECH FIG 5E,F**).

**PEARLS AND PITFALLS**

**Traumatic injury**
- With prompt treatment of nail bed injury, subacute and chronic problems can be avoided and a more complex reconstruction may be avoided.
- Failure to treat a nail bed laceration and concomitant distal phalanx fracture as an open fracture may result in osteomyelitis.
- Too much tension at the site of nail bed repair or a lack of support from the distal phalanx may result in a hook nail deformity.

**Nail growth**
- An accurate repair of the nail matrix allows the nail plate to grow out with a smooth, flat appearance.
- The germinal matrix produces about 90% of the nail.
- The sterile matrix contributes cells that are responsible for nail adherence to the underlying nail bed.
- The nail grows at 0.1 mm a day.
- New nail growth is completed by 6 to 9 months.

**Nail bed reconstruction**
- The goal of reconstruction is to restore the nail bed after loss due to trauma, scarring, or excision to allow more normal growth.
- Reconstruction of the sterile matrix can be accomplished with a split nail bed graft from the adjacent nail bed, an adjacent digit, or a toe.
- Reconstruction of the germinal matrix and sterile matrix can be accomplished with a germinal matrix and sterile matrix graft from the second toe.
POSTOPERATIVE CARE

- The postoperative dressing is left on for 5 to 7 days and may need to be soaked in a mixture of hydrogen peroxide and water for removal. The repaired nail is checked for signs of infection, seroma, and hematoma.
- Nonadherent gauze placed to maintain the eponychial fold should be removed. Any suture used to hold the nail or silicone sheet within the fold should also be removed at 5 to 7 days postoperatively.
- Sutures placed in the skin of the hyponychium or paronychium should be removed at 10 to 14 days after repair.
- Early motion of the proximal interphalangeal joint should be encouraged. The fingertip splint provides protection of the tip and will allow earlier motion of the injured digit.
- Hypersensitivity of the tip may be present for 1 to 3 months after injury, and desensitization exercises may be necessary to promote use of the affected digit.

OUTCOMES

- While repair in the acute period provides the best chance for a normal-appearing nail (FIG 7), scarring at the site of injury may produce a nail deformity, and patients should be reminded of this possibility at the time of repair. 10,13,14
- Results of nail bed repair are adversely affected by avulsion or crush injury of the fingertip, presence of a distal phalanx fracture, three or more sites injured, and the need to use a silicone sheet for replacement of the nail. 1,4,13
- Late reconstruction of the nail bed is often not as successful as surgeon or patient would desire. 9
- Management plans must be individualized and realistic expectations must be discussed when treating patients with nail bed injuries.

COMPLICATIONS

- Complications in the acute or subacute setting include soft tissue infection, osteomyelitis of the distal phalanx, nonunion of the distal phalanx fracture, and posttraumatic stiffness and loss of motion at the distal interphalangeal joint.
- Complications or unfavorable outcomes in the chronic setting include scarring in the sterile matrix, leading to a split nail or nonadherent nail; scarring at the eponychial fold, which may interfere with nail plate growth; and persistent nail growth after an unsuccessful attempt at nail ablation.

Chapter 104

Soft Tissue Coverage of Fingertip Amputations

Christian Ford and Jeffrey Yao

DEFINITION
- A fingertip injury or amputation involves trauma to the finger distal to the distal interphalangeal (DIP) crease.
- The fingertip is the most sensitive area of the hand.
- Fingertip injuries are common, accounting for 45% of emergency room hand injuries.

ANATOMY
- **FIGURE 1** depicts the anatomy of the fingertip.
- Eponychium: the cuticle or the thin membrane over the dorsum of the nail at the nail fold
- Perionychium: the skin at the lateral nail margin
- Hyponychium: the skin below the distal aspect of the nail plate, consisting of a mass of keratin with a high concentration of lymphocytes and polymorphonuclear cells; serves as a barrier to infection
- Nail root: portion of the nail plate proximal to the eponychial fold
- Lunula: the curved white opacity representing the distal, visible portion of the germinal matrix
- Germinal matrix: produces 90% of the nail plate volume
- Sterile matrix: contributes to nail plate adherence
- Nail plate: consists of flattened sheets of anuclear keratinized epithelium
- Nail bed: the floor of the nail plate, comprising proximal germinal matrix and distal sterile matrix
- Distal phalanx: lies deep to the nail bed
- Pulp: composed of fibrous septa

PATHOGENESIS
- Various mechanisms of trauma
  - Avulsion
  - Crush
  - Compression
  - Sharp
  - Dull

NATURAL HISTORY
- Fingertip injuries with no bone exposed will ultimately heal by secondary intention.
- In the setting of wounds less than 1 cm², secondary-intention healing aided by daily dressing changes actually allows for increased recovery of sensation.
- The use of secondary-intention healing for larger injuries involves a prolonged period of dressing changes with associated risk of infection and unfavorable scarring.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Full history and physical examination
- Mechanism of injury
- Age
- Handedness
- Occupation
- Level of cooperation and understanding
- Injury assessment
  - Digit or digits involved: thumb versus finger
  - Transverse versus dorsal oblique–volar oblique versus radial–ulnar
  - Damage to nail or nail bed
  - Exposure of bone
  - Static and moving two-point discrimination: There is decreased density of innervation with increased two-point discrimination.
  - Terminal flexion and extension: Injury to tendons will require more significant flap coverage.
  - Vascularity: Prolonged capillary refill is suggestive of arterial injury.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs in orthogonal planes (posteroanterior, lateral)

NONOPERATIVE MANAGEMENT
- Most fingertip amputations can be treated at the bedside using sterile technique and employing a metacarpal block, finger tourniquet, and loupe magnification.
There should be a low threshold for operative management.
- If no bone is exposed, options include healing by secondary intention, primary closure, or skin grafting.
- Secondary-intention healing aided by daily dressing changes provides the best recovery of sensation and is appropriate for wounds less than 1 cm².
- Primary closure is an option only if there is minimal skin loss.
  - Tight closures should be avoided. This can minimize function by causing joint contracture and distal tip tenderness due to poor soft tissue coverage of the bony prominences.
  - Sewing the volar skin tightly to the distal nail can result in a cosmetically displeasing “hook nail.”
- If a nail bed laceration is suspected, the nail plate should be removed with a Freer elevator, allowing repair of the nail bed with either 6-0 or 7-0 simple interrupted absorbable sutures (chromic gut). Loupe magnification is extremely helpful.
- The eponychial fold should be stented open with either trimmed and carefully cleansed nail or other material (e.g., foil from a suture pack) to prevent abnormal growth of the future nail.
- With amputations through the germinal matrix, any remaining unrepairable matrix should be removed to prevent formation of a painful nail remnant.

**SURGICAL MANAGEMENT**
- The decision to take a patient with a fingertip injury to the operating room depends on the size of the defect, presence of exposed bone, angle of amputation, willingness of the patient to do dressing changes, and surgeon experience.
- The goals are to preserve function and sensation and allow early return to activity.
- In terms of functional outcome, healing by secondary intention provides equal or better results for defects less than 1 cm in diameter.
- Full-thickness grafts are preferable to split-thickness grafts.
  - Split-thickness grafts should be used only on the ulnar side of the index, middle, and ring fingers.
  - Donor site options include the volar wrist skin (should be avoided as it can mimic a suicide attempt laceration), antecubital skin, medial upper arm skin, and hypothenar skin.
  - These donor sites can be closed primarily.
- If salvageable, the original skin from the amputated segment can be defatted and applied as a graft–biologic dressing.
- If bone is exposed, options include bone shortening and primary closure and bone shortening and healing by secondary intention or fingertip flaps.

**Preoperative Planning**
- Preliminary irrigation and débridement, exploration
- Antibiotics
- Patient comorbidities
  - Is the patient a diabetic? Smoker? Recreational drug user?
  - Is the tetanus status up to date?
- Anesthesia assessment

**Positioning**
- Supine with standard hand table. An arm, forearm, or digital tourniquet is used. The arm is placed in the center of the hand table for equal access by the surgeon and assistant.

**Approach**
- Once the decision to perform a flap has been made, the angle of amputation, patient age, and patient gender determines whether an advancement or regional flap is appropriate.

**SKIN GRAFTING**
- Measure the size of the defect carefully and create a template.
  - This template is used to draw a corresponding defect on the donor site (TECH FIG 1A).
- Harvest the full-thickness graft with a no. 15 blade. Take great care to defat the graft down to dermis (TECH FIG 1B,C).
- Sew the graft into place and secure it using absorbable suture (TECH FIG 1D).
  - At four corners the suture is left long so that later it may be tied over a bolster.
- Cover the skin graft with Xeroform dressing and mineral oil-soaked sterile cotton balls.
- Tie down the four long sutures over the cotton balls to create a bolster, placing gentle pressure on the graft to minimize shear.
- The finger is padded with gauze and protected with a finger splint, leaving the proximal interphalangeal (PIP) joint free for 5 to 7 days.
- After 5 to 7 days, the splint and dressing should be carefully removed, the graft inspected, and daily Xeroform dressing changes instituted until the graft is fully healed.
**TECH FIG 1 • (continued)** B. The hypothenar full-thickness skin graft is harvested, taking great care to defat the graft; only the dermis and epidermis are harvested. C. The hypothenar full-thickness skin graft ex vivo. Note a paucity of fat. D. The skin graft is inset using absorbable sutures. Four bolster sutures are then tied over a mineral oil-soaked cotton ball placed on top of the graft (not pictured). A dry dressing is applied. The bolster is left in place for 5 to 7 days.

**MOBERG ADVANCEMENT FLAP**

- Indication: thumb tip amputation less than 1.5 cm; preserves sensation and length (TECH FIG 2A,B)
- Make a longitudinal incision just dorsal to the neurovascular bundles, based at the metacarpophalangeal joint flexion crease (TECH FIG 2C).
- Elevate a flap elevated from the flexor sheath (TECH FIG 2D).
- If the flap is difficult to advance, consider the following (TECH FIG 2E):
  - Flexing the interphalangeal joint
  - Extending the lateral incisions toward the palm with excision of skin at base to create an island flap; skin grafting of the secondary defect
  - Excise a triangle of skin at the bilateral flap base (ie, triangle of Burow).
  - Carefully preserve bridging vessels.
  - Close with permanent suture under minimal tension (TECH FIG 2F).

**TECH FIG 2 • A.** Distal thumb defect with exposed proximal phalanx. B. Nonreplantable distal phalanx. C. Intraoperative photograph indicating planned Moberg flap with longitudinal incisions just dorsal to neurovascular bundles and based at metacarpophalangeal joint flexion crease. D. Moberg flap elevation from flexor sheath. E. Advancement of Moberg flap was possible without creation of an island flap or use of a triangle of Burow. F. Closure of the defect after advancement of Moberg flap. (Courtesy of James Chang, MD.)
LATERAL V–Y ADVANCEMENT FLAPS (KUTLER)

- Indication: transverse fingertip amputation with exposed bone
- The apex of the V is located at the lateral distal digital crease (TECH FIG 3).
- Adequately mobilize the flap: only nerves and vessels need to be kept intact.
- Bilateral triangles are advanced and sutured together distal to the nail bed.

VOLAR V–Y ADVANCEMENT FLAP (ATASOY-KLEINERT)

- Indication: dorsal oblique fingertip amputation (ie, more dorsal than palmar skin loss) with exposed bone
- The apex of the V is at the volar midpoint of the distal digital crease (TECH FIG 4).
- The base of the triangle should be as wide as the nail bed.
- Adequately mobilize the flap.

CROSS-FINGER FLAP

- Indication: volar fingertip defects up to $1.5 \times 2.5$ cm with an uninjured adjacent digit present (TECH FIG 5A–C)
- The donor area is the dorsal aspect of the middle phalanx skin of the adjacent finger.
  - The middle finger is used for an index finger tip amputation; otherwise the donor skin is derived from the radial digit.
  - Make two transverse midaxial to midaxial incisions on the donor area at roughly the DIP and PIP extension creases. Make one longitudinal midaxial incision on the side of the donor digit away from the injured digit to connect these two transverse incisions.
  - Dissection is carried out in the loose areolar plane above the extensor paratenon.
  - The graft is mobilized to the midaxial line adjacent to the injured digit (TECH FIG 5D).
  - Apply a full-thickness skin graft to the secondary defect.
- The full-thickness graft should be first sewn to the hinge margin of the primary defect.
- The flap and full-thickness graft are then each rotated 180 degrees, allowing the flap to cover the primary defect and the full-thickness graft to cover the secondary defect (TECH FIG 5E).
- The flap is divided 2 to 3 weeks after the index procedure (TECH FIG 5F,G).

TECH FIG 5 • A. Intraoperative photograph depicting ring finger volar fingertip avulsion with exposed flexor tendon and small finger amputation at middle phalanx level. B,C. Two weeks after successful replantation of small finger with continued problem of ring finger wound, which had been treated with daily dressing changes. D. Intraoperative photograph after elevation of cross-finger flap from dorsal aspect of middle phalanx skin of adjacent finger. E. Intraoperative photograph after cross-finger flap from middle finger for coverage of volar ring finger defect. Donor site was covered with a full-thickness skin graft. Blue background indicates preservation of sensory branch. F,G. Intraoperative photographs after cross-finger flap division at 3 weeks.

REVERSE CROSS-FINGER FLAP

- Indication: dorsal fingertip injury
- Raise a de-epithelialized full-thickness flap from the dorsal middle phalanx skin (TECH FIG 6A,B).
- Elevate the subcutaneous tissues underlying the raised graft (TECH FIG 6C,D).
- Cover the primary defect with the elevated deep tissue and then with a full-thickness graft (TECH FIG 6E).
- Cover the secondary defect with the previously described native full-thickness flap (TECH FIG 6F).
- The subcutaneous flap is divided in 2 to 3 weeks (TECH FIG 6G).
The designed H-flap should be 50% wider than the defect to fully cover the pulp’s semicircular contour. Raise the flap at the level of the thenar muscles with as much subcutaneous tissue as possible (TECH FIG 7C). Take care to avoid injury to the digital nerves to the thumb. The H-flaps may either be “tubed” around the defect or one flap may be advanced to fill the defect of the other flap that is sewn to the amputation site (TECH FIG 7D). The flaps are divided at 3 weeks. One or both H-flaps can be used to close the donor defect primarily.

**TECH FIG 6** • **A.** Dorsal defect of the right index finger with the flap drawn out on the adjacent long finger. **B.** Ulnarly based skin flap raised from the long finger. **C, D.** The subcutaneous tissue is elevated off the paratenon of the long finger. **E.** The flap is inset onto the index finger defect. **F.** Split-thickness skin graft placed on the recipient site. The native ulnarly based skin flap is restored onto the long finger. **G.** Three months postoperatively. (Courtesy of Phani Dantuluri, MD.)

**THENAR FLAP**

- **Indication:** index or middle fingertip injury with exposed bone and more palmar than dorsal skin loss (defects roughly 1 × 1.5 cm in size) in patients younger than 35 years of age who are less likely to develop PIP joint contractures.
  - Women are better candidates for this flap than men.
  - Press the amputated tip against the thenar eminence with the digit in the position of least PIP flexion (TECH FIG 7A).
  - The position of the H-flap is indicated by the bloody imprint from the amputation site (TECH FIG 7B).
**NEUROVASCULAR ISLAND PEDICLE FLAP (LITTLER)**

- **Indication:** Volar distal thumb defect as well as volar radial index or volar ulnar small finger defects sufficient to produce a scarred pulp and an anesthetic tip (TECH FIG 8A,B).
- **Use Doppler to ensure that flow is present in the ulnar digital artery of the ring finger and the radial digital artery of the middle finger.**
- **Create a template of the defect on the ulnar aspect of the donor digit.**

- Apply the pattern to the distal ulnar aspect of the middle finger with small V-shaped indentations at the DIP joint creases.
- The flap may be continued posteriorly, beyond the midaxial line.
- Make a Bruner incision to the distal flexor retinaculum.
- Dissection is commenced in the palm to ensure normal anatomy.
- Isolate and ligate the radial digital artery to the ring finger.
POSTOPERATIVE CARE

- Mobilize the vessel to the level of the superficial palmar arch to allow maximum pedicle length (TECH FIG 8C).
- Pass the entire pedicle beneath the digital nerve if it causes tension.
- Create a subcutaneous tunnel to the thumb using blunt scissor dissection.
- The tourniquet is released and flap viability assessed.
- The flap is then gently placed into a Penrose drain and secured in place with a 4-0 nylon suture to the tip of the flap skin.
- The Penrose drain is used to avoid kinking and twisting of the pedicle as the flap is passed through the subcutaneous tunnel to the recipient site.
- The flap is sutured in place under minimal tension and the donor site is closed primarily or with a full-thickness graft (TECH FIG 8D).

PEARLS AND PITFALLS

- Fingertip injuries less than 1 cm² can generally be treated with dressing changes with equal or better results than flap closure.
- The bridging vessels should be carefully preserved when performing a Moberg flap to prevent skin necrosis.
- V–Y advancement flaps may lead to scarring and hypersensitivity at the fingertip.
- The radial digital nerve should be carefully preserved and protected when performing a thenar flap.
- Cross-finger flaps (nonglabrous skin) may lead to hair growth on the fingertip and deficiency of pulp.
- Thenar flaps (glabrous skin) allow good sensibility in the flap but may be complicated by development of PIP joint contractures, especially in older male patients.
- Poor sensory outcome in neurovascular island flaps can be minimized by use of the most distal portion of donor skin, preservation of as much subcutaneous skin on the pedicle as possible, and avoidance of tension and kinking in the pedicle.

POSTOPERATIVE CARE

- When possible, the patient should meet the hand therapist preoperatively.
- Active and passive range of motion
- Sensory re-education
- Scar massage
- Moberg advancement flap: thumb spica splint for 10 days to 2 weeks followed by range-of-motion exercises
- Lateral V–Y advancement and volar V–Y advancement flaps: finger splintage of only the involved joint for 10 days to 2 weeks, followed by range-of-motion exercises
- Cross-finger flap and reverse-cross finger flap: A nonadherent bolster dressing is applied to the skin graft site and a splint is applied. PIP joints and the DIP joint of the donor finger can be gently ranged 2 weeks after flap inset, taking care to avoid tension on the flap. After flap division at 3 weeks, range-of-motion exercises are directed toward extending the PIP joints. Severe contractures may be treated with static progressive splinting.
- Thenar flap: A splint is applied postoperatively. Gentle range of motion of unaffected digits is started 2 weeks after flap inset, with care taken to avoid tension on the flap. Full range-of-motion exercises are started after flap division at 3 weeks. Severe contractures may be treated with static progressive splinting.
- Neurovascular island flap: The splint is changed 10 days after surgery, when sutures can be removed; gentle active range of motion is started, with full range of motion delayed until 3 weeks after surgery. Sensory re-education is necessary to help differentiate thumb from middle finger sensation.
OUTCOMES

- Moberg flaps consistently provide return of normal two-point discrimination or within 2 mm of the contralateral digit and may result in a decrease in the hyperextensibility of the interphalangeal joint with no functional impairment.3
- V-Y advancement flaps result in return of sensation to within 2.75 mm of the contralateral digit but may also result in paresthesia, hypersensitivity, and cold intolerance (50%).3
- Patients who undergo a cross-finger flap have a return of protective sensation (8 mm of two-point discrimination), most predictably in younger patients, but the sensation remains less than the normal pulp.3
- Hematoma or seroma significantly impairs the return of sensation.8
- Thenar flaps provide superior return of sensation compared to cross-finger flaps, but still less than normal.3
- Neurovascular island flaps may result in hyperesthesia (23%) and cold intolerance (32%), which can be minimized by proper attention to detail and technique.3

COMPLICATIONS

- Moberg flap: interphalangeal joint flexion contracture and skin necrosis19
- Lateral V–Y advancement flaps (Kutler): scarring at the fingertip, which may be insensate or painful5
- Volar V–Y advancement flap (Atasoy-Kleinert): hook nail or hypersensitivity3
- Cross-finger flap: deficiency of fingertip pulp and hair growth on the fingertip8
- Thenar flap: PIP joint flexion contracture of recipient finger8
- Hematoma8
- Seroma8
- Infection8
- Skin necrosis8
- Dysesthesia or altered sensation8
- Flexion contractures8
- Loss of flap8
- Epidermal inclusion cysts8
- Nail deformities8
- Symptomatic neuromas8

REFERENCES

DEFINITION

- Upper extremity wounds that are candidates for skin grafting very closely parallel wounds suitable for skin grafting in other areas of the body. Certain wound conditions must be adhered to, and the principles of grafting remain constant, no matter the location of a wound.

Terminology

- **Autograft** refers to skin that is harvested from the same individual to whom it will be applied at a different location.
- **Isograft** refers to skin harvested from an identical twin of the recipient individual. Isograft behaves like autograft.
- **Allograft** refers to skin harvested from an individual of the same species as the recipient individual. Due to histocompatibility mismatch, these grafts eventually separate from the wound, except in immunosuppressed patients, and so provide only temporary coverage.
- **Xenograft** refers to the use of skin grafts from a species different from the recipient individual. Due to histocompatibility mismatch, these eventually separate from the wound, except in the immunosuppressed patient, and so provide only temporary coverage. Xenograft use is associated with an elevated rate of wound bed infection.
- **Split-thickness skin grafts** contain epidermis, along with a varying thickness of dermis that represents less than the full thickness of the dermis.
- **Full-thickness skin grafts** incorporate the full thickness of dermis and epidermis.
- **Donor site** refers to an area from which either a split- or full-thickness skin graft is harvested. Depending on the thickness of the graft, donor site treatment varies, from topical dressings, which typically are used for split-thickness skin graft donor sites, to direct closure, which is the usual method for addressing full-thickness skin donor defects.
- **Skin substitutes** are semisynthetic or purely synthetic constructs designed to act as replacements for lost skin structures. Ideally, they will be incorporated into the host to act as durable long-term replacements for lost tissue. In 1984, Pruitt and Levine described the characteristics of ideal biologic dressings and skin substitutes. Their list of qualities considered to be ideal for skin substitutes still holds true more than 20 years later:
  - Little or no antigenicity
  - Tissue compatibility
  - Lack of toxicity
  - Permeability to water vapor, as would be seen in normal skin
  - Impenetrability to microorganisms
  - Rapid and long-term adherence to the wound bed
  - Capacity for ingrowth of fibrovascular tissue from the wound bed
  - Malleability, which would allow the construct to conform to the wound bed
  - Inherent elasticity that would not impede motion
  - Structural stability against linear and shear forces
  - Smooth surface to hinder bacterial proliferation
  - Good to tensile strength that would allow it resist fragmentation
  - Biodegradability
  - Low cost
  - Ease of storage
  - An indefinite shelf life

Wound Bed

- Before making a decision about using skin grafts or a substitute, it is important to be familiar with the characteristics of a wound bed that make it suitable for grafting.
- **Graft beds** should be properly débrided so that they are free of dead tissue and made as clean as possible to help minimize the risk of graft loss from infection.
- Beds that are being considered for grafting must have an appropriate substrate from which the graft can derive its blood supply. In the context of upper extremity wounds, the bed specifically should contain no areas of denuded tendon or bone, as these denuded areas will not support inosculation (ie, neovascularization of the graft).
- A further requirement, once débridement is complete, is the reduction of bacteria in the wound, which usually is effected through the use of a pulse lavage system. Enhanced skin graft survival by means of reducing bacterial counts is supported by studies published by Perry in 1989.
- A useful tool in maturing a wound bed for grafting is the vacuum-assisted closure device (VAC). This device provides microdébridement of the wound bed and can help to promote the development of healthy granulation tissue, an ideal substrate for the support of skin graft adherence. Moreover, the vacuum-assisted closure device can be used over the top of a skin graft applied to a wound and, through its negative pressure effect, limit fluid collection beneath the graft, also helping to ensure contact between graft and bed through an even distribution of pressure across the interface.
- Elements key to the development of an adequate graft bed are:
  - Débridement of all nonviable tissue
  - Minimization of bacterial colonization within the wound bed
  - Ensuring that there exists an appropriate substrate for adherence of graft
  - Microdébridement and maturation of the graft bed using appropriate dressings, which may include myriad measures ranging from the use of wet-to-moist saline gauze dressings to use of the VAC device.
ANATOMY

- The decision-making process in choosing split- versus full-thickness graft in the distal upper extremity involves both gross and microanatomic considerations.
- The lack of secondary contraction seen in full-thickness skin grafts supports their use on surfaces that overlie or are juxtaposed to joints. This lack of secondary contraction helps minimize the risk of unwanted joint contracture as the grafts mature.
- Over broad flat surfaces, such as the dorsal or volar aspect of the forearm, split-thickness skin grafts perform well.
- Wounds that involve the glabrous surface of the hand ideally are replaced with skin that possesses the same characteristics as the adjacent skin.
- Harvest of glabrous skin from the sole of the foot or from the contralateral uninjured hand should be considered for such use.
- In some cases, the wound may be so large that it is not possible to harvest sufficient donor skin while still permitting primary closure of the donor site. When this is the case, the arch within the sole of the foot may yield a full-thickness glabrous skin graft sufficient to cover the area of the original wound; however, the donor site then may require a skin graft itself. The donor site from the arch of the foot can be grafted with nonglabrous, meshed split-thickness graft with minimal morbidity due to its minimal weight-bearing requirement.

Microanatomy

- As suggested earlier, the surgeon must be concerned with the microanatomic conditions of the wound bed.
- An appropriately vascular substrate is required to ensure proper graft take. Healthy fat, muscle, paratenon, or periosteum must be present within the base of the wound to ensure success.
- Additional considerations include proper débridement of nonviable tissues from the wound bed as well as the minimization of bacterial contamination.

Donor Sites

- Glabrous skin
  - The sole of foot within the arch, beginning at the junction of glabrous and nonglabrous skin along the medial aspect of the arch
  - The ulnar aspect of the hand, beginning at the junction of the glabrous and the nonglabrous skin along the ulnar aspect of the palm
- Full-thickness skin
- Redundant areas of full-thickness skin available for harvest that maintain ease of primary closure of the donor defect include the lower abdomen, running from the anterior superior iliac spine in a gentle arc around the lower portion of the abdomen to the contralateral anterior superior iliac spine.
- Skin harvested from this area may be hair-bearing. Depending on requirements of the recipient site, selection of full-thickness skin graft can range from the relatively hairless portions found laterally to the hirsute areas found centrally.
- Smaller areas of satisfactory full-thickness skin can be harvested from the upper inner arm. This skin, located at the junction of the medial biceps and triceps muscle groups, is thin and usually hairless.
- Split-thickness skin graft
- Traditionally preferred sites have included the anterior thighs due to the ease of harvest and postoperative care of these areas.
- Another site that has favorable characteristics in terms of quality of graft donor, as well as healing of donor site, includes the scalp.
- Harvest of split-thickness skin graft from the scalp requires shaving of the head and the injection of epinephrine-containing wetting solution, eg, Pitkin's solution or Klein's solution, which is directed via puncture into a subgaleal plane to help minimize blood loss from the harvest.
- The very rich vascular supply to the scalp makes split-thickness skin grafts from this site quite robust.
- If the harvest is kept within the hair-bearing portions of the scalp, little to no donor defect can be detected once hair has grown back. Moreover, because of the high density of epidermal appendages in the scalp, re-epithelialization of this area is more rapid than at other sites on the body. This rapid re-epithelialization helps to minimize the potential for donor deformity (ie, scarring and dyspigmentation).

Harvest

- Skin harvest is greatly facilitated by proper preparation of the chosen site.
- First, a template of the bed to be grafted should be transferred to the donor site to ensure an adequate harvest. This is easily done with gentian violet and a sterile glove wrapper.
- Limiting blood loss from the harvest site is desirable and is easily achieved by pre-injecting the hypodermis of the planned harvest area with an epinephrine-containing local anesthetic.
- If a long-acting local anesthetic such as Marcaine with epinephrine is used, the patient will have the additional benefit of prolonged donor site anesthesia postoperatively.
- As split-thickness donor sites are typically quite painful, this is a real benefit and is appreciated by the patient.
- When a large area is planned for harvest, attention must be paid to the appropriate maximum dosage for the local anesthetic selected. Dilute solutions in these cases can provide the benefits sought for these larger surface areas while still respecting the maximum allowed dosages.

PATHOGENESIS

- Wounds in the distal upper extremity requiring coverage arise from a host of different mechanisms. Among the most common are traumatic injuries, which commonly result in avulsive loss of skin. Other causes include burn injury to the upper extremity, as well as defects created by tumor removal.
- Any one of these mechanisms may result in a wide range of injuries, from simple skin loss to injuries of deeper structures, including loss of paratenon or periosteum.

NATURAL HISTORY

- Skin graft healing varies from site to site on the body, and each location will vary from person to person.
- Skin in young adults is thick and healthy; however, in about the fourth decade the skin begins to thin.
- Despite differences in skin thickness at differing anatomic locations, the overall dermal-to-epidermal ratio remains relatively constant: about 95% dermis to 5% epidermis.
- Blood vessels form arborizations into the dermis of the skin through access portals in the dermal papillae.
How Do Grafts Work?

- After application to an appropriately prepared wound bed, both split- and full-thickness grafts undergo a process that has been commonly termed “take.”
- The process involved in adherence of skin graft to wound bed is complex and involves an initial hypermetabolic condition within the graft, supported by plasmatic imbibition. Plasmatic imbibition is the process whereby nutrients and oxygen are drawn into the graft by absorption and capillary action. During this time, the graft remains adherent by a thin and friable film of fibrin between wound bed and graft.
- This early phase of graft support is followed by inosculation and capillary ingrowth. Before inosculation, there is a period during which ischemia and, therefore, hypoxia within the graft, with attendant histologic findings, are present.
- Once capillary ingrowth occurs and makes contact with the vascular network inherently present within the graft, blood flow is re-established, and the skin graft takes on a pinkish hue. This process likely involves both the use of the inherent network of vessels within the graft and new vascular proliferation.
- Secondary adherence is mediated through fibrovascular ingrowth. The new vascular connections between graft and bed, as well as the new fibrous connections, solidify graft adherence.

Properties of Skin Grafts

- Skin grafts have been used to provide both temporary and permanent coverage, offering the inherent benefit of protection of the host bed from additional trauma while also providing an important barrier to infection.
- Split-thickness grafts tend to adhere to wound beds more easily and under adverse conditions that would not typically support full-thickness graft viability. This characteristic of split-thickness skin grafts provides a considerable advantage in managing difficult wounds; however, certain disadvantages can arise from their use. Once healed, split-thickness skin grafts undergo secondary contraction which, under uncontrolled conditions, can lead to pathologic contracture.
  - Contracture refers to a disability in function that arises from secondary contraction.
  - Additional disadvantages arising from the use of split-thickness skin grafts include dyschromia, poor elasticity, and reduced durability when referenced against their full-thickness counterparts.
- Full-thickness skin grafts include the full thickness of the dermis, along with the epidermis. In the initial phases, full-thickness skin grafts tend not to show the hardy “take” often seen with split-thickness skin grafts. To ensure full-thickness graft success, their use should be limited to well-vascularized recipient beds only.
  - Once established, full-thickness grafts offer distinct advantages; specifically, secondary contraction is far less problematic. Their thickness offers more resistance to external trauma and tends to be less likely to experience the dyspigmentation often associated with split-thickness grafts. They have much better inherent elasticity than split-thickness grafts, and for this reason they are the graft of choice for use over and around joints.

Contraction

- As mentioned earlier, split-thickness skin can undergo a process of secondary contraction that ultimately may lead to pathologic contracture. Immediately on harvest, full- and split-thickness skin grafts behave differently.
  - The phenomenon of primary contraction refers to the tendency of a graft to shrink on elevation from the donor site. Substantial primary contraction is more often associated with full-thickness skin grafts than with split-thickness skin grafts.
  - It is clinically important to remember that the immediate and long-term elasticity of full-thickness skin grafts is much greater that in split grafts. It is this elastic property that makes full-thickness skin grafts an ideal choice for use around joints.
- Once skin grafts have healed in place, the secondary process of contraction occurs more than in split-thickness grafts.
  - Full-thickness grafts tend to remain about the same size and, for practical purposes, show little to no secondary contraction. Full-thickness skin grafts have the capacity to increase their surface area with limb growth over time, whereas split-thickness grafts tend to decrease in size by a process of contraction, or, alternatively, their size remains static.

Reinnervation

- The restoration of sensation in skin grafts is mediated through both peripheral ingrowth and direct growth into the graft from the bed.
  - Factors affecting reinnervation of skin grafts include the location and quality of the recipient bed, as well as the choice of full- versus split-thickness skin graft.
  - Timing of recovery is variable, with some sensory recovery at between 4 and 6 weeks post-grafting. The return of normal sensation occurs between 12 and 24 months.
  - The speed with which sensory recovery is realized depends on the accessibility of graft neural sheaths to wound bed nerve fibers. Accessibility of neural sheaths is improved in full-thickness grafts over their split-thickness counterparts, and, therefore, sensory recovery in full-thickness grafts is both more rapid and more complete.

Dyspigmentation

- The harvest of a graft disrupts its normal circulation, causing a loss of melanoblast content. This reduction results in a significant decrease in the number of pigment-producing cells within the graft.
- After graft revascularization, the initial hypoxia is corrected, and the melanocyte population recovers to a normal level.

Skin Substitutes

- The use of skin substitutes for wound coverage in the distal upper extremity typically is considered when the surface area involved is greater than that which could be reasonably covered with a full-thickness skin graft, but for which a split-thickness skin graft is suboptimal, for cosmetic or functional reasons.
- Of the several skin substitutes on the market, the most clinically relevant are AlloDerm (LifeCell Corporation, Branchburg, NJ) and Integra Dermal Regeneration Template (Integra LifeSciences Corporation, Plainsboro, NJ). AlloDerm is a de-antigenized human cadaveric acellular dermal construct. Integra consists of a bovine collagen dermal matrix sheathed with a silicone top membrane creating a bilaminar structure.
Wounds with a bacterial content greater than $10^5$ colony-forming units (CFUs) have significantly reduced successful graft take. A quantitative culture can be performed to assess this variable before skin grafting. A punch biopsy is used to obtain a portion of vascularized wound bed, and this tissue sample is sent to the laboratory, where it is homogenized and then plated. CFUs on the culture plate are counted and then referenced against the initial sample weight. A concentration of more than $10^5$ CFUs per gram of sample tissue is a negative predictor of successful graft adherence.

The area of tissue biopsied must be delivered from the viable portions of the tissue bed and not from devitalized tissues, which will show very high colony counts and are not representative of the grafted bed.

**DIFFERENTIAL DIAGNOSIS**
- Superficial or partial thickness skin loss
- Full-thickness skin loss
- Full-thickness skin loss concomitant with deep tissue injury
- Loss of paratenon or periosteum
- Wound over or adjacent to joints
- Wound over broad, flat surface that does not overlie a joint

**NONOPERATIVE MANAGEMENT**
- Superficial abrasions or burns over broad surfaces with maintained viability of the dermal and hypodermal structures can be treated by local wound care without the use of grafting. Areas of skin with abundant epidermal appendages (sebaceous glands, sweat glands, and hair follicles) have inherent source tissue for re-epithelialization of these superficial wounds.
- Conservative management ideally includes a moist wound-healing environment that limits bacterial growth and does not inhibit the process of neoeapithelialization, such as the petrolatum-based antimicrobial ointments (eg, Neosporin [Johnson & Johnson, New Brunswick, NJ] and Xeroform gauze [Covidien, Mansfield, MA]).
- When conservative wound management is being employed, serial observation is advised to ensure that the process of neoepithelialization is underway and is not hindered by the development of local infection or other unforeseen factors.
- If the process of re-epithelialization is complete by the end of 2 weeks after the event of the initial injury, scarring at the site of injury will be minimized.
- Smaller wounds that are deeper and penetrate through dermis into the hypodermis may be treated conservatively as well.
- Local wound care, with serial wet-to-moist changes or by use of the Vacuum-Assisted Closure (VAC) Device (KCI, Inc., San Antonio, TX) can help facilitate healing by secondary intention.
- Larger areas of skin loss allowed to heal by secondary intention can result in a substantial delay in wound healing. In addition, functionally limiting contractures can develop as a byproduct of secondary intention healing.
- Larger, superficial dermal wounds such as second-degree burns can be managed nonoperatively by use of synthetic membrane dressings such as Biobrane (Smith & Nephew, Hull, UK, FIG 1) or TransCyte (Smith & Nephew). These dressings are applied immediately after debridement of nonviable skin.
- This class of dressing is effective for superficial wounds that penetrate only to middermal levels. They depend on retained epidermal appendages (ie, hair follicles, sebaceous and sweat glands) to accomplish the task of re-epithelialization.
- Deeper, full-dermal thickness areas of wounding require deeper débridements that typically are followed by skin grafting or skin graft substitutes.

**SURGICAL MANAGEMENT**

**Preoperative Planning**
- Once appropriate débridement has been performed, and the wound is deemed clean and the wound bed is appropriately vascularized, the surgeon can proceed with skin grafting.
- Before beginning in the operating room, the surgeon should have discussed the proposed donor site with the patient and also should have decided whether a full- or split-thickness graft is most appropriate.
Positioning
- The volar and dorsal aspects of the distal upper extremity can be accessed easily with the patient in a supine position with the arm placed on an arm table.
- Occasionally, patients who have limited range of motion in their joints at the shoulder or elbow must be placed prone to facilitate access to certain areas.

Approach
- Wounds that are being considered for placement of skin graft or skin graft substitutes are, by definition, vascularized wound beds with direct superficial access.
- Logical preoperative planning determines the approach.
- Decisions about positioning should be made well in advance of initiation of the procedure.

SPLIT-THICKNESS SKIN GRAFT

Determining Wound Size and Making a Template
- To begin the procedure, a sterile ruler is used to measure the size of the wound to be addressed with skin grafting.
- A simple and effective way to determine the shape of a wound bed is to place a sheet of sterile glove paper within the wound. The mark left on the paper by the wound is a close match of the wound bed. (This technique is not as accurate for wounds with markedly irregular contours.)
- Once the wound has transferred moisture onto the glove paper, the paper can be trimmed with scissors to provide a template of the wound bed. This template then can be transferred to the area of planned skin harvest.
- The shape of the template is marked with a dashed line, using a gentian violet marker, on the skin that is to be harvested.

Harvesting the Graft
- Most modern dermatomes are designed to harvest skin in a quadrangular pattern.
- To ensure that the harvested graft is capable of proper wound coverage, it should be larger than the gentian violet marks on all sides, both to offset shrinkage from primary graft contraction and to compensate for the difficulties in harvesting amorphous shapes with an instrument designed to cut quadrangular patterns.
- The degree of primary contraction is a function of the depth of dermis harvested. For very thin split-thickness grafts, primary contraction is virtually absent.
- Grafts usually are harvested with either nitrogen- or electric-powered dermatomes (TECH FIG 1), which can be adjusted for depth of harvest as well as the desired harvest width.
The usual appropriate depth for harvesting skin to be applied to a wound bed in the distal upper extremity is between 0.012 and 0.014 inch.

Unmeshed versus Meshed Grafts
- Once a graft of appropriate size has been harvested, it must be decided whether to use the graft as a sheet graft (unmeshed) versus an expanded graft (meshed) (TECH FIG 2).
- Sheet grafts, because of their contiguous nature, have a greater tendency to develop subgraft seromas and hematomas.
  - This complication can lead to graft loss; for this reason, it is worth considering the use of meshed grafts.
- Under ideal circumstances, a meshed graft can be used in its nonexpanded state.
  - To do this, simply mesh the graft using the appropriate device, and after placing it in the wound bed, close the small fenestrations made by meshing.
  - This closure will give a final healed appearance very close to that of a sheet graft but without the complication of accumulated fluid beneath the graft, which can lead to graft loss.

Placing the Graft
- Once the graft has been placed in the wound with the dermis side down, the graft can be secured in place using either staples or sutures around the periphery.
  - As this is done, excess peripheral graft may develop. This is the byproduct of the quadrangular shape of the harvest versus the amorphous shape of the typical wound.
  - Excesses are easily trimmed by holding the graft in place and using thin, sharp scissors to skirt just outside the periphery of the wound.
  - Once excess has been removed and the entire peripheral edge of the skin graft has been secured, any surface irregularity leading to noncontact with the undersurface of the graft can be addressed by placement of quilting sutures.
    - These sutures are placed through the surface of the graft into the depth of the contour irregularity and then back out of the graft.
    - When tied, the sutures draw the deep surface of the graft into contact with the wound bed.
    - A suitable suture for this purpose is 4-0 chromic.
- A nonadherent interface (eg, Xeroform [Kendall, Mansfield, MA] or Aquaphor [Beiersdorf AG, Hamburg, Germany] gauze) should be placed over the graft to prevent the graft from adhering to the bolster that will further secure the graft in position.
  - If Aquaphor gauze is used and the patient is not allergic to bacitracin ointment, a triple antibiotic ointment doping of the Aquaphor further inures the graft from injury when the overlying bolster is removed.
  - In the upper extremity, lightly applied circumferential dressings work well as bolsters.
  - Tie-over bolsters typically are not required, but they can be used if preferred. Reston foam (3M, St. Paul, MN) or saline- and mineral oil–doped cotton batting secured in place with light gauze and an elastic overwrap from the tips of the fingers to a point several centimeters beyond the most proximal aspect of the grafted site is sufficient.
  - A sugar-tong splint should then be applied to help prevent the shear stress created between the wound bed and the undersurface of the graft, which occurs as a byproduct of pronation and supination, as well as wrist and finger flexion and extension.
  - The patient’s arm should be elevated to help minimize accumulation of edema at the graft site.

Postoperative Care
- On postoperative day 5, dressings should be removed and the graft examined. Typically, at this time, the graft will have acquired a pink coloration, and although most of the fenestrated areas may not have fully epithelialized, it should be clear that graft take is underway. If this is not the case, the wound should be inspected to determine why the graft is not taking.
  - For fenestrated grafts, it is unusual for either hematoma or seroma to be a cause of graft failure. The more common cause for graft failure with fenestrated split-thickness grafts is wound infection.
  - Quantitative cultures obtained preoperatively will help guide the surgeon in appropriate antibiotic treatment for these patients pre-, intra-, and postoperatively.
  - Once early graft healing has occurred, wound infection is unlikely, and the application of a hypoallergenic emollient cream helps keep the graft supple and moisturized while at the same time promoting slough of scaling stratum corneum and eschar.

FULL-THICKNESS SKIN GRAFT

Donor Site
- If the area of the wound is over or in proximity to a joint, it may be decided to use a full-thickness graft. Again, a template can be made using sterile glove paper, with this glove-paper template then transferred to the area desired for harvest of the full-thickness graft.
There are limitations on the surface area that can be obtained from full-thickness skin graft donor sites, and, therefore, consideration should be given to the recipient bed surface area when deciding on the type of graft. Typical donor sites include the lower abdomen and the inner aspect of the upper arm.

**Graft Harvest**

- Once the template has been transferred to the skin, harvest can be facilitated by injection of 1% lidocaine with epinephrine into the subcutaneous fat directly beneath the area planned for harvest.
  - Allow approximately 7 minutes for the epinephrine to take effect and help minimize bleeding during harvest.
- A no.15 scalpel blade can be used to accurately incise the periphery of the planned graft harvest, followed by elevation of the full-thickness graft in the plane directly beneath the undersurface of the full thickness of dermis, directly above the subdermal fat and below dermal papillae.
- In most cases, some fat is adherent to the underlying dermis after elevation.
  - The full-thickness skin graft can be stretched over the finger and curved scissors used to directly excise fat from the undersurface of the full-thickness graft.
  - The removal of unwanted fat maximizes the surface area of deep dermis in direct contact with the wound bed, which helps to facilitate the ingrowth and revascularization process.
- Full-thickness grafts have a greater degree of primary contraction than do split-thickness grafts; therefore, upon immediate harvest the graft will appear much smaller than it did when in situ. Once sewn in place around the periphery, however, the graft will return to the actual size of the template with little effort.
  - This ability to return to the template size, and even extend beyond it, means that when harvesting full-thickness graft, the harvest should not be extended much beyond the periphery of the template, as is done with split-thickness grafts.

**Graft Preparation**

- To minimize the accumulation of hematoma or seroma beneath the graft, a well-prepared bed is required.

**SKIN SUBSTITUTES**

- The goal with skin substitutes is to place within the wound bed a biosynthetic dermal construct that will offer the advantages of a full-thickness skin graft, but without the physical cost of obtaining such a large full-thickness skin graft harvest from the patient.
- The dermal constructs are placed within the wound in much the same manner as a full-thickness graft. They become fibrovascularly integrated into the wound bed as a synthetic neodermis. After maturity, application of a thin split-thickness skin graft (0.008 to 0.010 inch) converts these nonepithelialized constructs to closed wounds.
- One measure to help prevent subgraft fluid accumulation is “pie-crusting,” a technique in which the surgeon simply makes random perforations through the full thickness of the graft using a no.11 scalpel blade.
- These perforations provide avenues of egress for accumulated subgraft fluid in much the same way that meshing does for split-thickness grafts.

**Graft Placement**

- To improve the precision of dermal edge contact of the graft in the wound, suture fixation is preferred over staple fixation. Again, an ideal suture for this purpose is 4-0 chromic.
- The process for dressing this graft is the same as that for a split-thickness graft: the use of either Aquaphor or Xeroform gauze dressings with an overlying bolster of Reston foam or cotton batting secured with gauze and an elastic wrap, followed by appropriate immobilization of the area.
- The VAC is not recommended for unmeshed grafts and so should not be used for full-thickness skin grafts even if pie-crusted (TECH FIG 3).

**SKIN SUBSTITUTES**

- The technical application of AlloDerm and Integra is the same as placement of a full-thickness skin graft.
- AlloDerm and Integra usually are secured in place around the periphery with either 4-0 chronic or staples (TECH FIG 4A).
- Once a split-thickness skin graft is applied to a site treated with either AlloDerm or Integra, these split-thickness grafts should be treated in just the same manner as split-thickness skin grafts on any wound bed, observing the postoperative technical requirements of such grafts (TECH FIG 4B).
AlloDerm
- When using AlloDerm, bolstering dressings are applied over a petrolatum-doped nonadherent gauze interface, and the dermal construct is observed periodically at twice-weekly intervals.
- AlloDerm will demonstrate granulation tissue issuing through the pores of the dermal construct, typically at about 2 to 3 weeks after graft placement.
- Once this has occurred, the AlloDerm is ready for split-thickness skin grafting.

Integra
- On initial placement, Integra appears white, with a transition over the succeeding 2 to 3 weeks to a rosy color, the byproduct of neovascularization. At this point the Silastic layer of the Integra can be separated and the vascularized dermal construct grafted with a thin split-thickness skin graft.
- If desired, Integra can be meshed 1:1 with a specialized mesher designed not to crush the construct (eg, Brennen Medical Skin Graft Mesher, Brennen Medical, LLC, St. Paul, MN).
  - Meshing may help the construct conform to the wound bed and also help limit subgraft fluid accumulations.
  - The meshed construct should not be expanded on the wound bed, since its purpose is to replace absent dermis. Its expansion thins the Integra construct and diminishes its benefits.
  - Fenestrations in Integra are made only for the purpose of creating an avenue for fluid escape. Integra has a Silastic membrane that acts as an external barrier.
  - Integra’s Silastic membrane obviates the need for petrolatum-doped dressing and is transparent, which allows direct observation of the process of maturation of the dermal construct beneath.

Biobrane
- Biobrane is appropriate for use only in wounds that have some retained dermis and, because of this distinction, acts as an advanced wound dressing rather than a skin substitute. For wounds with full-thickness loss of skin, Biobrane is not an appropriate choice, because epidermal appendages, which are required to act as the source of cells needed for re-epithelialization, must be present.
- Biobrane acts as a protective barrier and a scaffold for the healing process. It notably decreases pain; allows for the retention of moisture within the wound, improving the healing environment; acts as a barrier to infection; and promotes more rapid healing.
- Its clinical use is most evident in treatment of burn injuries, but it also may be used to treat split-thickness skin graft donor sites to minimize morbidity in these areas.
- The application of Biobrane includes tangential excision of nonviable tissues or rough débridement with an antibiotic solution–doped lap sponge, followed by drying and then application of the Biobrane to the wound surface.
  - It is secured in place around the periphery using staples.
  - This is followed by application of a nonadherent gauze dressing with placement of an absorbent dressing, such as a sterile absorbent gauze pad held in place with gauze and an elastic wrap.
  - The site is immobilized for 24 hours, after which all dressings are removed, leaving Biobrane in place.
  - At this stage, the Biobrane should be adherent to the wound bed.
  - Biobrane is observed over time and allowed to separate from the wound without disturbance.
  - Small abscesses below the Silastic layer, if they develop, can be treated by simple incision and drainage. As edges release they are trimmed.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Category</th>
<th>Advice</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary contraction</td>
<td>Full-thickness grafts tend to shrink immediately on harvest. This primary contraction is easily overcome by application of peripheral sutures to draw the elastic full-thickness graft back out to its original surface area when applied to the wound.</td>
</tr>
<tr>
<td>Secondary contraction</td>
<td>Split-thickness grafts tend to shrink over time as a function of harvesting less than the full thickness of dermis. This problem is exacerbated by meshed graft expansion. Secondary contraction can lead to functional contracture, especially when grafts are used over or near joints.</td>
</tr>
</tbody>
</table>
Proper immobilization to prevent shear stress across the wound-graft interface cannot be overemphasized. Preparation requires débridement of nonviable tissue and bacteria. Quantitative culture can assist the surgeon in defining the species and number of bacterial colonies within the wound. More than 10^5 colony-forming units per gram of harvested tissue increases the likelihood of graft loss secondary to infection.

Enhancing graft adherence
Proper immobilization to prevent shear stress across the wound-graft interface cannot be overemphasized.

Vacuum-assisted closure device
The VAC device may be used as a skin graft bolster over fenestrated grafts. Its negative pressure serves to effectively immobilize graft on the wound bed, as well as draw interstitial fluid from the wound, preventing its accumulation beneath the graft.

POSTOPERATIVE CARE
- On admission to the postanesthesia care unit, the patient’s operated extremity should be placed in elevation and kept relatively immobile until time to take down dressings and evaluate the graft.
- Examination of the graft can be done as early as 3 days postoperatively; however, the graft at this point is very sensitive to manipulation.
- If takedown of the dressings is done on postoperative day 5 or 6, allowing time for additional graft maturation, the risk of disturbing the graft is reduced.
- Once maturation of the graft has been noted to be underway, application of a nonadherent dressing such as Xeroform or Aquaphor gauze should be continued, with light overpressure provided by an absorbable gauze dressing held in place by gauze and a light elastic wrap and splinting.
- After the graft has more fully matured, with all interstices fully epithelialized, at between 2 and 3 weeks postoperatively, the graft will require no further application of nonadherent dressings. Instead, light application of a hypoallergenic emollient cream such as Eucerin (Beiersdorf North America Inc., Wilton, CT) is preferred. This helps to keep the graft hydrated while maturation continues without the restrictions of constant compression and splinting.
- An occupational therapist should be consulted to help develop a program of appropriate splinting in tandem with an exercise regimen that will provide the foundation for maximizing the patient’s final functional range of motion.

OUTCOMES
- Because of the disparate nature of wounds and the significant variation that exists in patient physiology, it is impossible to provide standardized outcome measures for skin grafting.
- The goal of the general principles defined in this chapter is to assist the surgeon in optimizing outcomes for all cases. Collectively, they will work to help limit complications while maximizing functional outcomes.

COMPLICATIONS
- Wound or graft infection with loss
- Subgraft seroma or hematoma
- Hypertrophic or keloid scarring
- Contractures
- Loss of functional range of motion
- Tendon adherence to graft
- Poor durability
- Hyperpigmentation

REFERENCES
DEFINITION

- A flap is a composite collection of tissue (i.e., skin, fascia, muscle, bone) that is moved from its original location to another location in or on the body.\(^5\)
- Several different types of flaps exist, defined by their blood supply.
  - Random flaps (e.g., Z-plasty, V-Y, cross-finger) depend on preserving enough of the subcutaneous and subdermal vascular plexus for flap survival (FIG 1A).
  - Axial flaps depend on the blood supply from a single consistent (usually named) blood vessel; this includes radial forearm and dorsal metacarpal artery flaps (FIG 1B).
  - Free flaps depend on the division and microscopic reanastomosis of the artery and vein to re-establish blood flow to the flap.
  - Flaps also can be defined by how the tissue is moved.
    - Advancement flaps are elevated and advanced in a linear direction away from the base of the pedicle (FIG 1C).
    - Rotational flaps are elevated adjacent to the defect and re-inset within the same bed\(^10\) (FIG 1D).
    - Transpositional flaps are elevated and moved across normal tissue to a new defect site (FIG 1E).
    - Island flaps are elevated, then moved within a subcutaneous tunnel to the defect site.

---

FIG 1 • A. Random flap. The distal skin flap is not supplied directly by the underlying vessels, but relies on circulation from the dermal and subdermal plexus for nutrition.
B. Axial flap. The entire flap is carried over an underlying vascular pedicle. C. Advancement flap. This is a direct tissue advancement. This figure also shows Burow’s triangles, which will decrease the dog-ears at the corners.
D. Rotational flap. The flap rotates into the adjacent defect. The radius of the flap decreases with the rotation. A backcut can be used to extend the arc of coverage.
E. Transposition flap. This flap is similar to a rotational flap, but the flap is moved across normal tissue to fill the defect.
Grafts are differentiated from flaps in that there is no native blood supply to the tissue. A skin graft survives initially by osmosis (imbibition) before it obtains vascular ingrowth into the graft. This process works only for fairly thin tissue grafts.\(^3,4\)

**ANATOMY**
- A thorough understanding of the anatomy of the area injured and the donor area of the flap is necessary for safe elevation and inseting of these flaps.
- A full description of the anatomy of the forearm and hand is beyond the scope of this chapter, but the key points of the relevant anatomy will be addressed in the separate sections.
- The skin and soft tissue covering the forearm and hand vary by location, and this variation must be accounted for when considering coverage.
- The palm (volar surface) of the hand consists of very thick dermis and epidermis that is structurally anchored to the underlying tissues by numerous vertical fascial connections.
- The glabrous skin of the palm should be used to cover palmar defects, if possible.
- The dorsum of the hand has thin dermis and subcutaneous fat covering gliding extensor tendons.
- Coverage here should be as thin as possible, to match the lost tissue.
- Fingertip sensation and durability should be of high consideration when deciding on type of coverage.
- The forearm has thin soft-tissue coverage.
  - Proximally there is muscle, which often can be covered with a skin graft.
  - Distally there is tendon on the palmar and dorsal surfaces. Trauma to the soft tissue often disrupts the paratenon and will require flap coverage.

**PATHOGENESIS**
- The mechanism of injury has a considerable effect on the need for flap coverage.
  - Sharp injuries can usually be closed primarily, without the need for flap coverage.
  - Abrasive injuries commonly occur as a result of motor vehicle accidents. These usually involve one surface of the hand, and the extent of injury is usually relatively apparent. However, the level of contamination often is high, and extensive débridement of contaminated and devitalized tissue is necessary.
  - Crush injuries can lead to necrosis of skin, tendon, bone, and muscle. The zone of injury often is large and can be underestimated on initial inspection.
  - Other systemic injuries may delay treatment of extremity injuries. However, treatment for compartment syndrome and gross contamination must not be delayed any longer than necessary.

**NATURAL HISTORY**
- The natural history of a wound depends greatly on the type of injury. The degree of original injury is the primary factor contributing to the prognosis for function of the hand.
  - A large wound involving the bones, tendons, or joints often has a profound negative affect on future function of the hand.
  - Early coverage can decrease total inflammation of the injured area and can limit the detrimental effect of the injury on the return to function.
- Many wounds will heal secondarily without coverage. Secondary healing can lead to acceptable results in some locations, but also may lead to very poor results in others. These factors must be taken into account when deciding type of coverage.
  - Small wounds (<1 cm) on the fingertips, without exposed bone or tendon, will likely heal well on their own. This secondary healing often gives the strongest soft tissue coverage with the best sensibility and is the preferred treatment for most wounds of this type.
  - If dorsal hand wounds secondarily heal or “granulate” over tendons, the tendons tend to scar, which limits gliding and impairs finger motion.
  - Exposed bones, tendons, nerves, or vessels usually should be covered with a flap. Secondary healing or skin grafts will result in more scarring or unstable coverage.
  - Skin grafts are best for wounds that have no exposure of tendons, nerves, or vessels. However, in dire circumstances, a skin graft can provide temporary coverage over most viable tissue. Skin grafts will not survive on bone or tendon when the periosteum or paratenon is not viable.
  - A well-performed flap will provide stable, durable coverage over any viable wound bed. This will allow earlier therapy and motion.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- After a traumatic injury, a complete history and physical examination are performed.
- The mechanism of the injury is important. Contaminated or crush injuries often require more than one procedure for adequate irrigation and débridement.
- Any past medical history of diabetes, smoking, heart disease, peripheral vascular disease, or hypercoagulability will impact the healing of any flap, but none of these is an absolute contraindication.
- Examination of the wound and extremity should be comprehensive:
  - Assessment of vascular status
  - Imaging for fracture
  - Motor and sensory examination to evaluate for nerve, tendon, or muscle injury
  - Examination for compartment syndrome in severe injuries

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs of the hand should be obtained to evaluate for bony injury.
- Advanced imaging, such as CT scan or MRI, may be warranted for fracture pattern delineation, but these studies rarely are needed to assess the indications for flap coverage.
- Questionable blood flow or limb perfusion warrants further evaluation, such as angiography.
- Adequate blood flow to the extremity must be restored before considering flap coverage.

**TYPES OF FLAPS**

**Radial Forearm Flap**
- Workhorse flap to cover upper extremity wounds. This flap can be a pedicle or free flap and provides excellent thin soft tissue coverage.\(^9\)
The donor site is the major area of morbidity.
- The volar forearm donor site is relatively conspicuous.
- If a skin graft is needed to close the donor site, the appearance is poor.
- The radial artery is divided during movement of the flap. Therefore, ulnar artery patency is critical. This must be confirmed with an Allen’s test, or with direct Doppler evaluation of the hand with the radial artery occluded with manual pressure.
- The flap can be elevated with a proximal (anterograde) or distal (retrograde or reversed) pedicle.
- The anterograde flap is useful for coverage of the elbow, as either a pedicled flap or a free flap.
- The reversed radial forearm flap can cover the volar and dorsal hand to near the tips of the fingers.
- The reversed radial forearm flap has arterial flow through the ulnar artery and palmar arches and back through the radial artery. The venous return is compromised due to valves in the vein, but occurs through interconnections in the vena comitans that bypass the valves.

**Advantages**
- Thin pliable tissue
- Reliable anatomy
- Fair color match
- Can be elevated under tourniquet control

**Disadvantages**
- Poor donor site
- Requires patent ulnar artery
- Reversed flap can often appear congested (but loss of flap is rare)

**Relevant anatomy**
- The brachial artery divides in the proximal forearm to form the radial and ulnar arteries. The ulnar artery is the dominant arterial blood supply to the hand in most people.
- The radial artery courses distally just deep to the interval between the brachioradialis (BR) and the flexor carpi radialis (FCR) muscles. In the proximal forearm, the superficial branch of the radial nerve is adjacent to the radial artery.
- The radial artery has paired venae comitantes that are important for venous egress from the flap once it is elevated.
- There is a loose tissue septum between the FCR and BR. Within this septum, there are perforating branches of the radial artery to the skin that provide blood supply to the overlying skin. These are meticulously preserved to perfuse the flap (**FIG 2**).

**Groin Flap**
- The groin flap is another workhorse pedicled flap for coverage of larger soft tissue avulsions of the hand.
- This fasciocutaneous flap is based on the superficial circumflex iliac artery (SCIA) and is located on the anterior thigh, just below the inguinal ligament.  
- It can be taken as a free flap, but more commonly is used as a pedicled flap and a two-stage operation.
- In the first stage, the flap is elevated laterally and inset onto the injured area. It is still attached medially to its pedicle coming off the femoral vessels.
- In the second stage (2 to 3 weeks later), the pedicle is divided, freeing the arm from its connection to the groin.

**Advantages**
- The flap is thin.
- It is nearly hairless, which may or may not be an advantage, depending on the recipient site.
- It is very reliable.
- Flap elevation is relatively quick.
- The donor site can be closed primarily with widths up to about 10 cm.

**Disadvantages**
- Mandatory two-stage operation
- The injured hand is connected to the patient’s groin for 2 to 3 weeks while waiting for vascular ingrowth.
- Poor color match
- Postoperative numbness in the lateral femoral cutaneous nerve is common.

**Relevant anatomy**
- The SCIA arises off the femoral artery about 3 cm inferior to the inguinal ligament and deep to the deep fascia of the thigh (**FIG 3**).
- SCIA travels superolaterally beneath the deep fascia.

**FIG 2** Cross-section showing the relevant forearm anatomy for a radial forearm flap. The septum lies between the brachioradialis and the flexor carpi radialis. The skin and subcutaneous tissue and fascia above the volar forearm musculature are elevated as a unit with the radial artery and septum with perforating vessels.

**FIG 3** Relevant groin flap anatomy. The superficial circumflex iliac artery (SCIA) arises from the femoral artery 3 cm distal to the inguinal ligament. It then travels laterally, anterior to the thigh musculature, parallel and inferior to the inguinal ligament.
As the SCIA crosses the sartorius, it supplies branches to the muscle.
About 6 cm from the femoral artery, the SCIA travels superficial to Scarpa’s fascia.

Kite Flap
- The kite flap, or first dorsal metacarpal artery flap, is a reliable flap taken from the dorsum of the index finger over the proximal phalanx.
- Its most common use is for reconstruction of palmar thumb defects. Both soft tissue coverage and sensibility can be provided if the dorsal branches of the radial nerve are moved with the flap.1
- It also can be used for web space reconstruction or covering smaller defects on the dorsum of the hand or wrist.
- The flap can be 2 x 4 cm in size.

Relevant anatomy
- The radial artery travels through the anatomic “snuff-box,” then onto the dorsum of the thumb, before diving between the two heads of the first dorsal interosseous muscle. This artery has three main branches:
  - The dorsal carpal arch
  - The princeps pollicis artery to the thumb
  - The first dorsal metacarpal artery

The first dorsal metacarpal artery extends dorsally out along the surface of the first dorsal interosseous muscle to the dorsum on the index finger (FIG 4).
- The venous drainage of the flap is from the dorsal venous system of the finger.
- The radial nerve provides sensation to the dorsum of the radial hand and fingers distally. These small branches can be preserved and brought with the flap, if desired.

Posterior Interosseous Flap
- The posterior interosseous flap, a fasciocutaneous flap, is a less-used flap on the dorsum of the forearm. This flap can be based proximally to cover the elbow or distally to cover the dorsum of the hand, or can be harvested as a free flap.
- The reversed flap, as used to cover the hand or wrist, relies on retrograde venous and arterial flow. The valves within the veins are bypassed by interconnections between the paired venae comitantes.
- The donor site on the dorsal forearm is more visible and subsequently less desirable than even the radial forearm flap.
- The flap is based on the perforating arteries coming from the posterior interosseous artery.
- The posterior interosseous artery travels on the posterior side of the interosseous membrane and arises from either a common interosseous artery or the ulnar artery.
- Septocutaneous perforators travel in the septum between the extensor digiti quinti (EDQ) and extensor carpi ulnaris (ECU) to the skin.
- The posterior interosseous artery connects with the anterior interosseous artery near the distal radioulnar joint (DRUJ), and also will get retrograde flow through the dorsal carpal arch. This site is the location of the distal pivot point of the flap.
- Proximally, the posterior interosseous artery enters the posterior compartment of the forearm at the junction of the proximal and middle thirds of the forearm (FIG 5).

Advantages
- Thin pliable tissue with good match to dorsal hand tissue
- Preservation of both the ulnar and radial arteries
- Can be closed primarily if flap width is less than 5 cm

FIG 4 • Anatomy of the dorsal metacarpal artery.

FIG 5 • The posterior interosseous flap is elevated with the posterior interosseous artery in a retrograde fashion. Perforating vessels are present within a septum that lies between the extensor digitorum quinti (EDQ) and extensor carpi ulnaris (ECU). The skin, subcutaneous tissue, fascia, and septum are all elevated with the artery.
- Disadvantages
  - Technically difficult dissection due to the proximity of the posterior interosseous nerve
  - The anatomy does not always allow safe dissection of the flap, and the surgeon should have a plan for an alternate flap if necessary.
  - Flap repair is contraindicated with wrist trauma due to disruption of the dorsal wrist vascular arcade.

**Z-Plasty**
- Although Z-plasty is not often used during immediate reconstruction, it is a useful adjunct for secondary reconstruction due to scar contracture.
- This method lengthens or redirects a scar by transposing two triangular flaps to bring normal tissue within a scarred area.
- A prerequisite is good tissue on either side of the area to be lengthened, because this tissue is interposed in the place of the original scar.

**NONOPERATIVE MANAGEMENT**
- As with all reconstructive procedures, if nonoperative management is possible, it should be considered and may be preferred.
- Small wounds often will heal secondarily with good results.
- Fingertip injuries that do not expose bone or tendon usually heal with good results and with good sensibility. These wounds should be débrided and cleaned, then dressed appropriately and allowed to heal over 2 to 3 weeks.
- Wounds on the distal forearm and hand often have exposure of tendon, bone, nerve, or vessel. Except in rare circumstances, these should all be covered with good tissue.
- Primary closure is the ideal, but with tissue loss this may not be possible.
- Skin grafts provide good coverage for muscle or clean wounds of the hand, but often do not offer the best coverage for future function of the hand.
- A skin graft will heal on bone or tendon if the periosseous paratenon is intact, but this may create a thin, unstable wound. Skin grafting over tendons is prone to scarring and may decrease tendon excursion.
- Skin grafts will heal over nerves or vessels, but can result in hypersensitivity with nerves or thin coverage over vessels increasing the chance of bleeding.
- In many cases, early flap closure with a good gliding surface (for tendon movement) may be better than delayed healing with increased scar tissue.

**SURGICAL MANAGEMENT**
- The wound should be débrided back to viable tissue before it is covered.
- If there is gross contamination, débridement often can be done in several stages to obtain a clean wound.
- The wound depth and size must be taken into consideration.

**Preoperative Planning**
- If there is tendon or bone involvement of the injury site, the selected reconstruction should consider these factors.
- The affected area should be well perfused when the patient is brought to the operating room for flap coverage.
- Only rarely should flaps be performed on an emergent basis in an unhealthy patient.
- Flap coverage should be performed over a stable skeleton, and devitalized or contaminated tissue should not be covered.

**Positioning**
- The arm usually is placed on an armboard at a 90-degree angle. The operating table is positioned to allow the surgeon and the assistant to sit on either side of the arm.
- This positioning gives excellent access to the palmar and dorsal forearm, arm, and hand.
- If a skin graft is considered, the ipsilateral groin or thigh is prepaped to allow for full- or split-thickness grafting, respectively.
- Small full-thickness grafts can be obtained from the antecubital fossa, the ulnar forearm, or the ulnar side of the palm (for thick glabrous skin).

**Approach**
- For all procedures, a padded tourniquet is used on the patient’s arm and inflated for the duration of the débridement of the wound and for flap elevation.
- At the end of the flap elevation, the tourniquet is released and bleeding controlled with bipolar electrocautery.
- Easily visible vessels are divided with clips or ties while the tourniquet is inflated.
- The wound site is always well débrided back to good tissue. Any foreign material is removed, and the wound irrigated with saline. Pulse lavage irrigation is used for heavily contaminated wounds.
- Careful handling of the tissue is imperative. Avoid handling the skin edges with pickups because the corners of flaps are particularly susceptible to trauma. Use retention sutures and skin hooks as much as possible.

**RADIAL FOREARM FLAP**
- A template of the defect is made (TECH FIG 1A).
- The position of the radial artery is established using Doppler ultrasound and marked on the forearm (TECH FIG 1B).
- The template is placed over the radial artery on the volar forearm and marked in place.
  - If a reversed flap is to be used for hand coverage, it usually is obtained from the proximal forearm.
  - If antegrade flap is to be used, it is obtained from the distal forearm.
  - The proximally based flap can pivot at the bifurcation of the radial and ulnar arteries. The distally based flap will pivot at the level of the radial styloid.

- An incision is made distal to the flap to identify the radial artery.
- Then, starting on the ulnar aspect, the skin and subsequently the forearm fascia are incised.
- The flap is elevated deep to the forearm fascia.
- Care must be taken when approaching the radial artery not to cross and divide the septum between the FCR and BR (see Fig 2).
- The perforating vessels that perfuse the skin paddle lie within this septum.
- Once the radial artery is identified along the course of the flap on the ulnar aspect, the radial aspect of the flap is elevated in a similar fashion.
The radial artery exposure is facilitated by lateral opposing traction on FCR and BR, which can be provided by a self-retaining retractor. The radial artery is then divided proximally (or distally) and the flap elevated (TECH FIG 1C). It is imperative that the venae comitantes be preserved with the flap during the dissection and elevation of the radial artery. These will provide venous outflow for the flap. Once flap elevation is complete, the flap is inset in the defect, and the donor defect covered with a skin graft (TECH FIG 1D).

A template of the defect is made (TECH FIG 2A). The inguinal ligament is marked from the anterior superior iliac spine to the pubic tubercle (see Fig 3). The origin of the SCIA is about 3 cm below the inguinal ligament, and off the femoral artery. A second line is drawn parallel to the first, 3 cm inferior to it, indicating the SCIA. The flap can be as large as needed up to the following guidelines—any larger and the donor site may not close primarily. The flap margins are marked as follows:

As the flap is elevated over the tendons of the FCR and palmaris longus, the paratenon must be preserved, because this will provide the vascular bed for the skin graft that will cover the donor site.

A second line is drawn parallel to the first, 3 cm inferior to it, indicating the SCIA. The flap can be as large as needed up to the following guidelines—any larger and the donor site may not close primarily. The flap margins are marked as follows:

GROIN FLAP

- A template of the defect is made (TECH FIG 2A).
- The inguinal ligament is marked from the anterior superior iliac spine to the pubic tubercle (see Fig 3).
- The origin of the SCIA is about 3 cm below the inguinal ligament, and off the femoral artery.

TECH FIG 2 • A. This patient had a traumatic amputation of his thumb, leaving reasonable bony length, but no soft tissue coverage. B. The groin flap is elevated from lateral to medial. Lateral to the sartorius, the superficial fascia is elevated with the flap. At the lateral border of the sartorius, the deep fascia is elevated, and the perforating branches are ligated. Elevation stops at the medial border. (continued)
TECH FIG 2 • (continued) C. After elevation and inset of the flap, the thumb is well covered. D. After 3 weeks, the flap had matured well in place. The pedicle is divided in the operating room. E. Three months after pedicle division, the flap is doing well. The preserved length of the thumb allows for a good post for opposition. The bulk of the flap can be reduced operatively over time.

- Superior margin: 2 to 3 cm above the inguinal ligament
- Inferior margin: 7 to 8 cm below the inguinal ligament
- Lateral margin: 8 to 10 cm lateral to the anterior superior iliac spine
  - The flap is then elevated from lateral to medial (TECH FIG 2B).
  - The skin is incised laterally, and the flap elevated at the level below the superficial fascia (Scarpa’s fascia).
  - When the lateral border of the sartorius is encountered, the dissection proceeds beneath the deep fascia, just on top of the muscle fascia.
  - The penetrating branches to the sartorius are ligated and divided.
- When the medial border of the sartorius is encountered, the dissection stops (for the pedicled flap).
- The donor site is then closed over a drain. Near the origin of the flap, care is taken not to strangulate the flap with the closure.
- The proximal portion of the flap is then tubed if possible; however, there cannot be any tension on the tube.
- The flap is then inset on the hand, usually over a Penrose drain (TECH FIG 2C).
- The flap may then be divided 2 to 3 weeks later (TECH FIG 2D,E). Perfusion of the flap can be tested before division by temporarily occluding the pedicle with a circumferential Penrose drain and assessing flap perfusion.

KITE FLAP: FIRST DORSAL METACARPAL ARTERY FLAP\(^1,11\)

- A template of the defect is made (TECH FIG 3A).
- The template is transferred to the dorsum of the index finger overlying the proximal phalanx, on the radial aspect.
- The flap is marked, then a proximal incision is marked in a zigzag or curvilinear fashion to extend to the takeoff of the first dorsal metacarpal artery (TECH FIG 3B).
- The flap is incised along the sides and distally down to the level of the extensor apparatus. Care is taken to preserve the paratenon of the extensors.
- The first dorsal interosseous artery will be elevated, with the subcutaneous tissue lying above it. The skin above the artery is left in its original location.

TECH FIG 3 • A. This wound of the volar thumb has exposed tendon and will not heal without a vascularized skin flap. B. The flap is planned on the dorsoradial aspect of the index finger. The proximal incision is for pedicle dissection. (continued)
The skin incision is made proximal to the flap. The incision around the proximal border of the flap needs to remain shallow, at the subdermal level as the venous drainage is through the small veins in the subcutaneous tissue.

The skin proximal to the flap is elevated on the radial and ulnar side of the artery. The skin is elevated off the fat at the subdermal level.

The pedicle should be elevated, with a total width of about 1 cm. On the ulnar side the pedicle border is the middle of the metacarpal. On the radial side, the pedicle border is 5 to 10 mm radial to the artery.

The artery lies on top of the fascia of the first dorsal interosseous muscle. To help preserve the artery and subcutaneous tissue, the muscle fascia is elevated with the pedicle.

Once the dissection of the pedicle has reached the radial artery proper, as it dives palmar to the deep palmar arch, the elevation typically ends.

This should allow enough pedicle length for coverage of many volar thumb defects and some dorsal hand defects.

The operation is performed under tourniquet control, but without Esmarch exsanguination, to maintain visibility of the small vessels.

The wound is débrided and irrigated, and then a template is made. A line is drawn from the lateral epicondyle to the DRUJ. The line approximates the position of the posterior interosseous artery (TECH FIG 4B, C).

The template is placed over the line marking the pedicle. It can be placed proximally as close as 6 cm from the lateral epicondyle of the humerus.

An incision is made along the flap outline proximal to the pivot point. Dissection is carried between the EDQ and ECU to look for the posterior interosseous artery (see Fig 4).

If the artery is found at this location, it is generally consistent with favorable anatomy. If the artery is not satisfactory, the operation is aborted.

Once the artery has been determined to be acceptable, the radial incision is made. The skin flap is elevated below the level of the muscular fascia. The EDC, extensor indicis proprius, and EDQ muscles are all retracted radially to facilitate exposure of the septum.

The muscular branches of the posterior interosseous artery (PIA) are carefully divided, exposing the PIA along the septum.

Once one good septocutaneous perforator is located, the PIA is divided proximal to this branch. Further dissection to obtain more perforators is discouraged because of the proximity to the posterior interosseous nerve and potential damage to this nerve.

After locating the major perforator and dividing the PIA proximally, the ulnar incision around the flap is made. This side is also elevated at a subfascial level.

The flap is then elevated from proximal to distal. This dissection is facilitated with ulnar retraction of the ECU. A generous cuff of surrounding tissue is taken with the PIA to help preserve its vena comitans.

A superficial vein may be preserved in the elevation for distal reanastomosis to help with venous drainage.
SOFT TISSUE LOSS, THERMAL INJURIES, AND CONTRACTURES

Z-PLASTY

- The angle of the flaps in Z-plasty is most commonly 60 degrees (TECH FIG 5A), but it can be varied to give more or less lengthening, depending on the quality of the adjacent tissue. Theoretically, 60-degree flaps will provide a lengthening of 75%.
- The central incision is designed along the tight scar. This scar often is excised during this part of the procedure (TECH FIG 5B).
- The two limbs are designed at opposing ends of the scar on opposite sides of the central member. These limbs are placed at about 60 degrees from the central incision (TECH FIG 5C).
- The flaps created are then elevated at a subcutaneous level. Then the two triangular flaps are transposed and sutured into place.
- Once the two flaps are elevated, they often “fall” into the correct position and are easily sutured in place.
- This usually gives an obvious and considerable lengthening immediately after flap transposition and insetting (TECH FIG 5D).

(continued)

TECH FIG 4 • A. This traumatic wound has exposure of the extensor tendons. B,C. The posterior interosseous flap is located proximally over the posterior interosseous artery. The flap is centered over a line from the lateral epicondyle to the distal radioulnar joint (DRUJ). D. After elevation, the flap is inset on the wound. E. The wound is well healed.
PEARLS AND PITFALLS

**Indications**
- A thorough physical examination must be completed before reconstruction of any defect.
- The choice of reconstruction is guided by the reconstructive ladder. Less invasive operations should be considered before more invasive procedures, but, ultimately, the expected outcome of the type of operation will direct the choice.
- Before any wound is covered, it must be clean, with no foreign material or dead tissue. Delaying reconstruction a few days until these goals are met is worthwhile.

**Flap elevation**
- Flap elevation must be done with care and precision, with attention to preservation of the feeding blood vessels. The small vessels perfusing the flaps are vital to flap survival.
- Frequent use of Doppler ultrasound facilitates vessel identification.

**Radial forearm flap**
- The dissection is safest when the fascia is elevated first from the ulnar side. The septum rises obliquely under the BR.
- Preservation of the paired venae comitantes and the septal perforators is critical to survival of the flap.
- The reversed flap needs a patent palmar vascular arch.

**Groin flap**
- The patient must be prepared to have the hand connected to the groin and must understand that a second operation is mandatory.
- This flap and the radial forearm flap are the workhorse flaps for large soft tissue flaps of the hand.

**First dorsal metacarpal artery flap**
- Reliable coverage for volar thumb or small dorsal hand defects
- Sensation can also be preserved with this flap through branches of the superficial radial nerve.
- The dissection is somewhat complex due to the small caliber of the vessels.

**Posterior interosseous flap**
- This flap is not typically a first choice.
- It is used when there is not a patent palmar arch (i.e., when a radial forearm flap is contraindicated) and when there is a reason not to use a groin flap.

POSTOPERATIVE CARE
- The postoperative care largely depends on the flap that has been used.
- For all of the operations, some of the same principles are followed.
  - Postoperative antibiotics often are indicated, because the wounds have been open for some time, have been contaminated, or have associated open fractures. The choice of antibiotic is individualized for each patient.
  - The operative site usually is splinted to allow for healing of the flap without movement. If there is no bony injury, this is usually for 7 to 10 days, but the length of time may vary.
  - The arm should be elevated above the level of the heart as much as possible. This will help decrease both edema within the flap and patient discomfort.
  - The radial forearm flap should be monitored in the hospital for 2 or 3 days.
  - When distally based, this flap may be susceptible to venous congestion.
  - Care should be taken during the operation to meticulously preserve the vena comitans.
  - If the cephalic vein has been preserved with the flap, it can be anastomosed to a vein in the field of the flap, but this is rarely necessary with the reversed flap.
  - Care should be taken not to make the splint or dressing too tight.
  - If a skin graft is placed during the operation, the bolster dressing is removed at 5 to 7 days, and the skin graft is dressed daily with petrolatum-infused gauze or a nonadhering dressing until fully healed.
  - Sutures around the flap are removed at 10 to 14 days.
  - Early active motion of the fingers is encouraged to promote tendon gliding and lessen edema, unless contraindicated after coverage.
  - Hand therapy is initiated in most patients at 1 to 2 weeks following surgery.
COMPLICATIONS

- Short-term complications include those related to flap survival and healing of the wound.
- Long-term complications result from undesirable scarring relating to both the primary injury and the method of closure.
- Complete flap loss due to flap ischemia is uncommon. More often, a small area of the flap margin may not heal to the native skin margin, due to inadequate débridement of the skin edges or rough handling of the flap skin.
- As the flaps heal, the function of the hand depends on subsequent scarring, which, if it occurs, leads to poor tendon gliding. Persistent tendon scarring requires later tenolysis. After 3 months, loss of the flap by inadvertent pedicle division is rare, but late flap loss has been reported.
- If scarring from the flap margin creates a contracture across a joint, a Z-plasty may be necessary.
- Overall, the complications related to flap closure are less than complications related to secondary healing. The long-term outcome will be better with flap coverage compared to secondary healing, because secondary intention creates an abundance of scar tissue, which can impair function of the hand.

REFERENCES

DEFINITION
- Burns and electrical injuries of the hand and forearm can present as both acute and long-term surgical problems.
- High-voltage electrical injury is defined as involving a power source with a voltage greater than 600 volts.
- Electrical burns constitute a unique type of injury, because “hidden” local and regional deep tissue damage exists beyond the confines of the cutaneous burn.
- Acutely, circumferential or near-circumferential full-thickness burns of the extremity may require escharotomy, in which the unyielding burned tissue is released to reduce soft tissue tension.
- Compartment syndrome is a serious sequela that warrants immediate surgical attention.
- Contractures are common in burn patients, resulting from loss of normal skin pliability when the skin is replaced by scar tissue after second- and third-degree burns.
- Despite aggressive acute care, splinting, and therapy, long-term hand and wrist deformities are common.6

ANATOMY
- Compartments are anatomic spaces enveloped by fascia, bones, and interosseous membrane.
- The forearm is divided into three compartments: volar, dorsal, and the mobile wad (FIG 1A).
- The hand has compartments housing four dorsal interosseous muscles, three volar interosseous muscles, thenar muscle, and hypothenar muscle (FIG 1B).
- Postburn scarring and contracture tend to produce the “classic” clawing deformity with flexed wrist and proximal interphalangeal (PIP) joints, extended distal interphalangeal (DIP) and metacarpophalangeal (MCP) joints, and adducted web spaces1 (FIG 1C,D).

PATHOGENESIS

Electrical Burns
- Electrical shock produces a complex pattern of injury in which the severity of injury depends on the intensity of the current and the duration of contact.
- Tissue damage occurs predominantly by two mechanisms: thermal injury and electroporation.7
- As an electrical current travels, heat is generated along its path, leading to thermal damage.
- Tissues with high electrical resistance, such as the skin and bone, generate more heat, causing more damage to both themselves and the surrounding tissues.
- Electroporation is cellular damage induced by the electric field. The severity of injury is determined by the cell’s size and its transmembrane potential.
- Cells with larger surface area, such as myocytes, are more prone to electroporation injury.
- In addition, it has been suggested that due to the architecture and orientation, myocytes near a bone may experience increased transmembrane potential compared to those further from the bone.
- Secondary to these mechanisms, patients with high-voltage electric burns often sustain extensive deep tissue and muscle injuries that predispose the patient to developing acute compartment syndrome.
Compartment Syndrome
- Arteriovenous gradient theory is commonly accepted as describing the relation between increasing soft tissue pressure and decreasing arterial inflow.
- In burns, vascular permeability leads to swelling of the soft tissues and, in particular, the muscles.
- The inelastic fascia housing each compartment does not allow the edematous muscles to expand. The increased pressure within the compartments eventually interrupts arterial inflow to the muscles.
- Although compartment syndrome most often is discussed in relation to fascial compartments, it can occur in full- or near–full-thickness burns because the inelastic skin limits the ability of underlying soft tissue to expand.
- The inelastic skin in a circumferential burn acts as a tourniquet, compromising venous return and capillary perfusion, and leading to tissue ischemia distal to the burns.8

Burn Contractures
- Increased and disorganized deposition of collagen fibers has been observed in burn wounds, forming compact and shortened scars.6
- The amount and severity of hypertrophic scarring and contracture is directly related to the depth of the burn and the time required for wound healing.
- Inflammation, pain, and edema from burn injuries promote immobility (in the position of comfort) and cause wound contracture.1
- Immobility and abnormal scarring lead to rapid formation of contractures in the pattern described under Anatomy.

NATURAL HISTORY
Evolution of Compartment Syndrome
- Acute burn management for large body surface area burns requires aggressive fluid resuscitation. Massive edema is seen within 36 hours of injury.
- Intracompartmental pressure can, in turn, elevate rapidly in the early postburn period.
- Classic studies have shown that myonecrosis occurs after 6 hours of ischemia. Once tissue is ischemic for longer than 8 to 12 hours, irreversible functional damage occurs.5,8
- Prompt fasciotomy minimizes functional loss and promotes recovery.
- If compartment syndrome is left untreated, the result is Volkmann’s ischemic contracture, a late sequela in which muscles and nerves die and are replaced by fibrous tissue.12

Natural Progression of Burn Injury
- Proper management of burn injuries includes early excision and grafting, followed by appropriate therapy programs.
- Even with splinting, range-of-motion exercises, compression, and positioning, 80% of patients will have decreased joint motion, and up to 10% will have difficulties with activities of daily living.3

PATIENT HISTORY AND PHYSICAL EXAMINATION
Acute Burn Injuries
- In addition to routine medical history, it is imperative to obtain the mechanism of the burn injury.
- High-voltage electrical burns, burns that occurred in an enclosed space, or burns associated with explosions require trauma and critical care consultation to evaluate for other life-threatening injuries.
- Thermal and electrical burns are evaluated for depth.
- First-degree burns involve only the epidermis and appear as a painful, erythematous plaque that blanches with pressure.
- Second-degree burns involve the epidermis as well as partial thickness of the dermis. Second-degree burns invariably are associated with blistering of the skin that evolve into moist, weepy, and painful wounds after sloughing of the epidermis.
Third-degree burns involve the entire thickness of the skin and are characterized by charred, painless, leathery skin with visible coagulated vessels.

**Acute Compartment Syndrome**
- Clinically, elevated soft tissue pressure presents with severe edema and tightness of the hand, wrist, and forearm distal to the burn.
- Treatment for fascial compartment syndrome of the forearm and hand should be initiated based on clinical suspicion.
- Compartment syndrome can present with a constellation of symptoms:
  - Pain with passive muscle stretch
  - Progressive pain despite immobilization
  - Nerve ischemia symptoms such as diminished sensation and muscle weakness
  - Compartments tender and firm to palpation
- Compartment and soft tissue pressures can be measured using a pressure transducer (FIG 2).
  - A simple device for measuring pressure can be made with an 18- or 20-gauge needle attached to a syringe containing saline and a pressure transducer, all connected via a three-way stopcock.
  - The transducer is set to zero at the level of the soft tissue or compartment to be measured.
  - After the needle is inserted into the subcutaneous tissue, a small amount (0.2–0.5 mL) of saline is injected to establish a water column.
  - The transducer is then opened to the needle for pressure monitoring.
- Compartment and soft tissue pressures can also be measured using a commercially available device.
- The recommended threshold for performing fasciotomy is pressure higher than 30 mm Hg for normotensive patients.
  - In patients with hypotension, when the compartment pressure rises to within 20 mm Hg of the diastolic pressure, fasciotomy is indicated.9

**Secondary Burn Reconstruction and Contracture Release**
- Preoperative examination for patients undergoing secondary burn reconstruction should include a complete hand examination, focusing on range of motion of the affected joints.
- Substantial limitation of active and passive joint motion in the PIP and MCP indicates contracture of underlying joint tissues.3,11
- Examination should also focus on the scar and skin quality, because immature scars may still be amenable to nonoperative management.
- Poor or unstable skin coverage may limit local tissue rearrangement options and necessitate coverage with a distant flap.

**Physical Examination**
- Vascular examination includes checking pulse and capillary refill.
  - Pulse is graded as normal, diminished, or absent compared to the contralateral side.
  - Capillary refill is graded as delayed, normal (2–3 second), or quickened.
    - Absent or diminished pulse is a late finding in compartment syndrome.
    - Quickened capillary refill is suggestive of venous congestion.
    - Delayed capillary refill may suggest increased soft tissue or compartment pressure.
- The neurologic examination includes light touch, two-point discrimination, and motor function testing.
  - Sensibility to light touch is graded as normal, diminished, significantly diminished, and absent.
  - Two-point discrimination is graded as normal (< 6 mm static, < 3 mm moving), and abnormal.
  - Motor examination is graded from 0 to 5, with 0 being absent, and 5 normal.
  - Altered neurologic finding compared to the contralateral limb is an indication of increased compartment pressure.
- A passive stretch test should be performed.
  - Pain with passive stretch is an abnormal finding.
  - A positive passive stretch test is indicative of muscle ischemia and injury.
- Measure subeschar and compartment pressure. Elevated pressure is confirmed if the measured pressure is greater than 30 mm Hg or within 20 mm Hg of the diastolic pressure. Persistently or worsening elevated pressure is an indication for escharotomy or fasciotomy.
- Examine MCP range of motion:
  - Type I: mild limitation in MCP flexion with wrist flexion, more than 30 degrees of flexion with wrist in extension
  - Type II: severe limitation in MCP flexion with wrist in flexion, less than 30 degrees of flexion with wrist in extension
  - Type III: severe limitation in MCP flexion with wrist in extension
  - Type II and III contractures signify underlying joint and ligamentous pathology that cannot be corrected with soft tissue release alone.
- Examine PIP range of motion:
  - Type I: near-normal PIP extension with MCP in flexion
  - Type II: moderately limited PIP extension with MCP in flexion
  - Type III: fixed PIP flexion regardless of MCP position
  - Type II and III contractures signify underlying joint and ligamentous pathology that cannot be corrected with soft tissue release.

**FIG 2** Pressure transducer adapted for measurement of compartment pressure.
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Currently, no available imaging modality can detect acute increases in compartment pressure.
- For secondary reconstruction of the contracted hand and fingers, plain radiographs should be obtained to evaluate the condition of the joint and determine whether heterotrophic ossification is present, because that requires alternative treatment options.

DIFFERENTIAL DIAGNOSIS
- The differential diagnosis for compartment syndrome includes:
  - Nerve injury
  - Arterial insufficiency or injury
  - Venous thrombosis
- Burn contractures should be differentiated from:
  - Intrinsic joint disease
  - Other scarring or contracture phenomena (eg, Dupuytren disease)

NONOPERATIVE MANAGEMENT
- Early in the healing process (usually within 6 months of injury), immature scars are hyperemic in appearance and amenable to conservative measures.
- Conservative management includes the use of pressure garments, silicone dressing, and physical therapy.
- Pressure garments and silicone have been shown to control hypertrophic scars and must be worn for several months. \(^6\)
- Therapy should focus on aggressive range-of-motion exercises and splinting in an antideforming posture (FIG 3).

SURGICAL MANAGEMENT
- Burn débridement, escharotomy, fasciotomy, local tissue rearrangement for linear and web space contracture, and pedicled groin flap coverage for soft tissue defects are discussed in the Techniques section.

Indications for Surgical Management of Acute Burns and Acute Compartment Syndrome
- High-voltage injury is an indication for immediate fasciotomy and burn débridement because it is difficult to assess the extent of deep thermal damage.
- Patients with thermal burns and low-voltage electric injury require closed monitoring by experienced personnel to assess potential increased soft tissue or compartment pressure, but may otherwise be débrided in 48 to 72 hours to allow for demarcation of burned areas.
- Elevated soft tissue pressure and fascial compartment pressure are indications for emergent surgical intervention.
- Despite the potential utility of pressure monitors, diagnosis of the pathology still relies on clinical judgment.
- If there is any doubt regarding the diagnosis, escharotomy and fasciotomy should be undertaken expeditiously.
- Fascial compartment syndrome may be masked by elevated pressure of the overlying soft tissue, and it is of the utmost importance to check muscle compartment pressures after an escharotomy.
- If elevated compartment pressure is not relieved by escharotomy of the overlying burned tissue, a full fasciotomy is necessary.
- After escharotomy or fasciotomy, patients must be observed closely for signs and symptoms of inadequate release, which will require urgent reoperation.

Considerations in Contracture Release and Secondary Burn Reconstruction
- Burn injuries cause soft tissue contracture and result in tissue deficiency. The secondary effects of soft tissue contracture are joint and tendon changes that also require release.
- Mild volar and dorsal linear scar bands, as well as web space contractures, can be corrected with scar release and local tissue rearrangement.
- Basic Z-plasty is a technique of local tissue rearrangement in which two equal triangular skin flaps are transposed (FIG 4A). Z-plasty is ideally suited for linear scar release because it lengthens and interrupts a scar, and also redirects the line of tension.
- The theoretical gain in length is proportional to the angle of the Z-plasty. A larger angle provides more lengthening but is more difficult to transpose (Table 1).
- However, an adequately sized Z-plasty flap often is difficult to fit into a contracted web space.
- For web space contracture release we prefer a five-flap “jumping man” Z-plasty, which is a combination of two Z-plasty flaps with a Y-to-V advancement flap (FIG 4B).

![FIG 3](image-url) Immature burn scars that are amenable to conservative treatment. A volar intrinsic-plus splint with the thumb in palmar abduction to prevent debilitating postburn contractures.

![FIG 4](image-url) A. Basic Z-plasty flaps and their theoretical gain in length. B. Five-flap jumping man Z-plasty, which is made up of two opposing Z-plasty flaps and a Y-to-V flap.
Compared to a basic Z-plasty, the additional flaps maximize gain in length. In addition, the Y-to-V flap introduces unscarred skin into the reconstruction, providing more pliability and elasticity to the reconstructed web space.

Even without scar resection, surgical release of burn scars often result in a large soft tissue defect due to tissue deficiency.

Thick split- or full-thickness skin grafts can be used to resurface the soft tissue defect.

Flap coverage may be necessary if contracture release or scar excision leads to exposure of joint structures, tendons, or neurovascular bundles.

Preoperative Planning

- If hand and forearm burns are part of a larger insult, the ABCs (airway, breathing, and circulation) of trauma resuscitation and patient stabilization cannot be overlooked.
- Burn débridements may incur a significant amount of blood loss, and blood products should be made available intra- and perioperatively.
- For secondary burn reconstruction, one must appreciate the structure involved in the deformity.
- If tightness of the deep tissue is present, capsulotomy and ligamentous release should be addressed simultaneously.

### Positioning

- Supine positioning with the affected arm extended on an arm table is adequate for most described procedures.
- For secondary reconstruction, an upper arm tourniquet is used.
- The ipsilateral upper thigh and lower abdominal quadrant is prepped and draped if a groin flap is planned for soft tissue coverage.

**ESCHAROTOMY FOR FULL OR DEEP PARTIAL-THICKNESS BURNS**

- Escharotomy can be performed at the bedside using electrocautery with the patient under sedation.
- A full-thickness skin incision is made the length of the full-thickness burn on the radial aspect of the forearm, along the line connecting the lateral end of the antecubital flexion crease and radial styloid (TECH FIG 1).
- The incision is deepened until viable tissue is encountered. The length of the incision spans the entire burn, from normal skin to normal skin.
- If the hand and the forearm are still tight after a radial release, a second escharotomy incision can be made along a line just volar to the ulna, spanning the entire burn (see Tech Fig 1).
- To perform escharotomy of the hand, one can extend the radial incision onto the hand with the radial incision at the midaxial line over the thenar eminence. The radial sensory nerve will lie along this incision and must be protected.
- The ulnar incision can be carried onto the hypothenar eminence as needed.

- Circumferential finger burns are treated with a digital escharotomy. A midlateral incision down into subcutaneous fat is made along one side of the finger, from the MCP joint to the fingertip.
- If the compartment pressure is still high after escharotomy, fasciotomy should be carried out as described in the following section.
- Escharotomy wounds are dressed with a moist dressing.

**Intrinsic Compartment Release**

- Two dorsal incisions centered over the index and ring metacarpals are used to release the interosseous muscle and the thumb adductor muscle compartments (TECH FIG 2A).
- Incisions are carried down ulnar and radial to the index and ring extensors. Dissection is continued until the fascia of the dorsal interosseous muscles is encountered. The fascia is opened sharply.

- Blunt dissection is performed along the ulnar and radial side of the index finger metacarpal to open the first volar interosseous and adductor pollicis muscles.
- The second volar interosseous muscle is opened with deep blunt dissection along the radial border of the ring finger metacarpal.
- Finally, through the ring finger metacarpal incision, deep blunt dissection along the radial border of the small finger metacarpal releases the third volar interosseous muscle.
Thenar muscles are released through an incision on the radial border of the thumb metacarpal between the volar glabrous and dorsal pliable skin. The dissection is volar to the metacarpal to expose the fascia of the thenar muscles, which is sharply opened.

The hypothenar muscles are released similarly with an incision on the ulnar aspect of the small finger metacarpal (TECH FIG 2B).

Carpal Tunnel Release
- The carpal tunnel is released through a standard incision over the palm, along the ring metacarpal.
- Incision begins at the Kaplan’s cardinal line (the line connecting the apex of the first web space to the hook of the hamate), and extends 2 to 3 cm proximally (TECH FIG 3).
- We prefer to avoid an incision across the wrist joint, to protect the median nerve from exposure.
- The palmar fascia is divided sharply to expose the transverse carpal ligament.
- The transverse carpal ligament is divided under direct visualization.

Forearm Fasciotomy
- We prefer to perform fasciotomy of all three forearm compartments at the same time to avoid lingering doubts regarding inadequate release. Two incisions are used (TECH FIG 4A).

A straight-line incision is made over the first third of the ulnar aspect of the volar forearm, beginning just proximal to the wrist crease and extending to just distal to the ulnar aspect of the elbow flexion crease (TECH FIG 4B).
- The incision is carried down through the fascia, into the volar compartment. The fascia is opened along the length of the compartment.
- The superficial and deep muscles are examined.
The mobile wad and dorsal compartment release is accomplished by placing a middorsal straight line incision beginning 3 to 4 cm proximal to the wrist crease and extending to the radial aspect of the flexion crease at the elbow (TECH FIG 4C).

The compartmental fascia for both compartments are incised over their entire length and the muscles are examined.

After release, the muscles should bulge out over the incision.

The muscles are not débrided until a second-look procedure at 48 hours, because some muscles with questionable viability may recover after fascial release.

The open wounds are packed with moist dressing until the second-look procedure.

**Burn Débridement**

Burn débridement is performed without a tourniquet and can be carried out with escharotomy or fasciotomy.

Sharp débridement is used to removed partial- and full-thickness burns.

- For small areas or areas with irregular contour, a no. 15 or no. 10 blade is used to remove burnt tissue, layer by layer, until bleeding tissue is encountered.
- For larger areas, a Weck blade with a no. 8 or no. 10 guard is used to tangentially remove burn tissue until punctate bleeding is encountered.

- For uncomplicated thermal burns, immediate coverage can be accomplished.
- For uncomplicated wounds, a .012-inch split-thickness skin graft can be placed. We typically use unmeshed graft for the hand and over the wrist joint. Forearm burns can be covered with a graft meshed 1 to 1½ expansion.
- For deeper wounds with small areas of exposed deep structures (eg, tendons or joints), a dermal substitute such as Integra is used to provide a revascularized dermal foundation. Delayed split-thickness skin grafting is done in 2 weeks.
- Large burn wounds with exposed deep structures or exposed neurovascular bundles are temporarily covered with moist dressing changes, and will require local flap, distant flap, or free tissue coverage within 48 to 72 hours.
- Electrical burns often have injuries to subcutaneous tissues and muscles in addition to cutaneous burns. After débridement of the cutaneous portion of the burns, as described in Burn Débridement, the subcutaneous tissue and muscles are sharply débrided with a no. 10 blade in a layered manner until bleeding tissue is encountered.
- Patients with electrical burns are managed with moist dressing changes and taken back to the operating room for a second look procedure in 48 hours.

**SECOND-LOOK PROCEDURE**

- The second-look procedure is performed without the use of a tourniquet.
- Necrotic tissues are aggressively débrided with a no. 10 blade in a tangential manner until bleeding tissue is encountered.
- Electrical burns may require multiple débridements every 48 hours until the area of injury is demarcated and all necrotic tissues are removed.
- Large wounds with exposed deep structures or exposed neurovascular structures are temporarily covered with...
moist dressing changes and will require local flap, distant flap, or free tissue transfer coverage within 48 to 72 hours.

- For uncomplicated fasciotomy wounds, once adequate débridement has been achieved, moist dressing changes are performed for 7 to 14 days in preparation for primary closure or skin grafting.

- With increasing frequency, a negative-pressure dressing is being used for fasciotomy defects as an alternative to traditional wound care.
- Edema often subsides and allows for primary wound closure (TECH FIG 5).
- Open defects are covered with a .012-inch split-thickness skin graft.

**Basic Z-Plasty**

- One or multiple Z-plasty flaps are used to break up mild to moderate linear contractures.
- The central limb of the Z is planned along the axis of the scar band, and the angle of the Z-plasty can be varied, with a larger angle providing more release. We prefer 45-degree flaps (TECH FIG 6A).
- The Z-plasty flaps are elevated just below the dermis, preserving a small cuff of subcutaneous fat on the underside of the flaps.
- Foreshortened fibrous bands that require release with scissors or a knife often are present in the underlying soft tissue.
- Care is taken to protect the neurovascular bundle.
- After release of underlying tissue and extension of the joint, the Z-plasty flaps should fall naturally into a transposed position.
- The flaps are sutured in place with nonabsorbable sutures (TECH FIG 6B).

**LOCAL TISSUE REARRANGEMENT FOR RELEASE OF CONTRACTURE BANDS**

**Five-Flap Z-Plasty for Release of Web Space Contractures**

- Xeroform (Covidien, Mansfield, MA) strips and bacitracin are applied to the incision, followed by a gauze dressing. A gentle elastic bandage is applied.
- The bandage is removed in 2 days, and patients are allowed progressive gentle range of motion. Stretching and scar massage are encouraged to begin 2 to 3 weeks postoperatively.

- The central limb of the five-flap Z-plasty is designed to lie on the axis of the web space contracture.
- The Z-plasty is oriented with the Y-to-V flap occupying normal skin, to maximize advancement of unburned skin into scar tissue (TECH FIG 7).
- Skin incisions are made in the central limb as well as the Y-to-V flap. The lateral limbs of the Z-plasty flaps are not incised initially.
- The Y-to-V flaps and the skin around the central limb are elevated just below the dermal fat junction.
Chapter 107  SURGICAL TREATMENT OF THERMAL AND ELECTRICAL INJURY, AND CONTRACTURE

The underlying fibrous tissues are released using a combination of blunt and sharp dissection.

At this point, the Y-to-V flap is advanced into place.

More advancement can be achieved by lengthening the Y-to-V limbs and enlarging the flap. The central limb is lengthened accordingly. Flap size is limited by the size of the web space.

The lateral limbs of the Z-plasty flaps are now incised corresponding to the length of the enlarged Y-to-V flap (now a V-flap).

The flaps are then secured in their transposed position with nonabsorbable sutures.

Xeroform and bacitracin are applied, followed by gauze dressing and a gentle elastic bandage.

The bandage is removed in 2 days, and the patient is allowed progressive gentle range of motion. Stretching and scar massage are encouraged to begin 2 to 3 weeks postoperatively.

Groin Flap for Extensive Burn Contracture

Scar Excision

An incision is made around the contracted scar into the subcutaneous fat and underlying structures. Often, the scar is adherent to underlying fascia, tendons, and joints.

Traction is applied to assist in identifying the areolar plane between scar and normal tissue.

The scar is lifted in its entirety. Tight underlying fibrous bands are broken up with blunt and sharp dissection.

After complete excision of the scar, the affected joints are put under stretched to evaluate the need for capsulotomy or ligamentous release.

Flap Harvest

Attention is then paid to harvest of the ipsilateral groin flap.

Doppler ultrasound is used to identify the superficial circumflex iliac artery.

At the ipsilateral groin, a line between the anterior superior iliac spine (ASIS) and pubic tubercle is drawn, identifying the inguinal ligament. A second parallel line is drawn 2 to 3 cm below as the midaxis of the flap, which should correspond to the course of the superficial circumflex iliac artery.

Using a pattern of the defect, a flap is designed inferior to the ASIS to lie along the previously marked midaxis. If necessary, the flap can be extended lateral to the ASIS for additional length (TECH FIG 8A).

A flap up to 20 × 10 cm can be closed primarily and is sufficient for most hand and wrist defects.

It is important to keep in mind that a small portion of the flap will be tubularized near the pedicle and will have to be included in the design.

The flap is oriented to minimize kinking and twisting of the pedicle after inset.

The flap is incised down to the underlying fascia. Inferiorly, the fascia lata and sartorius muscle fascia are identified.

The flap is elevated tangentially off the fascia in a lateral-to-medial fashion until the lateral aspect of the sartorius fascia is encountered (TECH FIG 8B).

The sartorius fascia is incised at its lateral margin and elevated from the underlying muscle, with care taken to avoid injuring the lateral femoral cutaneous nerve.

At this point, scissor dissection is used to identify the vascular pedicle as it traverses out of the femoral triangle and through the sartorius fascia.

A cuff of sartorius fascia is incised superior and inferior to the pedicle to untether the pedicle from the muscle (see Tech Fig 8B).

The proximal portion of the flap is tubularized around the pedicle.

The donor defect is closed primarily. The standing cutaneous deformity at the lateral aspect is excised. A small open area may be left at the base of the flap.

Completion of the Groin Flap

The flap is gently thinned along the margins.

The defect is then brought into the field, and the flap is inset using nonabsorbable sutures (TECH FIG 8C).

The forearm is then secured to the abdominal skin with several large nonabsorbable sutures.

Xeroform and bacitracin are applied, followed by fluffed gauze dressing.

An elastic bandage is wrapped around the hip to further stabilize the reconstruction.

Members of the surgical team must be present at the time of recovery from anesthesia to mitigate the chance of accidental flap avulsion.
**TECH FIG 8** • **A.** Design of a groin flap for a large dorsal hand wound after scar excision. The defect has been traced onto a template and transposed to the groin area. **B.** Elevation of the groin flap. A cuff of the sartorius fascia has been incised (indicated by the periosteal elevator) and elevated with the flap to improve mobility of the pedicle (superficial circumflex iliac artery; white arrow). The lateral femoral cutaneous nerve (black arrow) is visible just medial to the incised sartorius fascia. **C.** The groin flap is inset onto the dorsal hand wound. This patient also has soft tissue defects of the ring and small fingers that are buried in subcutaneous pockets for future skin grafting.

**PEARLS AND PITFALLS**

**Fasciotomy and escharotomy**
- Blood products should be made available before escharotomy, because significant bleeding can occur.
- Early recognition and intervention for compartment syndrome are key to prevent irreversible damage, and the threshold for pressure measurement should be low.
- The patient must be monitored closely after the procedure for evidence of inadequate release, especially with ongoing resuscitation.

**Web space release**
- The Y-to-V advancement of the five-flap Z-plasty provides most of the elongation.
- The five-flap Z-plasty should be designed to maximize the amount of unburned tissue in the Y-to-V flap.

**Groin flap**
- Flap orientation must be carefully designed.
- A template of the upper extremity defect can be made with an extension to simulate the pedicle to test various flap configurations and orientations.
- Postoperative congestion or ischemia is likely, secondary to kinking of the pedicle, and should resolve with proper positioning of the arm.

**POSTOPERATIVE CARE**
- After acute burn and wound management, the affected upper extremity will require appropriate splinting (intrinsic-plus with thumb in palmar abduction), elevation, and early range of motion to prevent secondary complications.
- A soft dressing consisting of gauze and an elastic bandage is applied after scar release and local tissue rearrangement. Sutures are removed in 2 weeks.
- Early mobilization and therapy are initiated about 2 weeks postoperatively to maintain release.
- Abduction or extension splints may be used at night to maintain posture.
- Upon completion of the groin flap, elastic bandages are used to strap the arm to the torso for 3 to 4 days. Care is taken to avoid kinking of the pedicle.
- During the immediate postoperative period, the flap is monitored for arterial insufficiency or congestion. A kinked pedi-
cle necessitates repositioning of hand or patient. Suture release near the pedicle may be needed for congestion.

- If present, the small open area at the base of the flap is cared for with daily Xeroform dressing changes.
- Range-of-motion exercises for the nonaffected joint can start immediately postoperatively. Exercises for the affected joints can resume 2 weeks postoperatively.
- Before flap division, the pedicle is gently occluded to check for viability.
- The flap is divided, thinned, and inset 3 to 4 weeks after the index procedure.

OUTCOMES

- When adequately done, the outcome after fasciotomy, in any location, is closely related to its timing. In fasciotomy performed within 12 hours of onset of compartment syndrome, normal function has been reported in 68% of patients. The number decreases sharply, to 8%, if fasciotomy is delayed beyond 12 hours.\(^\text{10}\)
- Approximately 30% of fasciotomy wounds can be closed primarily. The rest require skin grafting.\(^\text{2}\)
- Several articles describing various local tissue rearrangement procedures for contracture release document low complication rates and good results.
- Our experience agrees with published series that pedicled groin flaps provide stable soft tissue coverage of upper extremity defects with low complication rates.

COMPLICATIONS

- Complications for escharotomy and fasciotomy include:
  - Bleeding
  - Inadequate release
- Complications for local tissue rearrangement for contracture release include:
  - Partial skin necrosis
  - Dehiscence
- Recurrence
- Injury to neurovascular bundle
- Complications for groin flap include:
  - Flap necrosis
  - Avulsion
  - Excessive bulk requiring revisions

REFERENCES

DEFINITION

- Post-traumatic metacarpophalangeal (MCP) joint and proximal interphalangeal (PIP) contractures may develop directly as a result of injury to the joints and adjacent tissues or indirectly as a result of excessive immobilization or poor splinting of the hand.
- The circumstances precipitating the contracture determine the structures most involved:
  - Joint capsule and collateral ligament contracture
  - Flexor tendon adhesions
  - Intrinsic musculature contracture
  - Extensor tendon adhesions
  - Skin and subcutaneous tissue scarring
  - The MCP joint generally becomes stiff in the extended position. Flexion contractures are uncommon and, when present, generally do not cause significant disability.
  - The PIP joint often becomes contracted in the flexed position, although extension and combined contractures are not uncommon.
  - The key to successfully mobilizing a stiff MCP or PIP joint is anticipating the pathologic causes before surgery.

ANATOMY

- MCP joint osteology allows biaxial motion, including circumduction. The articular surface of the metacarpal head is asymmetrical, with a relatively flat mediolateral convex arc (abduction-adduction) and a large anteroposterior convex arc (flexion-extension) that extends more volarly (FIG 1A).
- The MCP joint is enveloped by a relatively loose capsule inserting onto ridges surrounding the articular cartilage.
- Proper collateral ligaments originate from a dorsolateral tubercle on the metacarpal head and insert on the lateropalmar edge of the phalangeal base (FIG 1B).
- The volar plate of the MCP joint is an extension of the phalangeal articular surface. Unlike the volar plate of the PIP joint, the volar plate of the MCP joint is collapsible and there is little tendency to produce check reins.
  - This is one reason why MCP joint flexion contractures are much less common than those in the PIP joint.
  - The flexor and extensor mechanisms surround the MCP joint.
  - Volarly, the flexor sheath lies directly on the palmar plate and is thick, forming the first annular pulley.
  - Dorsally, the extensor tendon gives rise to fibroaponeurotic sagittal bands that wrap around to insert on the palmar plate. The tendons of the lumbricals and interossei join the dorsal expansion of the extensor. A slip of the dorsal interossei inserts on the dorsolateral aspect of the phalangeal base.
  - The PIP joint is stabilized by a boxlike arrangement of structures consisting of the proper and accessory collateral ligaments, the volar plate, and the dorsal capsule (FIG 1C,D).

PATHOGENESIS

- The irregular contour of the MCP joint functions as a cam, transforming joint flexion into translation (or elongation) of the collateral ligaments. When flexed, the MCP joint has minimal capsular volume and is maximally constrained. Conversely, extension allows maximal capsular volume and joint laxity.
- Direct trauma to the MCP joint causes joint effusions and hemorrhosis. Hand trauma elsewhere results in edema, which also collects within the MCP joints. In both cases, as the capsule fills with fluid the MCP joint is hydraulically pushed into a nearly fully extended position.
- With time the dorsal capsule becomes thick and noncompliant, leading to an extension contracture. The overlying extensor mechanism may become adherent to the capsule. The underlying collateral ligaments shorten and scar laterally to the metacarpal head. The volar recess may fill with adhesions between the volar plate and condyles.
- The extended MCP joint increases flexor tone and relaxes the extensor mechanism, leading to interphalangeal joint flexion, and may indirectly result in a fixed flexion contracture of the PIP joint.
- The combination of extended MCP joints and flexed interphalangeal joints defines the intrinsic-minus hand.
- Injury, infection, excess immobilization, and inappropriate splinting may directly result in fixed flexion or extension contracture of the PIP joint.
- An accumulation of fluid or blood within the capsule leads to stiffness, as does articular damage.
- Curtis3,4 has reported that a contracture of the PIP joint can be due to:
  - Contracture of the volar plate or the capsular structures
  - Collateral ligament contracture
  - Scar contracture over the joint
  - Volar skin contracture
  - Flexor sheath contracture
  - Extensor tendon contracture or adhesions
  - Interosseous contracture or adhesions
  - A bony block or exostosis
- Additional causes not pertinent to this chapter include fascia contracture, as in Dupuytren disease.
- Watson et al11 reported that a flexion contracture of the PIP joint is due to contracture of the check reins on the proximal surface of the volar plate.

NATURAL HISTORY

- Longstanding scarring and contracture of the MCP or PIP joint capsule almost invariably leads to adhesions to the adjacent extensor mechanism.
- Residual joint kinetics is often altered with joint motion occurring through incongruous articular motions such as pivoting.
Cartilage gradually atrophies and softens with disuse. Surface irregularities may develop.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The history should identify:
  - The inciting cause of the joint contracture
  - The time of the insult
  - Efforts made to mobilize the digit
- The hand is evaluated for edema and the return of normal skin creases.
- Ongoing swelling and inflammation (FIG 2A) must subside before surgery.
- The dorsal soft tissues are assessed for mobility and compliance.
  - Capsulectomy after burns and crush injuries may fail due to inadequate dorsal coverage.
  - Skin contracture can also be an original inciting cause for digital stiffness.
- The MCP and interphalangeal joints are assessed for differences in active and passive motion. Passive motion is always greater than active; however, a large difference suggests extrinsic tendon adhesions.
- Bunnell intrinsic tightness test: Intrinsic release may be necessary to mobilize a PIP joint with extension contracture.
- Finger threshold sensitivity is checked, along with overall sensitivity to percussion and cold. Vascularity is assessed by checking capillary refill. The painful and insensitive stiff finger may be a better candidate for amputation than capsulectomy. Poor vascularity is a relative contraindication to capsulectomy.
- Concomitant PIP flexion and distal interphalangeal hyperextension mark a boutonnière deformity (FIG 2B), whereas hyperextension at the PIP joint is a sign of a swan-neck deformity (FIG 2C).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs of the hand are made to evaluate for extrinsic and intrinsic causes of joint stiffness.
  - Extrinsic
    - Metacarpal neck or shaft fracture: Extensor tendon adhesions at the fracture site may restrict MCP joint flexion (passive and active).
    - Proximal phalangeal fracture: Flexor and extensor tendon adhesions at the fracture site may limit active PIP (and sometime MCP) joint motion; passive motion may be maintained.
  - Intrinsic
    - Intra-articular fracture: Articular incongruity may serve as a bony restraint to joint motion.

---

**FIG 1**

- **A.** The articular surface of the metacarpal head protrudes volarly, making the capsule (and proper collateral ligaments) taut with flexion. **B.** Metacarpophalangeal joint anatomy can be considered in two layers: the capsule and collateral ligaments, which lie immediately adjacent to the articular surfaces, and the flexor and extensor mechanisms, which envelop the joint. **C.** Normal anatomy of the proximal interphalangeal joint showing the arrangement of the collateral ligaments and the volar plate. **D.** Normal proximal interphalangeal anatomy showing the arrangement of the proper and accessory collateral ligaments.
Arthritic changes: Cartilage softening and erosion often result in some degree of radiographically apparent arthritis.

A “true” lateral radiograph of the involved joint must be closely examined for significant arthritic changes or any subluxation.

There is little role for CT scanning or MRI of the digits.

DIFFERENTIAL DIAGNOSIS

- MCP extension contracture from extrinsic extensor muscle spasticity or intrinsic muscle paralysis or denervation
- PIP contracture from tendon imbalances, including boutonnière deformity and swan-neck deformity
- Skin contracture
- Dupuytren disease

NONOPERATIVE MANAGEMENT

- Nonoperative efforts to improve joint motion must be tried until motion has plateaued and the soft tissues are absolutely quiescent.
- As a general rule, inflammation and edema will subside and range of motion will improve for a minimum of 3 to 4 months after a traumatic or surgical insult to the hand.
- During this time a supervised hand therapy program is essential.
- Most MCP contractures occur in extension. In addition to regular exercises, dynamic flexion splints (daytime) and static extension splints (nighttime) are useful.
- Most PIP contractures occur in flexion. Treatment begins with application of a nonelastic extension force across the PIP joint for an extended time. This can be done with serial finger casts or commercially available splints such as the Joint-Jack (Joint-Jack Company, Wetherfield, CT) or wire-foam splints. Once the contracture is corrected, elastic splints such as the Joint-Spring or clock-spring splints can be used.
- Prosser\(^8\) presented one of the few studies to follow patients treated conservatively. Using a Capener splint to be worn for 8 to 12 hours per day over an 8-week period, there was an average improvement in the flexion contracture from 39 to 21 degrees. There was no association between time in the splint with final extension or with final stiffness.

SURGICAL MANAGEMENT

- A capsulectomy is indicated only for a contracture not associated with articular incongruity or persistent subluxation of the joint.
- A stiff MCP or PIP joint in the face of articular incongruity or subluxation is best treated as an arthritic joint with a salvage type of surgery such as arthroplasty or arthrodesis.
- Mild to moderate joint wear is not a contraindication to capsulectomy, particularly in younger patients. Focal areas of articular cartilage irregularity and dorsal osteophytes may be débrided at the time of surgery.
- The literature does not give any specifics as to when to recommend surgery. We usually make this decision when a “functional arc of motion” has not been achieved after 3 months of therapy.
- There is no absolute functional arc of motion for the MCP joint. In the absence of interphalangeal contractures, we have found that index, middle, ring, and small finger MCP flexion of 30, 35, 40, and 45 degrees, respectively, is generally satisfactory. When the interphalangeal joints have limited flexion, greater degrees of MCP flexion may be useful.
- Similarly, 45 degrees or more of total PIP motion is usually satisfactory. Flexion contractures greater than 45 degrees are poorly tolerated and may benefit from surgical release.
- Extreme flexion contractures (more than 60 or 70 degrees) may be best managed with arthrodesis.
- Extension contractures are better tolerated, especially if there is flexion to at least 75 degrees.
- When a patient has exhausted nonoperative management options and joint stiffness exceeds the preceding guidelines, surgery for contracture release is considered.

Preoperative Planning

- The patient is required to demonstrate a commitment to therapy before surgery is undertaken. A preoperative meeting between the patient and the therapist is arranged to plan...
the first postoperative visit and to fabricate a dynamic flexion splint.

- If possible, surgery is planned under a form of anesthesia that will allow patient cooperation and active motion during the procedure.
  - A wrist block with sedation is optimal; however, a Bier block may be used and reversed with deflation of the tourniquet.
  - In severely scarred hands (e.g., massive crush injuries and burn patients), the surgeon must anticipate inadequate dorsal soft tissue and extensor tendon excursion. A transverse incision and extensor tenotomy is indicated and coverage of the residual soft tissue defect is planned and discussed with the patient. Kirschner wire fixation of the MCP joints in flexion may be necessary to maintain a flexed joint and protect the dorsal soft tissue reconstruction.

**Positioning**

- Patients are positioned supine with the affected extremity on a hand table. A brachial tourniquet is applied that allows access to the forearm should a full-thickness skin graft be necessary.

**Approach**

- The approach for MCP contracture depends on three factors:
  - The number of involved MCP joints
  - The need to operate on the PIP joint
  - The quality of the dorsal soft tissues

- A single MCP joint is approached with a dorsal longitudinal incision. If the PIP joint has an extension contracture, the incision is carried over the PIP in the midline. If the PIP has a flexion contracture, the incision may be extended distally in the midaxial line (FIG 3A).

- Multiple MCP joint extension contractures are approached using separate dorsal longitudinal incisions.
  - This is the most extensile method and facilitates management of associated extensor tendon adhesions and PIP contractures (FIG 3B).

- Two adjacent MCP joints may also be approached by making a dorsal longitudinal incision centered in the web between affected rays.
  - If necessary, it is safe to extend this incision as a Y onto each digit to complete a tenolysis or operate on the PIP joints.

- Multiple MCP joints may be also approached by making a single transverse incision lying just proximal to the metacarpal heads.
  - This approach is preferred only when the dorsal soft tissues are fibrotic and noncompliant. In this situation, the surgeon should plan for skin graft or flap coverage of the anticipated defect.

- The surgical approach for isolated PIP joint contractures varies with the procedure used.
  - A capsulectomy for a flexion contracture is performed through a lateral approach, a check-rein release through a volar approach, and percutaneous release laterally.
  - A dorsal skin incision could be used with a capsulectomy for an extension contracture or when there is a previous dorsal incision or specific hardware to remove.

**MCP JOINT CONTRACTURES**

**Dorsal Capsulectomy of the Joint**

- Make the skin incision based on the aforementioned considerations (TECH FIG 1A).

- Carry dissection down sharply to the extensor mechanism, preserving small dorsal nerves.
  - If the soft tissues about the MCP joint are excessively scarred, identify the extensor mechanism proximally and distally with careful development of soft tissue planes in between.

- Raise full-thickness soft tissue flaps over the length of the extensor mechanism (TECH FIG 1B).

- Use a Freer elevator to lyse adhesions beneath the extensor mechanism, especially over the metacarpal proximally (TECH FIG 1C).

- As described by Curtis and later Tsuge, the extensor tendon is bisected sharply over the MCP joint (TECH FIG 1D); the sagittal fibers are preserved. Do not carry the extensor split into the transverse fibers of the extensor hood.

- In the index or small finger, the split is made between the extensor communis and the extensor proprius tendons.
Retract each half of the extensor tendon and attached sagittal band to expose the joint capsule.

At times it may be painstakingly difficult to develop the interval between the extensor mechanism and capsule, and a combination of both sharp and blunt dissection is necessary.

The capsule is usually quite thick and generally should be excised rather than released (TECH FIG 1E).

Attempt passive finger flexion; it usually is limited, necessitating release or excision of the collateral ligaments (TECH FIG 1F).

Start dorsally and release the proper collateral ligaments from the collateral recess and from any adhesions to the metacarpal head. Often, the collateral origin may be gently pried away from the metacarpal head with a Freer elevator.

Dense adhesions and excessively thick collateral ligament tissue may need to be incised at the metacarpal origin and removed.

Reassess passive MCP flexion (TECH FIG 1G). If flexion remains inadequate or the joint “jumps” or “snaps” when reaching full extension, then the accessory collaterals may need to be released as well.

The goal is an incremental collateral ligament release—enough to restore joint motion but not compromise stability, especially on the radial (pinch) side.

Assess the volar recess and release any adhesions between the volar plate and condyle with a Freer elevator.

Failure to release the volar adhesion can result in joint “hinging” with dorsal gapping of the joint during flexion.

The joint should now have a smooth arc of passive motion without any hinging during flexion or snapping into extension. Ninety degrees of flexion can usually be achieved.

If the patient is under a wrist or Bier block anesthesia, check active flexion.

Alternatively, a short incision may be made on the volar ulnar aspect of the forearm and traction applied to the appropriate extrinsic flexor tendons.
If active flexion is limited, consider performing a flexor tenolysis.
- We prefer to release the flexor at the same sitting, although the tenolysis may be staged, emphasizing passive motion between surgeries.
- Release the tourniquet and achieve hemostasis with bipolar electrocautery.
- While keeping the MCP joint flexed, close the extensor mechanism with 4-0 interrupted inverted nonabsorbable braided suture and close the skin with nonabsorbable interrupted sutures.
- If bleeding from scar is excessive, then use a small rubber vascular loop or a quarter-inch Penrose drain to stent open the wound to allow drainage for the first 24 hours.
- A dorsal splint is applied to maintain the MCP joints in 70 degrees of flexion.

**Limited Dorsal Capsulotomy of the MCP Joint**
- In mild contractures, a dorsal capsulectomy may not be necessary. Bode and Gottlieb\(^1\) have described a limited capsulotomy.
- Expose the extensor mechanism as described earlier (Tech Fig 1).
- Use a Freer elevator to release the extensor mechanism and sagittal bands from the dorsal capsule (TECH FIG 2A).

Retract the dorsal capsule distally.
- Incise the capsule transversely at the distal dorsal aspect of the metacarpal head (TECH FIG 2B).
- The incision extends from one collateral recess to the other.
- Using a Beaver blade or Freer elevator directed to the periphery of the capsulotomy, perform a stepwise release of the collateral ligaments off the metacarpal head (TECH FIG 2C).

**Extensor Tenotomy of the MCP Joint**
- In longstanding densely scarred multidigit MCP contractures, the extensor communis tendon may need to be tenotomized to achieve flexion (TECH FIG 3A).
- Make a tenotomy at the distal margin of the sagittal bands.
- Capsulectomy and collateral ligament release follow as described earlier.
- At closure, sew the proximal tendon to the sagittal bands; close the extensor hood upon itself in the midline dorsally.
- Given the chronicity of these contractures, consider temporary Kirschner wire fixation of the MCP joints in flexion (TECH FIG 3B).
- Kirschner wire fixation is especially useful for protection of skin grafts or flaps when the dorsal soft tissues are deficient (TECH FIG 3C).
TECH FIG 3 • (continued) B. The metacarpophalangeal joints are maintained in flexion with Kirschner wires. C. The dorsal soft tissue defect is covered with a pedicled tensor fascia lata flap.

**PIP JOINT CONTRACTURE**

**Capsulectomy for PIP Joint Flexion Contracture**

- If there is an adequate skin envelope, the finger is approached through a midaxial incision (TECH FIG 4A).
- Make a radial incision centered over the PIP joint; it is usually 4 cm long.
- Retract the neurovascular structures volarly and protect them. Take care to preserve the dorsal branch of the digital nerve, which typically crosses the proximal aspect of the incision.
- Open the flexor sheath just distal to the A2 pulley.
  - Excise a segment of pulley if it is contracted.
  - Perform a formal flexor tenolysis as necessary.
- If a more extensive tenolysis is required, the incision can be extended volarly over the flexor sheath. Take care to avoid injury to the digital nerve and artery that cross the operative field at the level of the web space.
- Excise a volar segment of collateral ligament (including the underlying capsule) using a no. 69 Beaver blade while carefully protecting the transverse retinacular fibers (TECH FIG 4B). Excise the entire accessory collateral ligament as necessary.
- Isolate and preserve the transverse retinacular fibers by bluntly dissecting perpendicular to the fibers (TECH FIG 4C).
- Do not excise the volar plate (joint capsule), but expand the volar pouch by lifting the volar plate from the phalanges with a Freer elevator. Lengthen the interossei as needed.

**TECH FIG 4 • A.** Skin incision. **B.** The transverse retinacular ligament is protected and the collateral ligament is exposed for excision. **C.** The collateral ligaments are excised. (continued)
If there is still stiffness after completing the dissection on the radial side of the finger, then make a similar incision on the ulnar side of the digit.

The ulnar incision is usually only 3 cm long, as the flexor and extensor tendon disorders have already been addressed. If there is concern that extensor tendon adhesions may limit active extension after release of the flexion contracture, then an extensor tenolysis is performed by elevating the dorsal skin. During the extensor tenolysis, protect the central slip insertion (TECH FIG 4D).

A skin graft or local flap may be required if there is inadequate soft tissue coverage after joint mobilization.

If there is insufficient volar skin or unstable volar skin, then raise a cross-finger flap from the adjacent finger. When a cross-finger flap is used, make a transverse incision over the volar aspect of the PIP joint and extend it with a radial midaxial incision.

Curtis3,4 originally described pinning the joint in extension for 1 week, but most surgeons do not follow this recommendation.

Check-Rein Ligament Release for PIP Flexion Contracture

According to Watson et al,11 the volar plate does not flex but rather slides proximally and distally with flexion and extension. PIP joint adhesions causing contracture occur proximal to the volar plate and involve the check-rein ligaments.

Excision of the volar plate or division of the collateral ligaments is rarely required to achieve full extension.

The joint is approached volarly, often with a V–Y incision to address palmar skin contracture.

Open the theca between the A2 and A4 pulleys and retract the flexor tendons (TECH FIG 5A).

Release the check-rein ligaments, preserving the nutrient vessel (TECH FIG 5B).

If there is still a contracture after release of the check reins, release the dorsal portion of the collaterals or the oblique retinacular ligament of Landsmeer.

This technique is helpful if a palmar exposure is required for excision of Dupuytren disease or during flexor tendon reconstruction.
Percutaneous Collateral Ligament Release for PIP Flexion Contracture

- Stanley et al\(^9\) described a percutaneous release of the collateral ligaments for persistent PIP flexion contractures.
- Place a no. 69 Beaver blade percutaneously adjacent to the proximal phalangeal head (TECH FIG 6A).
- Disinsert the proper collateral ligaments with a sweeping-type motion (TECH FIG 6B).
- Gently manipulate the finger into extension.

Use of an External Fixator for PIP Flexion Contracture

- Two types of distractors have been used.
- Kasabian et al\(^7\) described the use of a multiplanar distractor used for mandible reconstruction.
- The use of a Digit Widget (Hand Biomechanics Lab, Inc., Sacramento, CA) has become popular (TECH FIG 7).
- An external frame is applied without any soft tissue release.
- The frame is left in place for about 6 weeks.
- There are no outcomes reported in the literature. In several of our patients we have noted initial favorable results followed by contracture recurrence.

Capsulectomy for PIP Joint Extension Contracture

- Make a dorsal curvilinear incision.
- Preserve the transverse retinacular ligament by blunt dissection and excise the proper collateral ligaments with a no. 69 Beaver blade as described earlier (TECH FIG 8).
- Perform a dorsal capsulectomy and an extensor tenolysis. If there is intrinsic tightness, perform a lengthening or release.

TECH FIG 6 • A. Cross-section shows placement of the no. 69 Beaver blade parallel to the proximal phalanx and adjacent to the proximal interphalangeal collateral ligament origin. B. Sagittal view demonstrates the technique of “sweeping” the Beaver blade and detaching the collateral ligament from its origin.

TECH FIG 7 • Application of the Digit Widget for proximal interphalangeal flexion contractures.

TECH FIG 8 • Through a dorsal incision, the transverse retinacular ligament is protected and the collateral ligament is excised. The dorsal capsule is also released.
POSTOPERATIVE CARE

- Patients are instructed in strict elevation until the first postoperative visit.
- The wounds are assessed 48 to 72 hours after surgery and, if stable, immediate active-assisted range of motion is begun.
- Wound care and edema control measures are also instituted. A nonadherent gauze should be applied until the wound is watertight. A Coban wrap and gauze finger sleeve limit swelling. Once the wound is healed, compression gloves or elastic finger sleeves further decrease swelling.
- Therapy may quickly advance to include active and passive range of motion as the status of the extensor mechanism allows.
- For MCP extension contractures:
  - Patients are maintained in a static splint full time to keep the MCP joints in 70 degrees of flexion. A daytime dynamic flexion splint is applied at about 1 week once the initial postoperative swelling has subsided (FIG 4).
  - If Kirschner wire fixation was performed, then only interphalangeal joint motion is begun immediately and MCP therapy is delayed until wire removal at 7 to 10 days.
  - Patients are reassessed 2 to 3 weeks after surgery. If there is a significant extensor lag (as may follow an extensive extensor tenolysis), a dynamic extension splint can be alternated with the dynamic flexion splint during the day.
  - Nighttime static splinting is continued for a minimum of 6 to 8 weeks.
  - Therapy is usually continued for about 3 months.
- PIP release often benefits from early dynamic splinting during the day and passive splinting at night.

OUTCOMES

- Final motion is often much less than that obtained at surgery but often makes a substantial difference in hand function.
- Motion plateaus 3 to 6 months after surgery.
Results are best when the joint can be mobilized with capsulectomy alone. Each additional procedure, such as tenolysis, increases postoperative swelling and scar formation, limiting long-term gains.\(^4\)

In some cases, an improvement in MCP or PIP joint motion of 30 to 45 degrees is a reasonable expectation.\(^2,13\)

According to Gould and Nicholson,\(^6\) improvement in MCP and PIP motion depends on the cause of the contracture. In a study of 105 MCP capsulectomies and 112 PIP capsulectomies, patients with direct joint trauma (fractures or crush injuries) gained an average of about 20 degrees of active motion, slightly more for the MCP and less for the PIP. Patients with indirect causes of capsular contracture (nerve injury, stroke, or skin burns) did better.

Ghidella et al\(^5\) reported on the results of 68 PIP capsulectomies. The average overall improvement was a disappointing 7 degrees. The best results occurred in young patients without a history of crush injury, pain syndrome, or revascularization. The average improvement measured 17 degrees in this group compared with 0 degrees when there was a “complex diagnosis.”

Comlications

- Wound dehiscence and infection
- Persistent or recurrent contracture
- Extensor rupture
- Ulnar deviation of the finger at the MCP joint
- Postoperative subluxation or dislocation
- Injury to the dorsal branch of the digital nerve

References

DEFINITION
- Dupuytren disease (DD) is a fibroproliferative disorder that affects primarily the palmar fascial complex of the hand, with occasional secondary involvement of other areas of the hand as well as remote tissues.
- It is an unparalleled condition that clinically and pathophysiologically resembles no other known ailment.
- Although physiologically DD bears a resemblance to the processes associated with normal wound healing, the perpetual and progressive proliferation and abnormal collagen deposition with resultant tissue contracture is astonishing.
- There have been attempts to classify DD under other headings such as inflammatory and neoplastic disorders; however, its uniqueness places it in a class of its own.

ANATOMY
- The radial, ulnar, and central aponeuroses, palmodigital fascia, and digital fascia are elements of the palmar fascial complex.\(^{14}\)
- The radial aponeurosis has four components:
  - The thenar fascia, which is an extension of the central aponeuroses
  - The thumb pretendinous band, which is small or absent
  - The distal and the proximal commissural ligaments
- The ulnar aponeurosis has three components:
  - The hypothenar muscle fascia, which is an extension of the central aponeurosis
  - The pretendinous band to the small finger, which is consistent and substantial
  - The abductor digiti minimi confluence
- The central aponeurosis is the core of DD activity and has a triangular shape with a proximal apex (FIG 1A).

- Its fibers are oriented longitudinal, transverse, and vertical.
- The longitudinal fibers fan out as the pretendinous bands to the three central digits. Each pretendinous band bifurcates distally and each bifurcation has three layers. The superficial layer inserts into the dermis, the middle layer continues to the digit as the spiral band, and the deep layer passes almost vertically dorsally toward the flexor tendon and its digital sheath.
- The transverse fibers make up the natatory ligament (NL) located in the distal palm and the transverse ligament of the palmar aponeurosis (TLPA). The TLPA is proximal and parallel to the NL (FIG 1B) and lies deep to the pretendinous bands. Its distal, radial extent is the proximal commissural ligament. The TLPA gives origin to the septa of Legueu and Juvara, which protect the neurovascular structures and provide an additional proximal pulley to the flexor tendons.
- The vertical fibers of the central aponeurosis are the minute but strong vertical bands of Grapow and the septa of Legueu and Juvara (FIG 1C,D), which lie deep to the palmar fascia. There are eight septa that form seven fibro-osseous compartments\(^{3}\) of two types: four flexor septal canals that contain the flexor tendons and three web space canals that contain common digital nerves and arteries, and lumbrical muscles. These septa are inserted in a soft tissue confluence that consists of five structures: A1 pulley, palmar plate, sagittal band, inter-palmar plate ligament (IPPL; FIG 1D,E), and septum of Legueu and Juvara.
- The palmodigital fascia encompasses a number of fascial structures, including the terminal fibers of the pretendinous bands, the spiral bands, the beginning of the lateral digital sheet, and the NL. The middle layer of the bifurcated pretendinous band spirals about 90 degrees and the peripheral fibers run vertically adjacent to the metacarpophalangeal (MCP) joint.

FIG 1 • A. The central aponeurosis is the core of Dupuytren disease activity and has a triangular shape with a proximal apex. B. The transverse fibers make up the natatory ligament (NL) located in the distal palm and the transverse ligament of the palmar aponeurosis (TLPA). C. There are eight septa of Legueu and Juvara that form seven fibro-osseous compartments of two types: four flexor septal canals that contain the flexor tendons and three web space canals that contain common digital nerves and arteries, and lumbrical muscles. (continued)
They continue distally deep to the neurovascular bundle and NL and emerge distal to this ligament and contribute to the formation of the lateral digital sheet. The proximal fibers of the NL run in a transverse plane, but the distal fibers form a U that continues longitudinally along both sides of the digit, forming the lateral digital sheet. The lateral digital sheet therefore has deep and superficial contributions from the spiral band and NL.

- The digital fascia surrounds the neurovascular bundle in the digit, and this includes the Grayson ligament (palmar), the Cleland ligaments (dorsal), the Gosset lateral digital sheet laterally, and possibly fibers from the check-rein ligaments medially and dorsally that were described previously as Thomaine retrovascular fascia.

**PATHOGENESIS**

- In DD normal bands become diseased cords,¹¹ and Dupuytren nodules and cords are pathognomonic of the disease.¹²
- A nodule usually appears first, followed by the cord.
- The cords involve the palmar, palmodigital, or digital regions and progressively shorten, leading to joint and soft tissue contracture.
- The Grapow vertical bands become microcords, leading to thickening of the skin, which is one of the earliest manifestations of DD.
- Skin pits develop from the first layer of the split pretendinous band.
- The pretendinous cord develops from the pretendinous band and is the most common cord in DD. It leads to MCP joint flexion deformity and often extends distally, contributing to the digital cords. The pretendinous cord may bifurcate distally with each branch extending into a different digit, forming a commissural Y cord (FIG 2).
- The vertical cords, or diseased septa of Legueu and Juvara,² are short and thick. They are connected to the pretendinous cord and extend deeply in between the neurovascular bundle and flexor tendon fibrous sheath.
- Extensive palmar fascial disease is encountered in severe conditions and affects larger areas of the palm, leading to diffuse thickening of many components of the palmar fascial complex.
- The spiral cord has four components: the pretendinous band, the spiral band, the lateral digital sheet, and the Grayson ligament. It is encountered most often in the small finger.
- In the palm, this cord is located superficial to the neurovascular bundle. Distal to the MCP joint, it passes deep to the neurovascular bundle and in the digit it runs lateral to the neurovascular bundle as it involves the lateral digital sheet and again becomes superficial to the neurovascular bundle as it involves the Grayson ligament.
- Initially the cord spirals around the neurovascular bundle, but as it contracts, the cord straightens and the neurovascular bundle spirals around the cord.
- The distorted anatomy of the neurovascular bundle, which is displaced medially and centrally, becomes at risk of injury during surgery.¹⁹
- The natatory cord develops from the NL, converting the U-shaped web space fibers into a V shape, resulting in contracture of the second, third, and fourth web spaces.
- This cord extends along the dorsal lateral aspect of the adjacent digits and is best detected by passively abducting the digits and at the same time flexing one digit and extending the other at the MCP joints.
- The most commonly encountered digital cord is the lateral cord, followed by the central and spiral cords. These are responsible for proximal interphalangeal (PIP) joint flexion deformity.
- The central cord is an extension of the pretendinous cord in the palm.
- The lateral cord originates from the lateral digital sheet and attaches to the skin or to the flexor tendon sheath near the Grayson ligament. The lateral cord leads to contracture of the PIP joint but can also cause a distal interphalangeal joint contracture.
The abductor digiti minimi cord, also known as the isolated digital cord, takes origin from the abductor digiti minimi tendon, but may also arise from adjacent muscle fascia at the base of the proximal phalanx.

- It courses superficial to the neurovascular bundle, and infrequently entraps and displaces the bundle toward the midline.
- It inserts on the ulnar side of the base of the middle phalanx but may attach on the radial side or have an additional insertion in the base of the distal phalanx, causing a distal interphalangeal joint contracture.
- The distal commissural cord develops from the diseased digital commissural ligament, which is the radial extension of the NL. The proximal commissural cord originates from the proximal commissural ligament, which is the radial extension of the TLPA.
- Both of these cords cause first web space contracture.
- The thumb pretendinous cord originates from the thumb pretendinous band and causes thumb MCP joint flexion deformity, which is uncommon.

**NATURAL HISTORY**

- DD has three clinical phases: early, intermediate, and late.\(^\text{13}\)
  - Skin changes with loss of normal architecture and skin pitting characterize the early phase.
  - Nodules and cords form during the intermediate phase.
  - Contractures mark the late phase, with the MCP joint most frequently affected, followed by thePIP joint.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The classic DD patient is a Caucasian man with a positive family history. The condition is bilateral and progressive and may extend to the digits, leading to their contracture.
- Palmar involvement usually precedes disease extension into the digits, but the disease may begin and remain in the digits.
- The ring finger is the most commonly involved digit, followed in order of frequency by the small, middle, and index finger and last by the thumb.
- DD may affect areas outside the palmar surface of the hand.
- Ectopic disease can be either regional in the upper extremity or distant in other parts of the body.
- Garrod nodes are different from knuckle pads, occur on the dorsum of the hand, and are almost always limited to the finger (FIG 3).
Distant ectopic DD affects the plantar fascia and male genitals.

Patients said to express a Dupuytren diathesis or genetic predisposition typically have faster and more severe development of the condition.

- Positive family history
- Young age of onset
- Ectopic sites of fibromatosis such as the dorsal digital area (Garrod nodes), plantar fascia (Ledderhose disease), and male genitals (Peyronie disease)

DIFFERENTIAL DIAGNOSIS

- Non-Dupuytren disease
  - Occurs in a diverse ethnic group, is unilateral and non-progressive, usually involves a single digit, and frequently follows trauma or surgery
  - Patients with this disease rarely require surgical treatment. Confusing this with DD will produce contrasting epidemiologic data.
  - Epithelioid sarcoma
  - Occupational thickening and callus formation that mimic Dupuytren nodules
  - Palmar subcutaneous soft tissue lesions, such as localized pigmented villonodular synovitis, palmar ganglions, and inclusion cysts
  - Stenosing tenosynovitis without triggering can be associated with thickening and adherence of the skin to the underlying flexor tendon sheath.
  - Prominent flexor tendons can be confused with pretendinous cords because of attenuation of annular pulleys, as seen in rheumatoid arthritis.

NONOPERATIVE MANAGEMENT

- No treatment is necessary for non-Dupuytren disease.
- Observation is appropriate for non-progressive DD with minimal contracture and without compromise of function.
- Surgical treatment for minor disease or pitting can result in a disease flare and must be avoided.
- Basic science research has shown the potential of certain local agents in the treatment of DD. These include calcium channel blockers, nifedipine, and verapamil for early stages and collagenase for advanced stages of the disease.
- Steroid injection of nodules has been used to suppress the disease.

SURGICAL MANAGEMENT

- Surgery is the most widely used treatment method for symptomatic and severe DD.
- Outpatient surgery offers substantial savings and should be used in an otherwise healthy patient with moderate hand involvement.
- Local, regional, or general anesthesia can be used depending on the procedure performed.
- Flexion contractures of the MCP joint of greater than 30 degrees and PIP flexion contractures of 15 degrees interfere with function and, in the presence of a well-developed cord, are indications for surgical treatment.
- The outcome after surgery for MCP joint contracture is more successful than that for PIP joint contracture.
- PIP joint check-rein release is indicated if 40 degrees of residual flexion is present after conventional fasciectomy.

Procedures

Percutaneous Fasciotomy

- Percutaneous fasciotomy is indicated for palmar cords in elderly unhealthy patients.
- This technique carries a higher risk for complications when performed in the thumb than in the digits.
- In severe cases, this technique may be useful as a preliminary procedure before definitive removal of diseased tissue.
- Injuries to flexor tendons and digital nerves as well as chronic regional pain syndromes have been reported after percutaneous releases.

Open Palm Fasciectomy

- This method was first used by Dupuytren, who left the transverse palmar incision wound open after fasciectomy.
- This method is indicated for extensive involvement of the palmar fascia and if primary closure is not possible and skin grafting is not desired.
- Satisfactory results with this method continue to be reported in the literature, including less pain, better motion, and low rates of complication. The primary disadvantage is prolonged postoperative wound healing.

Partial Fasciectomy

- Partial fasciectomy is the excision of the diseased tissue with preservation of normal-appearing fascia.
- Other terms for this procedure are selective, regional, or limited fasciectomy.
- Partial fasciectomy remains the most widely used technique for treatment of DD among hand surgeons today. It is associated with a lower recurrence rate than fasciotomy.

Dermofasciectomy

- Dermofasciectomy involves excision of skin and diseased tissue simultaneously followed by grafting of the skin defect.
- Dermofasciectomy is the procedure of choice for recurrent or aggressive disease with marked adherence of skin to underlying diseased cords. It was reported to have lower recurrence rates compared to other surgical techniques even for recurrent disease.

Extensive Fasciectomy

- Extensive fasciectomy involves a wide, generous fasciectomy of diseased tissue involving most of the palmar fascial complex.
- This can be combined if necessary with partial fasciectomy in the digits.
- This technique is indicated when broad involvement of the palmar fascial complex is present.
- The NL and TLP may be involved in severe DD and these can be included in the extensive fasciectomy.
- After extensive fasciectomy, the skin sometimes can be closed primarily. If a defect is present, the wound can be skin grafted or left open.
- Total or radical fasciectomy entails removal of the entire diseased and normal palmar fascia with or without excision of the overlying skin.
- This highly morbid, radical approach is not warranted.

Positioning

- The patient is positioned supine and the hand is placed on a hand table with the shoulder abducted 90 degrees.
A padded pneumatic tourniquet is placed on the arm as proximally as possible. The upper extremity is exsanguinated and the tourniquet is inflated to 250 mm Hg.

**Approach**

- The most commonly used incision is the Brunner zigzag incision (**FIG 4A**).
- A midline longitudinal incision that is closed with multiple Z-plasties can be also used (**FIG 4B**).
- Transverse palmar incisions can be used for the open palm method or for removal of extensive palmar fascial complex disease.
- Local rotation flaps sometimes should be used to cover exposed flexor tendons or neurovascular structures, and the remaining secondary defect can be grafted with full-thickness skin.

**PERCUTANEOUS FASCIOTOMY**

- Local anesthesia is used.
- A tourniquet is not necessary.
- Select the point of fasciotomy adjacent to the cord.
- Use a no. 11 blade held vertically (**TECH FIG 1**).
- Make a stab wound and turn the blade horizontally to cut the cord while the digit is manually extended.
- A gratifying snap is felt and the finger should extend.

**TECH FIG 1** • The no. 11 blade is used to incise the midline cord to improve the proximal interphalangeal joint contracture in this elderly patient.

**OPEN PALM FASCIECTOMY**

- Make a transverse incision in the middle of the palm and extend it if necessary to the digits as a zigzag Brunner incision.
- Undermine the skin flaps and identify the diseased tissue.
- Carry the dissection proximally until a transition between normal and diseased fascia is identified.
  - Isolate the neurovascular structures from the diseased tissue and protect them.
- Release the diseased tissue proximally; dissection is followed distally and excised.
- Leave the transverse incision open to heal by secondary intention but close any extensions of the original incision into the fingers.
- Apply nonadherent gauze to the wound and immobilize the hand in a forearm-based splint with the fingers in extension.

**PARTIAL FASCIECTOMY**

- Make a zigzag Brunner incision; it may extend from the proximal palm to the digital pulp in cases of palmar and digital disease.
- Undermine the skin flaps by careful dissection to separate relatively normal dermis from the diseased tissue.
- This can be difficult in recurrent cases. Make every effort not to buttonhole the flaps.
- It is better to leave diseased tissue in the dermal flap rather than thinning the flap too much and running the risk of buttonholing the flap.
Identify the neurovascular structures, dissect them from the diseased cords, retract them, and protect them during the entire procedure (TECH FIG 2A).

Begin the dissection proximally in the palm until a transition between relatively normal and diseased fascia is identified.

Carry the dissection in a proximal-to-distal direction.

Transect the pretendinous cord proximally and follow the cord distally, dividing all connections to adjacent normal fascia.

If present, include in the excised specimen a vertical cord from the diseased septa of Legueu and Juvara and a natatory cord from the diseased NL (TECH FIG 2B).

Special attention must be given to a spiral cord (TECH FIG 2C) to prevent injury to the digital nerve and vessel, which are intertwined with and spiraled around the diseased cord.

If the diseased tissue is confined to the palm in the form of a pretendinous cord, the distal end of the cord can be seen inserted in the flexor tendon sheath distal to the MCP joint. The cord can be excised at this level.

If the diseased tissue extends to the digit, follow the digital cord into the finger.

Pretendinous cord extension in the digit can be in the form of lateral, central, or spiral cord.

The digital cord must be dissected in the finger with great care because of its proximity to the neurovascular bundle.

Identify and release the distal insertion of the digital cord.

Release the tourniquet and coagulate bleeders with a bipolar forceps.

After adequate hemostasis is achieved, close the wound without a drain.

If skin shortage is present, perform full-thickness skin grafting.

If the neurovascular bundle or flexor tendons are exposed, a flap may be rotated to cover these structures, and skin grafting is done for the secondary defect (TECH FIG 2D,E).

A palmar plaster splint with the digits in the corrected extended position is used for 1 week or less.
DERMOFASCIECTOMY

- Plan the incision by mapping the area of diseased tissue and skin with a marker. The remaining exposure is done through a zigzag Brunner incision that extends from the dermofascial island (TECH FIG 3).
- Remove the diseased fascia and adherent overlying skin as one component.
- Close the zigzag Brunner incision and cover the skin defect with full-thickness skin graft from the volar wrist.

TECH FIG 3 • In a patient with recurrent Dupuytren disease with two pretendinous cords in the palm in line with the small and ring fingers causing severe metacarpophalangeal and proximal interphalangeal flexion contracture of the small finger, dermofasciectomy was done for the small finger and partial fasciectomy through a zigzag Brunner incision was done for the ring finger. Correction of the contractures was achieved. Skin shortage in the small finger was covered with a full-thickness skin graft from the volar wrist.

EXTENSIVE FASCIECTOMY

- Make either a transverse incision in the middle of the palm or a U-shaped incision in the distal palm (TECH FIG 4A).
- The incision has two limbs extending proximally on the ulnar and radial aspect of the digits, forming a broad proximally based skin flap. These can be continued if necessary to the digits with zigzag Brunner incisions.
- Undermine the proximal skin flap and distal skin margin by separating the skin from the extensive diseased palmar fascial complex. Retract the flap proximally to expose the deeper structures (TECH FIG 4B).
- Carry the dissection proximally and distally to expose the majority of the palmar fascia. A transition between normal and diseased fascia may not be identified. Leave

TECH FIG 4 • A. A U-shaped incision is planned in a patient with diffuse Dupuytren palmar fascial disease with nodular thickening in the entire palm. B. The diseased fascia is exposed after reflection of the proximally based skin flap. C. The excised specimen includes a pretendinous cord from the ring finger and diseased transverse ligament of the palmar aponeurosis. D. The surgical wound after skin closure.
Injury to digital nerves is more common in cases with severe MCP and PIP joint contracture and altered nerve anatomy by a spiral cord. Separating diseased tissue from adherent skin is difficult, especially in recurrent cases. To reduce the risk of buttonholing the skin, vascular injury can be in the form of an arterial laceration, arterial spasm, intimal hemorrhage, or vessel rupture from vigorous correction of severe digital joint contracture. Arterial laceration that results in vascular compromise requires immediate repair or interposition vein graft. Arterial spasm and intimal hemorrhage are treated first by repositioning the digit in flexion, then irrigating with warm saline, applying topical lidocaine, even using intravenous heparin, and, if all else fails, vascular reconstruction.

Separating diseased tissue from adherent skin is difficult, especially in recurrent cases. To reduce the risk of buttonholing the skin, using a no. 15C scalpel and the back of the knife as a dissector will allow precise separation of diseased tissue from normal skin. In addition, using an operating room light to transilluminate from the epidermal side of the skin allows visualization of the thickness of the flap and can alert the surgeon when the dissection is too superficial.

PEARLS AND PITFALLS

- Injury to digital nerves is more common in cases with severe MCP and PIP joint contracture and altered nerve anatomy by a spiral cord. Such a complication is especially common in previously operated cases with an exuberant amount of scar tissue. Preventive measures include isolation of the neurovascular bundle by careful dissection, using loupe magnification, and knowledge of pathoanatomy. The dissection is carried out in a proximal-to-distal direction and is sometimes combined with distal-to-proximal dissection before removal of the diseased cord. If the nerve is transected, a primary repair should be performed.

- Vascular injury can be in the form of an arterial laceration, arterial spasm, intimal hemorrhage, or vessel rupture from vigorous correction of severe digital joint contracture. Arterial laceration that results in vascular compromise requires immediate repair or interposition vein graft. Arterial spasm and intimal hemorrhage are treated first by repositioning the digit in flexion, then irrigating with warm saline, applying topical lidocaine, even using intravenous heparin, and, if all else fails, vascular reconstruction.

- Separating diseased tissue from adherent skin is difficult, especially in recurrent cases. To reduce the risk of buttonholing the skin, using a no. 15C scalpel and the back of the knife as a dissector will allow precise separation of diseased tissue from normal skin. In addition, using an operating room light to transilluminate from the epidermal side of the skin allows visualization of the thickness of the flap and can alert the surgeon when the dissection is too superficial.

POSTOPERATIVE CARE

Open Palm Fasciectomy

- The surgical wound is covered with sterile nonadhesive gauze, which can be changed daily. By 4 weeks no dressings should be necessary.
- Forty-eight to 72 hours after surgery the patient begins active range of motion every 2 to 3 hours but maintains nocturnal extension splint immobilization.
- Whirlpool therapy can be used early in the postoperative period if unwarranted or excessive bleeding occurred.
- Wound healing takes place within 6 to 8 weeks, depending on the extent of the incision.

Partial Fasciectomy and Dermofasciectomy

- Range-of-motion exercises are encouraged out of the splint after 1 week. The sutures are removed and splint use is discontinued 2 weeks after surgery in uncomplicated cases.
- Formal hand therapy is used after surgery for extensive disease, especially if residual flexion deformity is present. Range of motion alternating with extension splinting is emphasized.

COMPLICATIONS

- Complications related to patient physiology include postoperative stiffness, chronic regional pain syndromes, recurrence, loss of digital flexion, and reflex symptomatic dystrophy. The surgeon has little influence in preventing these complications.
- Early postoperative complications
  - Hematoma is prevented by tourniquet deflation and adequate hemostasis before wound closure. Deflating the tourniquet and assessing the skin vascularity before closure to ensure adequate circulation is the best way to prevent skin necrosis.
  - Closure under tension should be avoided and consideration should be given to grafting or the open palm method if a primary closure is too tight.
  - Skin necrosis develops after excessive thinning of skin flaps and tight skin closure. Small areas of skin necrosis may be allowed to heal by secondary intention, but large areas of necrotic tissue should be excised, and skin graft or flap coverage is done.
  - Reflex sympathetic dystrophy, also referred to as a “flare” reaction, may occur after surgery. The patient presents with swelling, hyperemia, dysesthesias, and pain out of proportion to that expected. Direct trauma to the nerve and excessive dissection or stretch of the nerves are thought to be predisposing factors. A simultaneous carpal tunnel release with DD surgery, especially in women, is a predisposing factor. Atraumatic technique and gentle handling of nerves and tissues during surgery should minimize the risk of this complication. If no cause can be identified, the treatment is therapy for pain control. In recalcitrant cases a series of stellate sympathetic ganglion blocks can be helpful.
- Late postoperative complications
  - Inclusion cysts can occur near the scar due to dermal tissue entrapment in the subcutaneous space. This can be prevented by careful attention to skin approximation during wound closure. The risk of hypertrophic scar formation is lessened by careful attention to placement of the skin incisions.
OUTCOMES

- The recurrence rate varies between 2% and 60%, with an average of 33%. This may be a true recurrence (recurrent disease at the operated site) or disease extension (disease outside the area of prior surgery). Recurrence is more common in patients with PIP joint involvement, disease in the small finger, more than one digit affected, a longer time since surgery, and a secondary fasciectomy.
- Roush and Stern\(^{17}\) reported that the postoperative total range of motion of recurrent DD was better after fasciectomy and flap converge compared to skin grafting or arthrodesis.
- DD has intrigued basic scientists and clinicians for centuries. Both ancient\(^{6}\) and current publications\(^{5,18}\) underscore the interest in and the advances toward understanding the pathophysiology of this disease and improving its treatment.

REFERENCES

DEFINITION

- Vascular tumors are diverse, ranging from benign vascular malformations to malignant lesions.
- The incidence of vascular tumors is about 2% to 6%.\(^{14,16}\)
- About 26% of vascular and lymphatic tumors are found in the extremities.\(^{17}\)
  - When found in the upper extremity, they are more common in the hand and forearm.
  - Vascular tumors are fourth in frequency of upper extremity tumors, after ganglions, giant cell tumors, and inclusion cysts.
- Most vascular tumors are congenital, and 10% of pediatric tumors involve the upper extremity. Of these, 90% can be classified as hemangiomas or vascular malformations.\(^{23}\)
- Benign vascular tumors can be congenital or acquired and include hemangiomas, lymphangiomas, congenital arteriovenous fistulas, aneurysms, vascular leiomyomas, glomus tumors, and pyogenic granulomas.
- Malignant vascular tumors include hemangioendotheliomas, hemangiosarcomas, glomangiosarcomas, and malignant hemangiopericytomas.

ANATOMY

- The ulnar and radial arteries form the superficial and deep arches of the hand, which then branch into the common digital arteries. There are multiple anatomic variants.\(^{5}\) The common digital arteries then branch into the proper digital arteries that course along the midlateral aspect of each digit, slightly volar to midline.
- The arteries terminate at either a capillary bed or a glomus body. The glomus is a neuromyoarterial mechanoreceptor—that is, a specialized arteriovenous shunt. It lies in the stratum reticulum of the skin, especially in the subungual region and distal pads of the digits. The glomus body acts as a thermoregulator, and it regulates peripheral blood flow in the digits and possibly controls peripheral blood pressure. It contains the glomus cells surrounding the Sucquet-Hoyer canals, which are narrow vascular anastomotic channels.

PATHOGENESIS

- The theory is that vascular tumors occur as a failure of differentiation of the common embryonic vascular channels, which results in the congenital lesions.\(^{17}\) These are more commonly seen in the pediatric population, but they may be discovered late, in adults.
- Acquired vascular tumors are usually due to trauma that induces aneurysms or fistulas.

NATURAL HISTORY

Congenital Lesions

Hemangiomas

- Thirteen percent of hemangiomas are visible at birth, but this increases to 70% to 90% before the infant is 4 weeks old.
- These lesions show rapid growth, then slower growth that is proportional to the child. Next a slow involutional process occurs.\(^{29}\) Fifty percent of hemangiomas will involute by the time the child is 5 years old and 70% will involute by the age of 7.
- Hemangiomas consist of plump endothelial cells with high turnover rates.\(^{14}\) They may be classified by histology, location (superficial, subcutaneous, or intramuscular), or involutional status.\(^{17}\) Thirty percent of upper extremity hemangiomas will ulcerate. This becomes a problem with these hand and finger tumors that may present with acute or chronic paronychia, especially in children who suck their fingers.\(^{23}\)
- They present as reddish lesions that become raised during the growth phase.

Congenital Aneurysms

- The histologic classification of congenital aneurysms includes capillary hemangiomas, sclerosing hemangiomas, and venous or cavernous hemangiomas (FIG 1).\(^{17}\)
- Capillary hemangiomas consist primarily of proliferated capillaries. There is a compact mass of endothelial cells where

FIG 1 • A. Hemangioma of the volar fourth web space of the left hand. This patient had a raised, ulcerated lesion and pathology showing a polypoid lesion with central capillary and slightly larger vascular spaces. B. Cavernous hemangioma of the thumb. There is a pinkish hue to the skin without any raised tissue. Although the lesion appears ulcerated, on pathologic examination there were no ulcerations and large vascular spaces were found immediately beneath the epidermis.
there are small or no capillary lumina. These extend from the dermis into the subcutaneous tissue and make up about 57% of subcutaneous hemangiomas.  
- If the hemangioma is associated with thrombocytopenia and consumptive coagulopathy, it is termed Kasabach-Merritt syndrome. This is unrelated to the size of the hemangioma and may be life-threatening if untreated.  
- If there are thin-walled sinuses secondary to widely dilated thin-walled spaces with little stroma, they become cavernous or venous hemangiomas. These make up about 23% of hemangiomas.  
- Sclerosing hemangiomas contain a perivascular thickening of the lymphatic cells. There is a fibrous, not hematogenous, origin to these lesions. This type represents 10% of all hemangiomas.  

**Lymphangioma**  
- Lymphangiomas are rare and classified as simple, cavernous, and cystic. The most common variety is cavernous lymphangiomas. These present at birth or soon thereafter and are composed of dilated lymphatic sinuses.  

**Congenital Arteriovenous Fistula**  
- Congenital arteriovenous fistulas (AVFs) develop early in the embryo. The upper extremity is the second most common location for these lesions after the head and neck. They have several arteriovenous communications at birth and are associated with syndromes such as Parkes-Weber syndrome and Klippel-Trenaunay syndrome.  
- Parkes-Weber syndrome is a combination of multiple AVFs, vascular malformations, and skeletal hypertrophy of the affected limb.  
- Klippel-Trenaunay syndrome is characterized by a combined type of vascular malformation and limb enlargement due to hypertrophy of soft tissue and bone.  
- Both of these syndromes may have significant medical sequelae, including congestive heart failure, pulmonary embolism, venous thrombosis, bleeding, and cellulitis.  

**Vascular Malformations**  
- Vascular malformations are uniformly present at birth but may not be visible until childhood, adolescence, or adulthood. Most appear by ages 2 to 5 years. They enlarge proportionately with the child unless they are stimulated by trauma, hormones, infection, or surgery. These lesions have an equal sex distribution. Malformations generally have flat, slowly dividing endothelial cells.  
- They can be categorized as low-flow or high-flow lesions based on their hemodynamic features at the time of angiography.  
  - High-flow lesions have an arterial component. Marked enlargement and increased number of arteries, small vessels, and veins are consistent findings.  
  - Low-flow malformations have large channels without intervening parenchyma and often with associated phleboliths. These lesions are more common than high-flow lesions. They are subdivided into capillary, venous, lymphatic, and combined.  
- Capillary malformations (port wine stain, nevus flammeus) show dilated capillaries and postcapillary venules in the upper dermis. They are dark red to purple and may have another associated vascular lesion. Over time, they become darker and have a cobblestone appearance. They may be associated with limb or digit overgrowth.

**FIG 2** Venous malformation of the ulnar side of the left hand. Notice the blue color and slightly raised appearance.

- Seventy-five percent of venous malformations are recognized at birth. They are the most common anomaly of the low-flow group (40%). It is important to differentiate them from hemangiomas because venous malformations do not involute. They, like lymphatic malformations, present with a mass or skin discoloration. They enlarge shortly after birth and grow with the child. Slow commensurate growth, compressibility, and phleboliths are pathognomonic for venous malformation (FIG 2).  
- Patients with vascular malformations will complain of the mass effect of the lesion, increased size with exercise, or pain due to thrombosis. Elevation of the extremity eases symptoms. They may lead to nerve compression at the forearm and wrist, and digital compression may be seen with localized thrombosis.  
- Lymphatic malformations enlarge secondary to fluid accumulation, cellulitis, or inadequate drainage of lymphatic channels. They can limit hand motion, and infections are common. They can cause bone hypertrophy.  
- Mixed vascular malformations share the characteristics of their combination of vascular malformations.  
- High-flow malformations present early as a painless mass. They have a bimodal occurrence: 40% show up at birth and another 34% after 10 years old. They are not compressible. These lesions can lead to distal ischemia or even high-output heart failure if large and untreated. They have been divided into three types (FIG 3):  
  - Type A lesions have single or multiple arteriovenous fistulas, aneurysms, or ectasias of the arterial side.  
  - Type B lesions consist of arteriovenous anomalies with microfistulas or macrofistulas that are localized to a single limb, hand, or digit. They have stable flow characteristics and provoke minimal to no distal symptoms. As with type A lesions, they remain localized to a specific anatomic region.  
  - Type C lesions enlarge slowly. They are diffuse, with microfistulas and macrofistulas involving all limb tissues. With increasing size, vascular steal occurs. The lesions and associated symptoms worsen with pregnancy and do not reverse with delivery. They can cause distal ischemic pain, tachycardia, and congestive heart failure. Compartment syndrome, compression neuropathies, and ulceration secondary to ischemia or attempted surgical interventions can also occur. The result can be unremitting, progressive pain, eventually leading to amputation.
True aneurysms contain all three layers of the vessel wall: intima, media, and adventitia. False or pseudoaneurysms do not contain all three layers of the vessel wall.

**True Aneurysms**
- True aneurysms account for 6% of all tumors of the hand.\(^{17}\)
- True aneurysms, most notably hypothenar hammer syndrome, usually follow blunt trauma in the area of the vessel. The trauma may be a single event or repeated injury. The vessel dilates in response to injury to the arterial media, leading to a fusiform vessel.
- Aneurysms occur secondary to other disease processes such as arteriosclerosis, metabolic disorders, Kawasaki disease, Buerger disease, hemophilia, osteogenesis imperfecta tarda, granulomatous arteritis, and cystic adventitial disease (FIG 4).\(^ {14}\)

**Pseudoaneurysms**
- False or pseudoaneurysms account for most (83%) aneurysms of the hand and generally occur on the palmar surface of the hand.
- They may be secondary to a puncture wound (such as from a knife or pencil lead) or complete rupture of the vessel wall with continuity maintained by the surrounding soft tissues.\(^ {14,17}\)
- Pseudoaneurysms occur slowly over time and are usually not evident for weeks to months after the injury.
- A bruit may be noted on examination. Like true aneurysms, the most common site is in the ulnar artery.

**Acquired Arteriovenous Fistulas**
- Acquired AVFs occur secondary to trauma or surgical intervention. AVFs consist of a communication between an artery and a vein that shunts away from the higher-resistance capillary system.

---

**Acquired Lesions**
- Acquired lesions comprise both true and false aneurysms of the vessels, glomus tumors, pyogenic granulomas, fistulas, and vascular leiomyomas.

---

**FIG 3**
- **A.** Arteriovenous malformation of the digit. The margins are indistinct and it is difficult to dissect from the surrounding tissues. **B.** Arteriovenous malformation of the palm at the ulnar artery. There is a bulblous region where the malformation has occurred.

**FIG 4**
- **A.** Venous aneurysm of the palm. Again, a bluish tinge is noticeable over the lesion. **B.** Intraoperative view of a venous aneurysm. There is dilatation present at the vein. **C.** Ulnar digit artery false aneurysm. The patient sustained a traumatic injury at work and noted an increase in the size of the lesion over the ensuing 6 weeks. **D.** Hypothenar hammer syndrome. The patient was releasing a mechanical latch of a machine by using the heel of his hand, which caused a sharp pain. The patient presented with coolness of the ring finger-tip and associated pain.
Traumatic AVFs occur when there is penetrating injury to an artery and the adjacent vein, leading to a hematoma and shunting. This may occur secondary to injury with such objects as small knives or pencils, but it may also be due to venipuncture, arterial cannulation, or catheterization procedures. AVFs secondary to iatrogenic vascular injuries tend to occur slowly, while those that occur secondary to trauma are usually rapid in onset. This may be secondary to the size of the puncture that occurs; iatrogenic injuries tend to be smaller punctures than traumatic ones. Patients with intrinsic coagulation deficiencies are more vulnerable to this complication.

Surgical AVFs are formed for dialysis access in renal failure patients and can cause similar symptoms, including steal, ischemia, venous arterialization, and hand edema.

**Glomus Tumors**

- Glomus tumors make up 8% of the vascular tumors of the hand and 1% to 4.5% of all hand tumors. They arise in the neuromyoarterial apparatus that was first described by Wood in 1812 and then again by Masson in 1924. These lesions have been found in the stomach, trachea, and retina but are most commonly found in the digits. Glomus tumors are more consistent with a hamartoma than a true tumor. Sixty-five percent of these lesions are found in women 30 to 50 years old.
- Between 26% and 90% of solitary glomus tumors are located in the subungual region. These lesions tend to be small—normally 5 mm and usually less than 1 cm. They are encapsulated and contain numerous small lumina when found as single tumors. Multiple tumors tend to be unencapsulated, rarely subungual, with larger-shaped vascular spaces.
- Multiple glomus tumors tend to be asymptomatic and present earlier in life, whereas solitary tumors often go undiagnosed or misdiagnosed for years because the lesions are small and not palpable and with varying presentations. Glomus tumors are more commonly found on the glabrous portion of the palm and digits as well as in the mouth and around the lips and face. In adults, these are more commonly found on the fingers and toes.
- They may occur spontaneously but are more frequently present as an overgrowth of granulation tissue in an area of previous penetrating trauma.

**Vascular Leiomyomas**

- Vascular leiomyomas are very rare tumors of the hand. They arise in the smooth muscle of the tunica media of veins in 50% of cases. These masses are typically well encapsulated, small, round, firm, colorless, and curable.

**Pyogenic Granulomas**

- Pyogenic granulomas make up 20% of the vascular tumors of the hand and may be a variation of a capillary hemangioma. They appear as a circumscribed lesion.
- They develop rapidly and become a pedunculated, friable lesion that is easily traumatized and bleeds. In children, these lesions are more commonly found on the glabrous portion of the palm and digits as well as in the mouth and around the lips and face. In adults, these are more commonly found on the fingers and toes.
- They may occur spontaneously but are more frequently present as an overgrowth of granulation tissue in an area of previous penetrating trauma.

**Malignant Tumors**

- Malignant vascular tumors account for less than 1% of all vascular hand and forearm tumors. There are several types of malignant vascular tumors: hemangioendothelioma, glomangiosarcoma (malignant glomus tumors), angiosarcoma, Kaposi sarcoma, lymphangiosarcoma, and hemangiopericytoma.
- Hemangioendotheliomas tend to arise adjacent to or within veins. They extend centrifugally from the vessel. They are slow-growing tumors, and tumors that show more than one mitosis per high-power field on histology are more likely to metastasize. Metastasis may occur locally to nodes or be distant to the lungs, liver, or bone.
- Glomangiosarcomas are extremely rare and were first described in 1972 by Lumley and Stansfield. They tend to be...
low-grade tumors that are locally invasive. They occur in adults ages 20 to 89 years. There are three categories of glomangiosarcoma: locally infiltrative glomus tumor (LIGT), glomangiosarcoma arising in a benign glomus tumor (GABG), and de novo glomangiosarcoma (GADN).

- **LIGT** is identical to solitary glomus tumors except that it has infiltrating growth and tends to recur with resection.
- **GABG** is a sarcomatous tumor in association with a benign glomus tumor.
- **GADN** is a sarcoma with round cells and features of a benign glomus tumor.12,19,20

Angiosarcomas are rare and aggressive and metastasize early. They may occur after radiation therapy or long-term exposure to polyvinyl chloride. They are sometimes mistaken for hemangioendotheliomas on histology. The prognosis is extremely poor with these tumors, with survival times averaging 2.5 years.14,17,29

First described by Kaposi in 1872 in elderly men of Jewish and Mediterranean heritage, Kaposi sarcoma present as small, purple macules. They are a malignant degeneration of the reticuloendothelial system. These lesions tend to start on the hands or lower extremities, progress onto the trunk, and coalesce into large papules. In this patient population, the disease has an indolent course and may be treatable with surgery and radiation. In the age of HIV/AIDS, however, the disease is much more aggressive, with a larger number of lesions. In these patients, it is associated with human herpes virus 8.14,17,29

Lymphangiosarcoma is a rare cancer that occurs after longstanding lymphedema, as seen in some postmastectomy patients. These lesions metastasize rapidly.

Hemangiopericytoma is a diffuse proliferation of capillaries, encased in connective tissue and surrounded by pericytes. They have no nerve elements and are generally painless. Patients tend to delay treatment secondary to lack of pain. They may present as a nonpigmented bleeding mole, an ulceration with prominent telangiectasia, or a dark blue, hemorrhagic swelling. Histologically, they have sheets of spindle cells surrounding capillaries, regular oval nuclei without anaplasia, indistinct cytoplasmic borders, and a reticulin sheath surrounding each cell on silver stain.11,28 Pathologists have described three histologic grades based on the above criteria: benign, borderline malignant, and malignant. It has an unpredictable behavior and may metastasize years after excision; therefore, long-term (5 to 10 years) follow-up is recommended (FIG 8).

### Patient History and Physical Findings

- It is imperative to get a complete history and physical examination of the patient and family.
- Determine whether the lesion was present at birth or infancy or whether it appeared later in adolescence or adulthood.
- Rate of growth should be sought. This may help to differentiate between a hemangioma and an arteriovenous malformation in early childhood. Hemangiomas grow out of proportion to the growth of the child.

**Hemangiomas**

- Hemangiomas will appear as a reddish lesion that becomes raised. Lesions of the axilla or interdigital region will be chronically macerated. Fingertip hemangiomas may present with findings similar to an acute or chronic paronychial infection, especially in children who suck on their fingers.23
- Vascular malformations
  - Low-flow malformations most commonly present as a mass or skin discoloration. If a capillary component is present, there may be a reddish stain of the skin. The physician should ascertain whether there are any compressive symptoms from the lesion consistent with a mass effect, distention, or pain with exercise that would indicate a venous malformation.
  - Ulceration is uncommon in these lesions.
  - If there is a lymphatic component, patients may present with intralymphatic infections secondary to ruptured vesi- cules and maceration of large lesions.
  - They may also be found in association with syndromes such as Parkes-Weber, Klippel-Trenaunay, proteus (capillary malformations, venous malformations, macroactyly, hemihypertrophy, lipomas, scoliosis, and pigmented
nevi), and Mafucci (lymphaticovenous malformations and enchondromas).23

- High-flow malformations tend to be painless early on but then progress to be warm, painful masses with palpable thrills and bruits as the child grows.
- Asking the patient if he or she gets relief of the pain with elevation, if there is increased pain with exercise, and increased warmth in the lesion may help to distinguish these from low-flow lesions.
- It is also important to ask about any symptoms of congestive heart failure, which may occur as sequelae of an untreated high-flow malformation.23
- Any patient evaluated in the office for a suspected arteriovenous malformation should be evaluated for other lesions, Nicoldani sign (decrease in pulse with occlusion of the fistula), and any evidence of distal ischemia.14

- Aneurysms and pyogenic granulomas
  - For evaluation of possible aneurysms and pyogenic granulomas, it is important to know whether there is a history of trauma in the region, how long the lesion has been present, whether it is a pulsatile mass, and whether it has bled.

- Glomus tumors
  - The classic triad of paroxysmal pain, pinpoint tenderness, and temperature intolerance, especially cold, should be elicited if glomus tumors are in the differential.
  - On physical examination, the physician should look for a bluish discoloration (found in 28% of patients) and a pulp nodule or nail deformity (found in 33% of patients).15
  - The length of time that the patient has had symptoms can assist in differentiating glomus tumors from other tumors of the upper extremities, since most patients tend to have symptoms for more than 10 years. If the patient has had previous excisions of glomus tumors, it is necessary to find out the amount of time between resection and recurrence. This can help to determine whether the lesion is an incomplete excision or a new tumor.26
  - During the physical examination, the patient should also be evaluated for multiple glomus tumors, which tend to be less symptomatic.

- Patients with lesions of the hand, wrist, or distal forearm should have an Allen’s test performed.
  - The hand is elevated and the patient is asked to make a tight fist for about 30 seconds. The ulnar and radial arteries are occluded and the patient opens his or her hand slowly. The ulnar artery is then released and the color should return in 5 seconds. If color returns to the radial aspect of the hand within 5 seconds, the superficial arch is complete and the radial artery may be ligated.
  - A thorough evaluation of the rest of the patient’s medical history, including a history of axillary dissections, HIV/AIDS status, and irradiation, is also necessary if the patient presents with a lesion that may be cancerous.

- Methods for examining the vascular lesions of the hand
  - The examiner should look at the hand to check for blue spots, nail ridging, reddish, raised lesions, pulsatile masses, or traumatic injury, which helps to differentiate between malformations, aneurysms, pyogenic granulomas, and glomus tumors.
  - A stethoscope is gently placed over the lesion to listen for bruits or thrills. In fast-flow arteriovenous malformations, a bruit or thrill may be heard, which would not be found in other vascular lesions.
  - The mass is gently palpated. If a pulsatile mass is felt, the examiner should ascertain whether the lesion is compressible and whether there is associated pain.
  - Love pin test: The head of a pin or paperclip is gently pressed against the tender area to localize the pain. This locates a glomus tumor. In subungual tumors, the pin is placed on the nail plate at various locations to find the tumor.15
  - Hildreth test: The digit is exsanguinated by placing a tourniquet at its base or the hand is exsanguinated by elevating it and making a tight fist. The point of tenderness located by the Love pin test is then repalpated. If the patient has diminished or resolved pain with this maneuver, then the test is considered positive for a glomus tumor.8

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs of the digits and hands
  - Phleboliths (in 6%) and bony hypertrophy may be noted.14,17
  - There may be evidence of a soft tissue mass or signs of bone erosion or destruction of the cortical surface, which is seen in about 6% of patients with hemangiomas.17
  - Doppler ultrasonic flow detection is a noninvasive study that does not require the use of contrast.
  - It has been used to confirm high-flow anomalies and to help differentiate between hemangiomas and malformations.24 Doppler ultrasonography will show these lesions to be monophasic with low-flow velocity averaging 0.22 kHz.22
  - Computed tomography with contrast enhancement may show bony involvement of the tumor, especially in type A high-flow malformations.24
  - MRI can be used to evaluate the site, size, flow rate, and characteristics of the lesion as well as involvement of contiguous structures.24
  - It may be used to determine whether a malformation is low-flow or high-flow and can also distinguish between dense parenchymal lesions and malformations with large vascular channels.14
  - It can also be used to evaluate glomus tumors, which have a high signal intensity on T2-weighted spin-echo MRI or after gadolinium injection.15
  - MRI has a sensitivity of 90% and a specificity of 50% for glomus tumors, so that it cannot be used as the single diagnostic study for glomus tumors, especially if they are less than 2 to 3 mm in size.1
  - Hemangiomas will appear as well-circumscribed mass lesions that enhance with gadolinium and will have a high T1 signal secondary to infiltrative margins and fatty tissue overgrowth as well an extremely high, heterogeneous T2 signal. A serpentine pattern in the mass may also be seen on MRI.29
  - MR angiography may be performed at the time of MRI to evaluate lesions in patients who are unable to undergo angiography secondary to renal problems or contrast allergies. It can be used to define the anatomic extent of lesions and their relationship with the surrounding tissue. It can be used to evaluate for both arterial and venous tumors without contrast enhancement.7
  - Technetium-99m red blood cell perfusion and blood pool scintigraphy will show increased activity on early and late blood pool images with increased perfusion in hemangiomas and may be useful in their diagnosis.29
  - Angiography is the gold-standard evaluation of certain tumors, including vascular malformations. No longer routinely used for diagnosis of a lesion, it is used as an evaluation for
operation or embolization. It may show a cluster of anomalous arterial branches with multiple communications with venous trunks draining the site of involvement.

Closed venous angiography uses contrast injected into the venous system distal to a proximal arterial tourniquet applied on the upper arm. Dye is injected into the exsanguinated extremity distal to the tumor and radiographs are taken as the vascular tumor fills to get an accurate assessment of the anatomy. Arterial angiography is performed through a stick into the femoral artery with a catheter that is fed into the involved extremity. Dye is then injected and both the arterial and venous phases of circulation are evaluated. This can be used to evaluate the size of the tumor, locate the feeding vessels, and embolize feeding vessels before operation (FIG 9).

DIFFERENTIAL DIAGNOSIS

- Foreign body
- Bacillary angiomatosis
- Pyogenic granuloma
- Glomus tumor
- Hemangioma
- Arteriovenous or lymphatic malformation
- AVFs (traumatic, congenital, iatrogenic)
- Traumatic aneurysm (true or false)
- Mycotic aneurysm (hematogenous or exogenous)
- Arteriosclerotic aneurysm
- Congenital aneurysm
- Metabolic aneurysm (eg, osteogenesis imperfecta, granulomatous arteritis, Buerger disease)
- Vascular leiomyomas
- Glomangiosarcoma
- Angiosarcoma
- Hemangioendothelioma
- Hemangiopericytoma
- Kaposi sarcoma
- Lymphangiosarcoma

NONOPERATIVE MANAGEMENT

- Observation is important for hemangiomas. Up to 70% of these lesions will involute by the age of 7.
- Large venous or capillary malformations should be observed for limb growth disturbances and a possible underlying high-flow lesion.
- Limb compression garments can be used to compress massive congenital arteriovenous fistulas that are inoperable, giant venous malformations, lymphatic malformations, or large hemangiomas in the arm and forearm. For larger lymphatic lesions, home compression pumps can be used to decrease edema at night.
- Antibiotic prophylaxis is indicated in patients who have recurrent infections in lymphatic malformations. The bacteria most commonly responsible for these infections is penicillin-sensitive beta-hemolytic streptococcus.
- If a patient with venous malformations or capillary-venolymphatic malformation has recurrent intralesional thrombosis, then low-dose aspirin may be added to the compression garments for effective therapy.
- Local wound care and dressings may be required if ulcerations occur in the periangual regions or the central portions of large lesions during the involutional phase.
- Pulsed-dye laser or argon laser may be used with some hemangiomas to treat the pigmented lesion without damaging the overlying skin, sweat glands, and hair follicles. Lasers of 585-nm wavelength work well on vascular lesions, such as hemangiomas, which are rich in hemoglobin. The laser heats the hemoglobin, causing coagulation of the vessels in the dermis. Scar formation ensues and replaces the damaged blood vessels.
- Sclerotherapy with 1% sodium tetradecylsulfate, for small superficial lesions, or 100% ethanol, for large, deep saccular lesions, may be used in treating venous malformations.
- With the larger lesions, there is a possibility of skin ulceration, necrosis, inflammatory changes, and contracture due to the treatment, and patients should be warned to watch for these sequelae.
- In arteriovenous malformations interventional radiology may be used for embolization of selectively catheterized vessels with polyvinyl alcohol foam or tissue adhesive. This may be helpful if surgical resection is performed 24 to 48 hours later. If the lesion is small, this may completely occlude the malformation and destroy the lesion, eliminating the need for surgical resection. Several embolizations may be necessary to fully destroy small lesions.

FIG 9 • A. Angiogram of hypothenar hammer syndrome. The ulnar artery flow is absent and collaterals have formed to allow for flow in the palmar arch. This patient was relatively asymptomatic until a trauma to the hand. B. Angiogram of a second patient with hypothenar hammer syndrome. In this patient, there are no collaterals present, and he presented with coldness of the ulnar distribution digits.
■ Embolization may lead to residual tissue loss, neurologic deficit, and enlargement of the malformation if the lesion is large and not excised promptly.9,16
■ Either intralésional or systemic steroids may be useful for the treatment of hemangiomas, and a 6-week course may help to treat life-threatening or tissue-threatening lesions. This is also true for interferon alpha-2a or 2b. However, neither of these medications has been shown to have any effects on malformations, and the morbidity (neutropenia, elevation of liver enzymes, and spastic diparesis) of interferon must be considered before its use.24,29
■ Radiation therapy was used in the past for sclerosis of hemangiomas; however, it leads to atrophic changes in the skin and subcutaneous tissue as well as arrest of skeletal growth.17

SURGICAL MANAGEMENT
■ Indications for surgery include pain, intralésional thrombi, episodic bleeding or ulceration, recurrent infection, or functional problems related to the size or weight of the extremity. It is important to consider whether the extremity will be functional after the proposed surgical treatment; in many cases amputation may be a better option.23
■ Lymphatic malformations have the added difficulties of beta-hemolytic streptococcal sepsis, skin maceration, and vesicular eruptions. This makes the planning of surgical resection complex. Complications occur in 25% of all procedures. The surgeon should be aware that tumor-free tissues, such as grafts or flaps, may be necessary for coverage.23

Preoperative Planning
■ Radiographic studies should be reviewed carefully to plan resection of large or complex lesions.
■ An Allen’s test should be performed on the patient to evaluate for the patency of the superficial palmar arch and to see if the patient has an adequate ulnar artery.
■ If the Allen’s test is positive, reconstruction of the radial artery is necessary if it is to be resected.

Positioning
■ The patient should be placed in supine position with the arm abducted.
■ A proximal arm tourniquet is used, but the arm should not be exsanguinated with an Esmarch bandage to avoid the proximal spread or localized compression of the tumor. Exsanguination with the Esmarch bandage may also obscure the margins of hemangiomas and malformations.
■ Injections around the tumor should also be avoided to reduce the risk of local spread and compression of the mass, which could cause incomplete resection.

Approach
■ The technique chosen is based on the location of the lesion and the access necessary for excision.

Ligation of Feeding Vessel
■ For lesions that are small, with few feeder vessels, direct exploration and ligation of the feeding vessels can lead to involution of the lesion without significant tissue loss.
■ If tissue loss occurs, excision of the area and either primary closure, skin grafting, or flap reconstruction can be performed.

Staged Excision
■ Staged excision is useful for venous malformations, lymphatic malformations, combined malformations, and types A and B high-flow malformations.24
■ For larger lesions, the interventional radiologist may be helpful in embolizing feeding vessels. This will decrease or limit the amount of open exposure necessary in the first stage.
■ In this approach, the extremity is not exsanguinated completely to allow identification of the vessels more readily.
■ In the first stage, the tributary and exiting vessels are ligated proximal and distal to the tumor. It is possible that ligation of the vessels may induce distal ischemia. If this occurs, the surgeon should be prepared to bypass the anatomic defect with autogenous vein grafts.
■ At a second stage, the lesion is removed after the above procedure and depending on the condition of the patient. If necessary, the second procedure may be delayed. If the tumor is adherent to the skin, that portion of tissue is excised as well and the area is covered with grafts or flaps.17

Amputation
■ Amputation is the treatment choice for highly aggressive malignancies such as hemangiosarcoma, lymphangiosarcoma, aggressive hemangioendothelioma, and massive arteriovenous malformations that have created a nonfunctional extremity.
■ This should be performed with a proximal tourniquet for operative hemostasis.
■ If the lesion is too proximal for a tourniquet, an internal vascular balloon can be used to occlude the feeding vessel or vessels.
■ Guillotine amputation is an option if infection is present; otherwise, closure should be performed at the time of amputation.
■ The most common error we have seen after amputation of a digit or hand is failure to obtain adequate, tension-free soft tissue coverage.
■ Wide local excision may be considered for less aggressive hemangioendothelioma, hemangiopericytomas, malformations, and hemangiomas that have not involuted.

TRANSUNGUAL EXCISION
■ Transungual excision is an approach to subungual lesions, such as glomus tumors.
■ Make small radial and ulnar corner incisions over the nail fold (TECH FIG 1A,B).
■ Half the nail is then elevated and folded over, allowing for visualization of the nail matrix (TECH FIG 1C).
■ The nail can be completely removed with a Freer elevator if necessary for access to the tumor (TECH FIG 1D).

Approach
■ Make a longitudinal incision with a no. 15 blade into the nail matrix, directly over the tumor, and excise the lesion circumferentially down to the phalanx (TECH FIG 1E,F).
■ Curette the bone before the nail bed is closed with 6-0 plain gut.
■ Replace the nail into the eponychial fold as a dressing for the nail bed and suture the corner incision closed (TECH FIG 1G).15,21
TECH FIG 1 • A. Radial and/or ulnar incisions of the nail fold are drawn. If the lesion is proximal in the nail bed, one or both of these incisions may be necessary to access the lesion. B. The incisions are at oblique angles to the nail fold to avoid contracture of the area. C,D. The nail plate is elevated off the nail bed with a Freer elevator. Half the nail is elevated primarily (C), but the entire nail may be removed to allow for access to the lesion (D). Incision(s) are then extended, if necessary, to allow for visualization. E,F. A longitudinal incision is made in the nail bed to allow for removal of the lesion. The bone is curetted to remove any tumor and the nail bed is then closed with 6-0 or 7-0 plain gut. G. The nail plate is then replaced as the dressing and the incision(s) are closed with 5-0 or 6-0 nylon or chromic.

LATERAL INCISION

- This is an alternative to the transungual excision and allows exposure of the dorsal distal phalanx without violating the nail matrix. Because the view of the tumor is narrower, we do not recommend this approach.15
- If this approach is to be used, then a longitudinal midaxial incision slightly dorsal to the neurovascular bundle is used (TECH FIG 2A).
  - The incision is placed on the radial or ulnar surface of the digit, based on the location of the lesion.
  - Sharp dissection is carried out to the distal phalanx without manipulating the surrounding soft tissue.

- A small, sharp elevator is used to create a subperiosteal dorsal flap (TECH FIG 2B).
- A small curette or elevator is used to excise the lesion.
- The flap is replaced and the incision is closed with interrupted or running nylon suture.21,27

TECH FIG 2 • A. A midlateral incision is drawn just dorsal to the midaxial line. The incision is carried sharply down to the bone, keeping the neurovascular bundle volar to the incision and dissection. B. A Freer elevator is then used to create a subperiosteal flap to allow removal of the lesion. The incision is then closed with 5-0 or 6-0 nylon.
**EPIPHYSIODESIS**

- Epiphysiodesis, destroying the growth plate by scraping or drilling, may help to diminish hypertrophy in patients whose digits have reached adult size.
- Make a midaxial incision sharply, with dissection continued to the bone.
  - Retract the neurovascular bundle volarly to avoid injury (TECH FIG 3A).

- The dorsal branches may be transected if it is necessary to gain access to the dorsal aspect of the phalanx.
- Use a drill to destroy the growth plate of the phalanx (TECH FIG 3B).
- Close the incision with 5-0 or 6-0 nylon.

**PEARLS AND PITFALLS**

| Have a tourniquet on the extremity before the incision for arteriovenous malformations. | Avoid overly aggressive resection of lesions. |
| Make the family aware of the guarded prognosis for complete removal of arteriovenous malformations and the possibility of overgrowth or recurrence of the lesions. | Exsanguination of an arteriovenous malformation may lead to incomplete excision. |
| Insist on multiple high-quality imaging studies to evaluate the lesions | For small lesions, imaging may not fully show the lesion. |
| Check patient for associated syndromic abnormalities. | |

**POSTOPERATIVE CARE**

- After excision of the lesion, most patients will require a bulky dressing, and most will be able to return to their normal activity within 1 to 2 weeks.
  - Patients with partial resection of arteriovenous malformations may need to continue wearing compressive garments postoperatively when the dressings are removed.

- If patients required skin grafts or flaps, dressings and splints can be left in place to keep the patient from shearing the graft or pulling at the flap until the incisions are healed.
  - Graft bolsters or splints should be left in place for about 3 to 5 days to allow the graft to adhere well.
  - For patients who require amputations, prosthetics may be formed, depending on the level of the amputation. These are
more readily available for patients who have below- or above-elbow amputations, although patients who have forequarter amputations may also be candidates for specialized prosthetics.

- Patients will require physical therapy to teach them how to use prosthetics or to relearn hand function, if wide excisions were necessary.

OUTCOMES

- The prognosis of hemangiomas is not affected by race, gender, tumor site, size, or presence at birth.\textsuperscript{16}
- Attempts to excise arteriovenous malformations may lead to serious complications.
  - Complications are seen in about 22% of slow-flow lesions and 28% of fast-flow lesions. Wound dehiscence, seromas, and hematomas are noted early on. Partial skin loss and incision site infection are seen in the late postoperative period.
  - In fast-flow malformations, episodic bleeding and wound breakdown are more common.\textsuperscript{21}
  - After resection of venous malformations and lymphatic malformations, persistent edema and swelling are more frequent. Patients with type C malformations more consistently require multiple operative procedures due to complications.
  - Disseminated intravascular coagulation has been reported, and coagulation studies should be obtained before any intervention.
  - In the study by Mendel and Louis,\textsuperscript{16} 13 of 17 lesions persisted after excision through extension or recurrence. Ten of these lesions were diffuse. Thus, two thirds of lesions that are thought to be localized are diffuse and will require more than one procedure for complete excision.
  - In view of the high recurrence rate, excision should be considered in specific situations. Partial resection might be chosen to provide relief of symptoms, but as a balance between aggressive resection and preservation of function.\textsuperscript{16}
  - Patients who had wide local excision of venous malformations were found to have a 2% recurrence rate.\textsuperscript{14}
- It is generally accepted that primary tumor excision is the treatment of choice in all adults with venous malformations and children who have been observed for 1 year without regression of the lesion.
- Glomus tumors recur in 15% to 24% of patients, with an average time before recurrence of 2.9 years.
- Late presentation of recurrence is thought to be due to a new tumor near the site of excision. Patients who had incomplete excisions had recurrence of the tumor within weeks of surgery.
- In patients who had transungual excisions, nail deformities were noted in 26% of patients postoperatively.
- The prognosis of hemangiendothelioma depends on the grade of the tumor. Patients with low-grade lesions have a good long-term survival rate, and those with aggressive tumors may not survive longer than 2 years.\textsuperscript{11}
- Kaposi sarcoma in elderly non-HIV patients may be cured with wide-local excision; however, the accepted treatment for these patients is chemoradiation and alpha-interferon therapy. The 5-year survival rate of these patients is only 19%. In patients with HIV/AIDS, the mortality rate of Kaposi sarcoma was 80% at 2 years, but this has improved with highly active antiretroviral therapy (HAART).\textsuperscript{17}
- For patients with hemangiosarcoma, early radical amputation is the treatment of choice. Palliative radiation has also been used. The average survival is 2.5 years, and the 5-year survival rate is less than 20%. One third of patients with hemangiosarcoma have hemorrhage or coagulopathy, and 45% have nodal metastases.\textsuperscript{4,17}
- Glomangiosarcomas are believed to be low-grade malignancies; however, more than 25% of reported cases develop metastases.\textsuperscript{12} Wide local excision is the treatment of choice for these lesions, and close long-term follow-up is necessary.

COMPLICATIONS

- High-output cardiac failure
- Consumptive coagulopathy
- Bacterial endocarditis
- Distal ischemia
- Tissue loss
- Local infection
- Compartment syndrome
- Arterial steal
- Hematoma
- Seroma
- Partial wound dehiscence
- Cellulitis at the operative site
- Hypertrophic scarring
- Joint contracture
- Neuromas
- Reflex sympathetic dystrophy
- Pain
- Partial or total extremity gangrene
- Vesicle formation
- Recurrence
- Amputation

REFERENCES

DEFINITION
- Squamous cell carcinoma and melanoma represent malignant transformation of specific cells in either cutaneous or noncutaneous regions of the body.
- Both squamous cell carcinoma and melanoma demonstrate ability to extend locally, involve regional lymph node basins, and metastasize to distant sites.
- In the upper extremity, the nail matrix is the noncutaneous location for these malignancies (FIG 1).
- In 1886, Hutchinson first described subungual melanoma and initially termed it melanotic whitlow, because it often resembled an infection. Subungual melanoma is rare, accounting for only 1% to 3% of all cases of melanoma.
- Critical to management of squamous cell carcinoma and melanoma of the hand and upper extremity are early diagnosis, accurate histopathologic evaluation, detailed staging, appropriate surgical, medical, and radiation management, and appropriate follow-up.

ANATOMY
- Both squamous cell carcinoma and melanoma develop from different skin layers. Intact skin demonstrates histologic features of the epidermis and dermis that act as physiologic barriers to infection and malignancy.
- Squamous cell carcinomas develop from epidermal keratinocyte cell layers but can develop in the nail matrix complex.
- Melanoma cells derive from the dendritic cells of the epidermis; they originate from neural crest cells. These neural crest cell–derived melanocytes migrate to both cutaneous and noncutaneous locations. For the hand and upper extremity, the nail apparatus is a significant migration site. Melanomas are not always pigmented (amelanotic melanomas). However, melanomas are typically pigmented and reflect irregular color, surface, and perimeter.

PATHOGENESIS
- Squamous cell carcinomas develop from epidermal keratinocyte cell layers. Risk factors include the following:
  - Damage from sun, heat, and wind
  - Severe burns and chronic ulcers
  - Increasing age
  - Immune compromise (organ transplantation and AIDS)
- The typical squamous cell carcinoma lesion is a rapidly growing, firm, scaly papule or nodule that develops a central ulcer and an indurated raised border with some surrounding inflammation (FIG 2A–D).
- In contrast to basal cell carcinomas, there is no pearly telangiectatic perimeter.
- Major risks for melanoma include:
  - Personal or family history of melanoma. Patients with a history of melanoma have a 3.5% chance of developing a second melanoma.
  - The presence of a mole that has changed over time
  - Other general risk factors for skin cancer, including sun sensitivity; excessive sun exposure; immune compromise; prior basal cell or squamous cell cancers; or exposure to coal tar, pitch, arsenical compounds, x-radiation, or radium.

FIG 1 • Thumb eponychial lesion treated as both an infection and mucous cyst. Histopathology demonstrated invasive squamous cell carcinoma. Treatment included amputation at the IP joint level and selective lymph node sampling.

NATURAL HISTORY

- In 2007, the American Cancer Society estimated 59,940 new cases of melanoma for both sexes, with an estimated 8110 deaths. Additionally, an estimated 48,290 cases of melanoma in situ were diagnosed.
- The probability of developing melanoma from birth to death is 2.04 (1 in 49) in males and 1.38 (1 in 73) in females. Neither basal cell carcinoma nor squamous cell carcinoma is a reportable disease. Basal cell carcinoma is the most common form of skin cancer and squamous cell carcinoma is the second most common type.
- For 2007, the American Cancer Society estimated more than 1 million new diagnoses of basal and squamous cell carcinomas of the skin. However, basal and squamous cell skin cancers account for less than 0.1% of patient deaths caused by all cancers.
- Nail matrix and nail bed squamous cell carcinoma or melanoma account for less than 1% of respective cutaneous malignancies. The histologic features of the epidermis and dermis, including physiologic barriers, are absent in the nail complex. In the nail complex, the matrix is adherent to the underlying phalanx.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present for evaluation of skin findings or after noting a change.
- Change or variation in an existing lesion and the presence of other risk factors are the important components of patient history.
  - Changes in size, shape, or color of a skin or matrix lesion or the development of a new skin or matrix lesion over a limited time should be monitored.
  - Such changes over a limited time must be diagnosed by histopathology.
- The lesion should be precisely characterized on physical examination. Critical findings include:
  - Irregularity or asymmetry
  - Diameter more than 6 mm
  - Presence of satellite lesions
  - Regional lymph nodes (epitrochlear and axillary) should be routinely examined in all suspected cases of squamous cell carcinoma and melanoma.
- Close regional lymph node examination is required in cases of squamous cell carcinoma arising in sites of chronic ulceration or inflammation, burn scars, or sites of previous radiation therapy, especially for high-risk areas of the hand.
- Melanoma and squamous cell carcinoma can metastasize. A full local, regional, and metastatic workup is necessary.
- Nail matrix and nail bed squamous cell carcinoma or melanoma requires specific consideration during the physical examination.
- The presence of the Hutchinson sign (extension of brown-black pigment from the nail bed, matrix, and nail plate onto the adjacent cuticle and proximal or lateral nail folds) is consistent with a subungual melanoma.
- Subungual melanoma is also suspected when the nail bed contains a new or enlarging pigmented streak wider than 3 mm.
- The absence of periungual pigmentation does not preclude the diagnosis of subungual melanoma.
- Although there have been reports of amelanotic melanoma of the nail bed, the actual incidence is unknown and has never been reported in the literature.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographic evaluation with plain views can reveal bone involvement, especially for matrix lesions.
- For both squamous cell carcinoma and melanoma, a chest radiograph, complete blood count, and liver panel should be obtained.
- More detailed imaging studies (CT, MRI, and PET) are performed to evaluate specific organ systems (central nervous system, pulmonary, gastrointestinal, and others) as indicated.
- Diagnosis of these pathologies requires adequate histopathologic evaluation. Full-thickness (surface to full depth) perimeter and core samples are required. Suspicious lesions must never be shaved, cauterized, or vaporized.
- If the initial surgical pathologist is uncertain of the histopathology, the specimen slides and appropriate imaging studies must be forwarded to an independent qualified pathologist for review.
- There is significant discordance among pathologists in the histologic diagnosis regarding melanoma and benign pigmented lesions. One study noted discordance in 37 of 140 cases examined by a panel of experienced dermatopathologists.
on melanoma versus benign lesions. Another study noted a 38% discordance rate in cases examined by an expert pathologist panel.

- Squamous cell carcinoma is graded 1 to 4 based on the proportion of differentiating cells present, the degree of atypicality of tumor cells, and the depth of tumor penetration.
- The clinicopathologic cellular malignant melanoma subtypes are (these are descriptive, not prognostic or therapeutic):
  - Superficial spreading: most common, 70%
  - Nodular: 15% to 30%, more aggressive
  - Lentigo maligna: most common subtype among Asians and African-Americans
  - Acral lentiginous (palmar–plantar and subungal)
  - Miscellaneous unusual types:
    - Mucosal lentiginous (oral and genital)
    - Desmoplastic
    - Verrucous
- Malignant melanoma microstage is determined by histopathologic evaluation of the vertical thickness of the lesion in millimeters (Breslow classification) or the anatomic level of local invasion (Clark classification).
- The Breslow thickness is more reproducible and more accurately predicts subsequent behavior of malignant melanoma in lesions thicker than 1.5 mm. Estimates of prognostic should be modified by sex and anatomic site in coordination with clinical and histologic evaluation.
- For cutaneous melanoma, Breslow thickness and presence of ulceration demonstrated the highest concordance. Discordance was significant for Clark level of invasion, presence of regression, and lymphocytic infiltration.
- The Clark classification ranges from level I (in situ lesions involving only the epidermis) to level V (invasion through the reticular dermis into the subcutaneous tissue).
- Micrometastases are diagnosed by elective sentinel lymphadenectomy; macrometastases are defined as clinically detectable lymph node metastases confirmed by therapeutic lymphadenectomy, or when any lymph node metastasis exhibits gross extracapsular extension.
- Clinical staging includes microstaging of the primary melanoma and clinical or radiologic (or both) evaluation for metastases. By convention, AFCC stage should be assigned after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.
- With the exception of clinical stage 0 or stage IA patients (who have a low risk of lymphatic involvement and do not require pathologic evaluation of the lymph nodes), pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after sentinel node biopsy and, if indicated, complete lymphadenectomy.

**DIFFERENTIAL DIAGNOSIS**

- Seborrheic keratosis
- Pigmented actinic keratosis
- Hemangioma
- Dermatofibroma
- Blue nevus
- Basal cell carcinoma
- Cutaneous T-cell lymphomas (e.g., mycosis fungoides)
- Kaposi sarcoma
- Extramammary Paget disease

- Apocrine carcinoma of the skin
- Metastatic malignancies from various primary sites
- The differential diagnosis of subungal melanoma includes chronic paronychia and onychomycosis, subungal hematoma, pyogenic granuloma, and glomus tumor.

**NONOPERATIVE MANAGEMENT**

**Squamous Cell Carcinoma**

- Electrodessication and curettage, and cryosurgery may be useful for small, well-defined in situ tumors in patients with medical conditions limiting excisional surgery.
- Depth of treatment may not correlate with depth of tumor and therefore may be inadequate.
- Cryosurgery should not be used for carcinomas fixed to the underlying bone, cartilage, or tendons.
- Proximity of nerves limits cryosurgery use, such as in tumors situated on the lateral margins of the digits and at the cubital tunnel.
- Cryosurgery is complicated by significant morbidity, particularly edema, which is common after treatment. Permanent depigmentation and atrophy are common.
- Radiation therapy is a logical treatment choice, particularly for medically compromised patients with primary lesions requiring difficult or extensive surgery.
- Radiation therapy can be used for recurrent lesions after a primary surgical removal.
- Radiation therapy is contraindicated for patients with xeroderma pigmentosum, epidermodysplasia verruciformis, or the basal cell nevus syndrome.
- Topical fluorouracil (5-FU) may be helpful in the management of selected in situ squamous cell carcinomas (Bowen disease).
- Deep follicular tumors may not be reached by topical 5-FU. In these instances, recurrence or progression can occur.
- Close follow-up over time is required.
- Carbon dioxide laser treatment may be useful in a subset of medically compromised patients with small squamous cell carcinoma in situ.
- Since the CO₂ laser coagulates, this technique is valuable for patients with a bleeding diathesis.
- Malignant melanoma can spontaneously regress, but the incidence of spontaneous, complete regressions is less than 1%

**SURGICAL MANAGEMENT**

- The fundamental oncologic principle of tumor clearance first and then reconstruction second should be followed without compromising tumor ablation.
- Lymph node management is directed by clinical involvement or selective lymph node sampling results.
- Wide local excision is recommended for melanomas.

**Cutaneous Squamous Cell Carcinoma**

- The two primary methods of treatment are surgical excision with frozen or permanent histopathologic sections and Mohs micrographic surgery.
- When surgically excising these lesions, the surgeon should maintain a 3- to 10-mm margin of disease-free tissue (depending on the diameter).
- Surgical excision without Mohs technique, using either frozen or permanent histopathologic control, is associated with a significant recurrence rate.
The Mohs technique to microscopically track subclinical tumor extensions results in the highest cure rate with maximal preservation of normal tissue.

**Nail Matrix Squamous Cell Carcinoma**
- For invasive squamous cell carcinoma of the nail matrix (FIG 3), the appropriate technique is amputation at the distal joint level for that digit.
- However, Mohs technique with grafting has been reported in small series of invasive squamous cell carcinoma of the nail matrix with limited follow-up.
- For noninvasive nail matrix squamous cell carcinoma, Mohs technique with grafting is performed.

**Cutaneous Melanoma**
- Melanomas of the hands and feet less than 1.5 mm thick have a low incidence of nodal metastases and are treated effectively with wide excision of the primary tumor with a 1-cm margin.
- Thicker melanomas are associated with a more than 50% rate of regional or systemic failure. In the absence of metastatic disease, these individuals should undergo local excision with a 2-cm margin and intraoperative lymphatic mapping followed by lymphadenectomy if the sentinel node is positive (FIG 4A,B).
- Specific recommendations are individualized for each patient. Factors that affect these recommendations include the primary tumor's anatomic location, specific tumor features, healing ability, and medical risk factors.
- The surgical goal is to minimize local and regional recurrence and metastasis while maintaining acceptable risks to minimize morbidity and mortality.

**Nail Matrix Melanoma**
- Melanomas of the nail complex (FIG 5) are unique because of the lack of the biologic barriers of skin and the proximity of the underlying phalanx and tendons.
- These features cause Breslow thickness and Clark level to be less useful.
- Complete digital or ray amputations of the thumb or fingers result in significant functional deficits without significant survival benefit.
- The respective digit is amputated proximal to the distal interphalangeal joint of the fingers and the interphalangeal joint of the thumb if the extent of nail apparatus involvement allows.
- For more proximal digital melanoma with bone involvement or perineural invasion, either complete digital amputation or ray amputation is indicated for more proximal phalangeal or metacarpal bony involvement respectively or nerve invasion.
- Without bony involvement or perineural invasion, the area of wide local excision is directed by the Breslow thickness.
Specific recommendations are individualized for each patient. Other significant factors, such as the primary tumor anatomic location, specific tumor features, healing ability, and medical risk factors, must be considered. The surgical goal is to minimize local and regional recurrence and metastasis while maintaining acceptable risks to minimize morbidity and mortality.

**Coverage and Reconstruction**
- After wide local excision, most wounds can be closed primarily without tension using minimal perimeter undermining and layered closure.
- If time is required to establish final histopathology, a temporary negative-pressure wound system can be used.
- Coverage and reconstruction must match requirements at the ablation site.
- The coverage options progress from less to more complex: closure, skin graft, local flap, regional flap, then microsurgically transplanted flap.
- Exposed vessels, nerves, tendons, and bone often necessitate flap coverage.
- Surgical flaps benefit poorly vascularized and chronic (more than 3 weeks) wounds.
- Skin grafting can be either split or full thickness depending on the wound bed vascularity, anatomic area, and aesthetics.
- Digital V-Y flaps, cross-finger flaps, flag flaps, dorsal metacarpal artery flaps, and radial forearm flaps are commonly used local and regional flaps.

**Preoperative Planning**
- To direct management of local tumor, regional lymph nodes, and metastatic disease, the patient must be staged for both squamous cell carcinoma and melanoma. The histopathology of the primary tumor is determined by an accurate histopathologic diagnosis.
- Mohs micrographic surgery requires the assistance of a trained dermatologist.
- Before resection, plans must be made for coverage.

**Positioning**
- Positioning is supine with the upper extremity supported on an arm table.
- Positioning should allow approach to the primary tumor and the regional lymph node basin.
- A sterile tourniquet is used. When access to the axillary lymph nodes is required, the tourniquet is removed.

**Approach**
- For wide local excision, the primary lesion is marked and the indicated margin is measured around the lesion using calipers.
- Wide local excision includes the intact tumor or biopsy site en bloc with a defined perimeter of normal skin and underlying subcutaneous tissue. The underlying muscular fascia is not typically included.
- Inadequate, narrow excisions increase the risk of local and regional failure and affect survival.
- For primary closure, an ellipse is marked out incorporating the required margins for wide local excision.
- The excised length-to-lesion-diameter is at least 3:1.
- For amputation, the distal joint level is marked, along with the fish-mouth dorsal and volar flaps.
- For selective lymph node sampling, a grid is marked over the axillary area. The point of highest radioactivity is marked on the grid.

**MOHS MICROGRAPHIC SURGERY**
- Remove all gross tumor.
- Excise a thin layer of tissue with 2- to 3-mm margins. Flatten the specimen with the beveled peripheral skin edge positioned in the same horizontal plane with the deep margin.
- Map the tissue with color-coded three-dimensional orientation.
- Send the specimen for frozen-section processing.
- Both the deep and peripheral margins are examined in one horizontal plane by frozen-section analysis with total (theoretically 100%) margin control.
- After histologic interpretation of the frozen-section specimens, the precise anatomic location of any residual tumor is identified and re-excised until tumor-free three-dimensional margins are obtained.

**PEARLS AND PITFALLS**

</table>
POSTOPERATIVE CARE
- Initial postoperative care focuses on pain control and protection of the operated part.
- Occupational therapy is by protocol, depending primarily on the coverage performed.
- Patients must be monitored.
  - Squamous cell carcinoma has metastatic potential. Depending on the relative risk for recurrence and invasion, patients should be re-examined every 3 months for the first several years, then every 6 months for 3 years, and then yearly indefinitely. Evaluation is for local recurrence, lymph node involvement, metastasis, additional nonmelanoma skin cancers, and melanomas. Laboratory evaluation, blood count, and liver enzymes may be useful for monitoring particularly aggressive squamous cell tumors.
  - For melanoma, the follow-up schedule for patients who have surgically resected disease is based on the primary lesion’s Breslow thickness and the nodal involvement. Patients with thin primary melanoma and negative nodes are followed with clinical examination for evidence of occurrence every 6 months for the first 2 to 3 years and then yearly for 2 to 3 years beyond that. Patients with intermediate or thick melanomas and negative regional nodes are followed every 3 to 6 months for the first 2 to 3 years and every 6 to 12 months for the next 2 to 3 years. Patients with resected regional disease require follow-up every 3 to 4 months for the first 2 years, then every 6 months up to year 5, and yearly beyond that. All patients must maintain routine lifelong dermatologic screening. Patients with one melanoma remain at higher-than-average risk for a second primary melanoma and are at risk for basal cell and squamous cell carcinomas.

OUTCOMES
- Squamous cell carcinoma is the second most common type of skin malignancy. Although the basal cell and squamous types of skin cancer are the most common of all malignancies, they account for less than 0.1% of cancer deaths.
- The overall cure rate for squamous cell carcinoma is directly related to the stage of the disease and the type of treatment used. Since squamous cell carcinoma is not a reportable disease, precise 5-year cure rates are not known.
- Melanoma 5-year survival rates are related to stage and range from 18% for stage IV to 99% for stage IA.

COMPLICATIONS
- Sentinel lymph node biopsy is not without complications. The most common complications are hematoma and seroma. The rate of lymphedema after sentinel lymph node biopsy has been reported to be 0.7% to 1.7%, compared with 4.6% (axillary) and 31.5% (inguinal) with completion lymphadenectomy.
- Inadequate margin for squamous cell carcinoma on final pathology is corrected by re-excision using the Mohs technique.
- Inadequate margin for melanoma on final pathology is corrected by appropriate increase or expansion of the surgical margins.
- Excessive tension on wound closure is corrected by skin graft or appropriate flap coverage.

REFERENCES
DEFINITION

Ganglion Cysts

- Ganglion cysts, although not true cysts, are the most common tumors of the hand and wrist.
- These fluid-filled cysts are a frequent cause of hand and wrist pain.
- Ganglion cysts typically arise from either a joint or tendon sheath.
- Most ganglion cysts occur in the wrist. Dorsal wrist ganglion cysts account for 60% to 70% of all ganglion cysts, with volar wrist ganglion cysts accounting for about 18% to 20%.
- Ganglion cysts may also arise from a tendon sheath (volar retinacular cyst), or occur in association with arthritis (degenerative mucous cyst).

Giant Cell Tumors

- Giant cell tumors of the tendon sheath—also referred to as localized nodular synovitis, fibrous xanthoma, and pigmented villonodular synovitis—are benign, slow-growing soft tissue tumors.
- After ganglion cyst cysts, these lesions are the second most common tumor in the hand.

Epidermal Inclusion Cysts

- Epidermal inclusion cysts are well-circumscribed, firm, and slightly mobile lesions.
- They are often superficial and adherent to overlying skin.
- They may be flesh-colored, yellow, or white.
- They contain a thick white keratinous material.
- Cysts in the fingertip may erode into the distal phalanx, causing a lytic lesion.
- Histologically, they are cysts filled with keratin and lined with epithelial cells.

ANATOMY

Ganglion Cysts

- Ganglion cysts typically consist of a cyst sac that communicates through a stalk to an underlying joint or tendon sheath (FIG 1).
- The cyst sac may have a single cavity or be multilobulated.
- Although not a true cyst, lacking an epithelial lining, ganglion cysts are typically filled with a clear, viscous, jelly-like mucinous fluid made up of glucosamine, albumin, globulin, and a high concentration of hyaluronic acid.

Giant Cell Tumors

- The tumor is usually a multilobular, well-circumscribed mass, ranging in size from 0.5 to 7 cm.
- The color ranges from yellow to deep brown depending on the amount of hemosiderin, histiocytes, and collagen present in the lesion.
- These lesions have a thin pseudocapsule. Aggressive lesions may invade adjacent soft tissue, tendon, and capsular structures and can envelop neurovascular bundles. A large study showed joint involvement in one fifth of all cases.
- Longstanding lesions may erode into cortical bone but will not involve cartilage or the medullary canal of bone. Satellite lesions may occur.
- Histologically, giant cell tumors contain collagen-producing polyhedral-shaped histiocytes, scattered multinucleated giant cells, and hemosiderin deposits.

Epidermal Inclusion Cysts

- Epidermal inclusion cysts are well-circumscribed, firm, and slightly mobile lesions.
- They are often superficial and adherent to overlying skin.
- They may be flesh-colored, yellow, or white.
- They contain a thick white keratinous material.
- Cysts in the fingertip may erode into the distal phalanx, causing a lytic lesion.
- Histologically, they are cysts filled with keratin and lined with epithelial cells.
PATHOGENESIS

Ganglion Cysts
- The true causes of ganglion cysts remain unclear, although multiple theories have been proposed.
- Some early investigators theorized that ganglion cysts occurred as the result of synovial herniation, and others felt that ganglion cysts resulted from mucoid degeneration.
- A more recent theory proposes that ganglion cysts arise from stress at the synovial capsular interface. This stress, such as stretching of the capsular and ligamentous structures, stimulates the production of mucin from modified synovial, mesenchymal, and fibroblast cells, all of which have been shown to produce hyaluronic acid. The mucin then dissect through the capsular and ligamentous tissues, forming the main cyst. The fluid may enter the cyst from the capsular ligamentous interface via a one-way valve type of mechanism and then decrease as the water component is resorbed, accounting for the often-fluctuating cyst size.1

Giant Cell Tumors
- The cause of giant cell tumors is not known. There is a strong association of giant cell tumors with rheumatoid arthritis. There are no clinical studies associating these tumors with trauma.6
- Although these tumors are histologically similar to the pigmented villonodular synovitis seen in large joints in the lower extremity, they are thought to be clinically distinct lesions.

Epidermal Inclusion Cysts
- Epidermal inclusion cysts occur as a result of trauma when epithelial cells are introduced into the underlying subcutaneous tissues or bone. These cells slowly grow to produce a cyst lined with epithelial cells and filled with keratin.

NATURAL HISTORY

Ganglion Cysts
- Ganglion cysts typically arise spontaneously and are most common in the second through the fourth decade but may arise in the pediatric population20 as well as the aged.
- Once present, ganglion cysts tend to fluctuate in size depending on the amount of fluid present in the cyst at any given time. Patients often note that the cyst becomes larger after increased periods of activity and decreases in size with inactivity.
- Ganglion cysts tend to be self-limiting and do not typically continue to expand in size.
- If left untreated, ganglion cysts can persist for years. They may resolve or rupture spontaneously. One cannot predict how long that they will persist or if and when they will resolve.
- Resolution is far more common in the pediatric population.

Giant Cell Tumors
- The lesion begins as a single nodule, becoming multinodular as it enlarges.
- Malignant transformation of giant cell tumor of the tendon sheath in the hand has not been reported.8

Epidermal Inclusion Cysts
- These lesions occur months to years after a traumatic event. They grow slowly to produce a painless mass, most commonly seen in the fingertip.
- Malignant transformation of these lesions in the hand has not been reported.12

PATIENT HISTORY AND PHYSICAL FINDINGS

Ganglion Cysts
- Patients often present with an asymptomatic mass that has been present for weeks to years.
- A history of trauma is often absent.
- Pain if present is often described as a dull ache. Nocturnal pain is uncommon and pain is more common with active hand use.
- Paresthesias are rare but can occur if the ganglion cyst compresses any local nerves.
- Patients often report that the mass tends to fluctuate in size, a characteristic typical of ganglion cysts and not typical of other types of soft tissue tumors.
- Patients with wrist ganglion cysts—particularly dorsal wrist cysts—will often complain of weakness of grip.
- Patients with dorsal wrist ganglion cysts most commonly note a mass over the dorsum of the wrist, typically over the dorsal scapholunate region. In contrast, patients with volar wrist ganglion cysts typically note a mass over the volar aspect of the wrist in the interval between the flexor carpi radialis and first extensor compartment tendons.
- Volar retinacular cysts or ganglion cysts of tendon sheath usually present as a mass in the palm in the region of the first and second annular pulleys. The cyst is typically fluctuant but may feel like a firm nodule. The cyst is usually slightly mobile but does not often glide with flexor tendon movement.
- These types of cysts are often painless at rest but become painful when patients perform activities that involve forceful grip.
- Degenerative mucous cysts are ganglion cysts that arise from the distal interphalangeal joint, usually in association with underlying osteoarthritis.4 Patients often note a painless soft tissue mass that arises from the dorsal surface of the joint, radially or ulnarly (less commonly in the midline), often extending into the eponychial fold region.
- Commonly, the cyst will thin the overlying dermis, resulting in rupture of the skin, and the patient often reports drainage.
- Physical examination begins with inspection (FIG 2).
- Being fluid-filled, ganglion cysts will often transilluminate, whereas other more solid soft tissue lesions will not.
- Ganglion cysts usually occur in specific locations in the hand and wrist. Swelling or masses in these locations are diagnostic clues that a ganglion cyst may be present.
- The examiner should palpate the mass for fluctuance and mobility and assess tenderness.
- Ganglion cysts are generally fluctuant and slightly mobile. When they become more distended with fluid they may feel more firm and less fluctuant. Firm, less mobile masses suggest the possibility of other soft tissue lesions.
- Ganglion cysts of tendon sheath do not usually glide with tendon motion, but less common ganglion cysts, such as those that arise in the fourth extensor compartment, are often adherent and do glide with tendon motion.
- The examiner should assess joint mobility through the range of motion. With the exception of dorsal wrist ganglion cysts, which may cause some loss of wrist dorsiflexion secondary to impingement, loss of joint range of motion suggests the possibility of an underlying joint abnormality.
Giant Cell Tumors
- Giant cell tumors are most common in the fourth to sixth decade, with a slight predominance in women.
- Patients typically present with a slow-growing, multinodulated, firm, painless mass present for several months to years.
- Lesions usually occur in the radial three digits of the hand on the volar surface. Dorsal involvement, particularly around the distal interphalangeal joint, is not uncommon.7
- These lesions are typically firmer than ganglion cysts and do not transilluminate.
- Large lesions may limit range of motion or result in neuropathic symptoms as a result of compression of digital nerves.
- Direct palpation typically reveals a firm, multinodular, non-tender lesion.
- Loss of range of motion may occur when large lesions occur near the interphalangeal joints.
- Patients may have sensory deficits secondary to digital nerve compression. These can be revealed by testing two-point discrimination.

Epidermal Inclusion Cysts
- Epidermal inclusion cysts are more common in men than in women and occur in the third to fourth decade.2
- Patients commonly present with a painless, slow-growing mass after a laceration, puncture wound, or traumatic amputation of the finger.2
- These lesions should be suspected in laborers who have a painless mass in the palm.12
- Erythematous and painful lesions have been reported. One study reported two cases mimicking a collar button abscess resulting from rupture of the cyst in the palmar soft tissues.21
- These lesions are typically firmer than ganglion cysts and do not transilluminate.
- Direct palpation will reveal a lesion that is firm, nontender, superficial, and mobile.
- Loss of range of motion may occur when large lesions occur near the interphalangeal joints.

Two-point discrimination testing may reveal sensory deficits secondary to digital nerve compression.

IMAGING AND OTHER DIAGNOSTIC STUDIES
Ganglion Cysts
- Radiographs are obtained if there is clinical suspicion of an underlying bony abnormality noted on physical examination, such as joint crepitation, swelling, carpal instability, or a history of trauma.
- Radiographs are also useful in identifying an intrasosseous ganglion cyst in patients with wrist pain of uncertain cause (FIG 3A).
- Radiographs are also often obtained in patients with a degenerative mucous cyst of the digit since the cysts typically arise as the result of degenerative arthritis of the distal interphalangeal joint.
- If the clinical findings suggest the possibility of an occult ganglion cyst, or if there is suspicion that the patient may have a symptomatic intrasosseous ganglion cyst, magnetic resonance imaging (MRI) can be a useful tool to confirm the diagnosis (FIG 3B).
- MRI can also be used to better localize the site of origin as part of preoperative planning in ganglion cysts that occur in atypical locations (FIG 3C,D).
- Ultrasound can also be used to diagnose ganglion cysts, but this test is examiner-dependent and less sensitive and specific than MRI.
- Computed tomography scans are generally obtained only for preoperative planning to better localize and evaluate the bony architecture of intrasosseous ganglion cysts.

Giant Cell Tumors
- Plain radiographs show a soft tissue mass. Juxtacortical lesions may show bony erosion.
- MRI demonstrates a benign-appearing encapsulated mass, with decreased signal on T1- and T2-weighted images.
Epidermal Inclusion Cysts
- Plain radiographs show a soft tissue mass.
- A lytic lesion may be seen in the distal phalanx if it erodes into bone.

DIFFERENTIAL DIAGNOSIS
Ganglion Cysts
- Epidermoid inclusion cyst
- Giant cell tumor of tendon sheath
- Lipoma
- Synovial cyst

Giant Cell Tumors
- Fibroma of the tendon sheath, synovial chondromatosis, synovial hemangioma, tophaceous gout, foreign body granuloma, periosteal chondroma

Epidermal Inclusion Cysts
- Tophaceous gout, foreign body granuloma, giant cell tumor, ganglion cyst, sebaceous cyst
- Bony destruction may mimic a malignant or infectious process. Some patients with these lesions have been treated with primary amputation before pathologic diagnosis.

NONOPERATIVE MANAGEMENT
- Of the three tumors discussed in this chapter, only ganglion cysts can be managed without surgery.
- Ganglion cysts are benign cysts that may resolve spontaneously. Treatment often depends on the level of a patient’s symptoms. Many patients seek medical care because they are concerned about the presence of a soft tissue mass and possibility of malignancy. Once a diagnosis of a ganglion cyst is made, with proper counseling as to the nature of these lesions, many patients will be satisfied with a course of observation.
- In patients who are symptomatic, typical nonoperative treatments include rest and immobilization, oral analgesics such as nonsteroidal anti-inflammatories and acetaminophen, and aspiration of the cyst with or without injection. In wrist ganglion cysts, the results of aspiration have variable cure rates in the literature, ranging from 15% to 89%. Various agents have been injected into the ganglion cyst after aspiration, including hyaluronidase and methylprednisolone. On average, injection does not seem to increase the cure rate after aspiration, and we now typically perform aspiration alone. We generally inform patients that aspiration has about a 50% cure rate. The use of sclerosing agents is frowned on since these agents may cause articular damage.
- Traditional methods of traumatic rupture of the cyst from a direct blow with an object such as a large book (hence the term “Bible cyst”) are mostly of historical significance.
- Ganglion cysts of tendon sheath (volar retinacular cysts) when symptomatic often respond to aspiration and injection and rarely require surgery when not associated with stenosing tenosynovitis. When they occur in association with stenosing tenosynovitis (trigger finger, De Quervain tendinitis), they often resolve with successful treatment of the underlying tendinitis.
- We typically do not aspirate ganglion cysts of tendon sheath but have had great success by injecting these cysts with local anesthetic and a small amount of corticosteroid (1.5 to 2 mL of 1% lidocaine and 10 mg of Depo-Medrol). The cyst is entered with a 25-gauge needle and then distended...
to the point of rupture. The remaining fluid in the syringe is then injected into the tendon sheath. If necessary, gentle digital massage can be used to rupture the cyst after injection if the cyst fails to rupture with distention.

**SURGICAL MANAGEMENT**

**Indications**

**Ganglion Cysts**
- Surgery is generally indicated in patients who have symptoms and who either have failed nonoperative treatment or choose to proceed directly with surgery.
- In patients who have been diagnosed with a symptomatic wrist ganglion cyst, we generally describe the nature of the condition and outline the available forms of treatment, allowing the patient to decide which treatment is best for him or her. Some patients will choose observation, others will elect to undergo an aspiration, and some will chose to proceed directly with surgical excision.
- In the case of symptomatic ganglion cysts of tendon sheath, most of these will resolve with a corticosteroid injection, and surgery is reserved for cysts that continue to recur.
- Degenerative mucous cysts that are draining or have a history of draining should be treated operatively, since these cysts are at risk for infection that may extend into the distal interphalangeal joint and result in septic arthritis. If not draining, these cysts can be treated nonoperatively or surgically, depending on the patient’s symptoms and choice of treatment.
- Intraosseous ganglion cysts that are symptomatic or have resulted in pathologic fracture or may exhibit an impending pathologic fracture are often treated operatively.

**Giant Cell Tumors**
- Indications for surgery include appearance, neuropathic symptoms, or loss of function.
- Careful, meticulous marginal excision of the lesion is the treatment of choice.
- Care must be taken to protect the neurovascular structures.
- Satellite lesions must be identified and carefully removed to minimize the chance of recurrence.

**Epidermal Inclusion Cysts**
- Indications for surgery include appearance, diagnosis, pain, and loss of function.
- Marginal excision of the lesion is the treatment of choice.

**Preoperative Planning**

**Ganglion Cysts**
- When removing ganglion cysts arising in atypical locations, MRI studies can help to identify the cyst origin and plan appropriate surgical exposure.
- MRI and CT scans, along with plain radiographs, are valuable to determine the ideal exposure and for treating intraosseous ganglion cysts with curettage and bone grafting.
- Plain radiographs are reviewed before excising degenerative mucous cysts to determine the extent of underlying osteophytes that may need to be addressed.

**Giant Cell Tumors**
- While the diagnosis of giant cell tumor is primarily made based on history and clinical examination, radiographic studies should be reviewed to rule out other conditions.
- The patient should be advised that even with careful surgical techniques, the recurrence rate can be as high as 5% to 50%. Risk factors for local recurrence include proximity to the distal interphalangeal joint, degenerative joint disease, and bony erosion.
- Temporary digital nerve neurapraxias may also occur after extrication of these tumors during surgery.

**Epidermal Inclusion Cysts**
- While the diagnosis of epidermal inclusion cyst is primarily made based on history and clinical examination, radiographic studies should be reviewed to rule out other conditions.
- If a lytic lesion is present in the distal phalanx, a biopsy should be considered before surgical removal.
- The recurrence rate after marginal excision is low.

**Positioning**
- Patients undergoing hand or wrist surgery are positioned supine on the operating table with the operative extremity resting on a hand table. This position allows for circumferential access to the hand and wrist.
- The procedure is performed under regional anesthesia with a tourniquet applied to the upper arm, or under a digital block with a tourniquet applied to the digit.
- For arthroscopic procedures, a traction tower or longitudinal fingertrap traction is used (FIG 4).

**Approach**

**Ganglion Cysts**
- Standard approaches to the hand and wrist are used, depending on the location of the cyst.
- It is important to have a good understanding of the anatomy and the most likely origin of the cyst to best plan the incision and dissection to avoid injury to important neurovascular structures.
- When treating ganglion cysts in atypical locations, preoperative studies can aid in determining the best surgical
approach, since the origin of the cyst can be remote from the cyst (Fig 3D).

- Volar giant cell tumors and epidermal inclusion cysts are approached through Brunner zigzag incisions (FIG 5A).
- Dorsal giant cell tumors require dorsal midline or curvilinear incisions, whereas dorsal epidermal inclusion cysts can be approached through small longitudinal incisions directly over the lesion (FIG 5B).
- Incisions should be designed for a possible extensile exposure, which may be necessary for complete excision of the lesion.

**OPEN EXCISION OF A DORSAL WRIST GANGLION CYST**

- The location of the cyst is typically dorsal to the scapholunate interosseous ligament. The incision needs to provide access to this ligament. The scapholunate ligament is found just distal to the tubercle of Lister in the third and fourth extensor compartment interval (TECH FIG 1A).
- We generally perform a transverse skin incision centered over the scapholunate ligament region and cyst. This incision heals with the best appearance (TECH FIG 1B).
- Dissect the subcutaneous tissues with blunt dissection, taking care to protect and preserve any branches of the dorsal radial and ulnar sensory nerves. Loupe magnification is often helpful.
- The extensor retinaculum is generally not well developed at this level and is incised transversely as the cyst is dissected from the surrounding soft tissues (TECH FIG 1C).
- The cyst is identified typically in the interval between the third and fourth extensor compartments. Retract the second and third extensor compartment tendons radially and the fourth extensor compartment tendons ulnarly (TECH FIG 1D).
- The dorsal wrist capsule is also incised transversely as the cyst is traced to a stalk, which usually arises from the dorsal aspect of the scapholunate interosseous membrane, just proximal to the dorsal scapholunate ligament (TECH FIG 1E).
- Excise the cyst at the base of the stalk and send it for pathologic examination (TECH FIG 1F).
- Although excision of a small window of tissue at the site of cyst origin has been previously recommended, we have concern that overzealous excision may lead to injury to the scapholunate ligamentous complex. We
recommend the use of a bipolar cautery to precisely cauterize the site of origin (TECH FIG 1G).
- After excision of the cyst, inspect the joint for any abnormalities.
- Allow the capsular tissues and tendons to return to their anatomic position. Avoid capsular closure, as this may lead to joint stiffness.
- Skin closure is usually accomplished with a running subcuticular nonabsorbable monofilament suture (TECH FIG 1H).

We prefer to dress the wound with an antibiotic ointment and petroleum gauze, and a bulky hand dressing is applied with a plaster palmar splint maintaining the wrist in a neutral position.
- The dressing is removed along with the sutures at about 1 week postoperatively and Steri-Strips are applied to the wound.

**OPEN EXCISION OF A VOLAR WRIST GANGLION CYST**

- Volar wrist ganglion cysts most often arise from the volar radiocarpal ligaments. They may also arise from the scaphotrapezial joint or at times from the flexor carpi radialis (FCR) sheath. The cysts are typically located in the interval between the FCR sheath and first extensor compartment tendons, just proximal to the wrist flexion crease.
- Under tourniquet control, we prefer to use a zigzag type of incision that begins at the wrist flexion crease and extends proximally over the cyst in the FCR and first extensor compartment interval. This incision provides access in both the longitudinal and transverse planes. A longitudinal incision may heal with scar contracture, whereas a transverse incision may not provide adequate exposure in the longitudinal plane (TECH FIG 2A).
- Under loupe magnification, the subcutaneous tissues are carefully dissected and branches of the lateral antebrachial cutaneous nerve and dorsal radial sensory nerve are carefully protected. If dissection ulnar to the FCR tendon is required, the palmar cutaneous branch of the median nerve must also be identified and protected.
- Ganglion cysts in this location are commonly adherent to the radial artery and its venae comitantes (TECH FIG 2B). Take care to avoid injury to the artery. If the cyst cannot be freely dissected from the artery, a small cuff of cyst wall can be left adherent to the artery without a significant increase in recurrence.
- The cyst is traced to a stalk that most often arises from the volar radial carpal ligaments (TECH FIG 2C). The cyst
is excised at the base of the stalk. We routinely send the cyst for pathologic evaluation.

- As with dorsal ganglion cysts, we cauterize the site of origin of the cyst with a bipolar electrocautery.
- After excision of the cyst, the tourniquet is deflated to ensure that the radial artery is uninjured. Satisfactory hemostasis is achieved.
- We generally close the wound with a running subcuticular suture, removed about 7 to 10 days after surgery.

- We prefer to dress the wound with antibiotic ointment and petroleum gauze, and a bulky hand dressing is applied with a plaster palmar splint maintaining the wrist in a neutral position.
- The dressing is removed along with the sutures at about 1 week postoperatively and Steri-Strips are applied to the wound.

**OPEN CURETTAGE AND BONE GRAFTING OF AN INTRAOSSEOUS GANGLION CYST**

- The patient is positioned supine on the operating table with the operative hand resting on a hand table.
- Symptomatic intraosseous ganglion cysts most often involve the carpal bones. Surgical incisions are planned according to the preoperative studies (MRI and CT scans) to identify the best location for creating a cortical window and avoiding injury to cartilaginous surfaces.
- Under tourniquet control, make an appropriate incision and carry dissection to the level of the wrist capsule. Loupe magnification is often helpful during the dissection. Enter the wrist capsule, preserving important capsular ligaments.
- The bony cortex is generally weakened in the area of the cyst and access is easily accomplished with a handheld curette. If the cortex is not weak, a small cortical window can be created using 0.045-inch Kirschner wires to create small drill holes to create a cortical window.
- Curette the cyst cavity along with any mucinous material. Remove the cyst membrane.
- Pack the cyst cavity with bone graft or a bone graft substitute.
- Wound closure is accomplished in the usual manner.
- We usually immobilize the patient in a plaster splint for 1 week and then a cast for 3 to 5 weeks, depending on the cyst size and bone integrity.
- Obtain postoperative radiographs to monitor and ensure incorporation of the bone graft.

**EXCISION OF A DEGENERATIVE MUCOUS CYST**

- Mucous cysts can be excised under local digital block anesthesia.
- The hand is prepared in the standard fashion.
- A finger tourniquet is applied to the involved digit.
- We usually use a Brunner type of incision or a simple transverse incision incorporating the cyst and allowing access to the origin of the cyst, which arises from the distal interphalangeal joint capsule between the terminal extensor tendon and collateral ligament (TECH FIG 3A).
- During the dissection, take care to avoid injury to the germinal matrix of the nail bed (TECH FIG 3B).
- Excise the cyst at the base of its stalk along with a portion of the joint capsule (TECH FIG 3C).
- Excising underlying osteophytes and hypertrophic synovial tissue is the key to preventing recurrence of the cyst (TECH FIG 3D).
- The wound is irrigated, the tourniquet is removed, and hemostasis is achieved with bipolar cautery.
- Wound closure is accomplished with nonabsorbable monofilament sutures.
- I dress the wound with antibiotic ointment, petroleum gauze, gauze fluff, and tube gauze dressing.
- The patient is instructed to remove the dressing in 3 to 5 days and then cleanse the wound daily with antibacterial soap and water.
- Sutures are removed at 7 to 10 days.

**TECH FIG 3** • A. Degenerative mucous cyst in the eponychial region resulting in nail plate deformity. B. Aggressive dissection is avoided distally to protect the nail germinal matrix. The cyst is traced proximally to its origin at the distal interphalangeal joint. C. The cyst is excised along with a portion of the joint capsule at its point of origin between the central tendon and collateral ligament. D. A rongeur is used to débride underlying osteophytes.
EXCISION OF A GANGLION CYST OF TENDON SHEATH (VOLAR RETINACULAR CYST)

- The patient is supine on the operating table with the involved upper extremity resting on a hand table.
- Anesthesia is usually accomplished with local anesthetic.
- Under tourniquet control (well tolerated by most awake patients for the 10 to 15 minutes required), a skin incision is made over the suspected ganglion cyst.
- Loupe magnification aids in limiting the size of the incision and identifying important anatomic structures. Retract the soft tissues and the digital neurovascular bundles.
- The ganglion cyst is commonly identified arising from the first or second annular pulley region.
- Dissect the ganglion cyst from the surrounding soft tissues and excise it at its base. We usually cauterize the site of origin with the bipolar cautery, which lowers the chance of a recurrence.
- The tourniquet is released, hemostasis is achieved, and wound closure is performed.
- A light hand dressing is applied for 7 to 10 days.

ARTHROSCOPIC EXCISION OF A DORSAL WRIST GANGLION CYST

- The patient is positioned supine on the operating room table with the operative upper extremity positioned in an arthroscopic traction tower (TECH FIG 4).
- Identify the standard wrist arthroscopic and anatomic landmarks.
- The 3–4, 4–5, 6R, and 6U portals are typically used.
- Under tourniquet control, insert a 2.7-mm small joint arthrooscope into the 3–4 or 4–5 portal sites to inspect the joint and identify the ganglion stalk. The stalk in the typical dorsal wrist ganglion cysts is found arising from the dorsal distal margin of the scapholunate intraligamentous membrane just proximal to the dorsal scapholunate intraligamentous ligament. The stalk is not always identifiable or visualized.17
- Introduce a 2.9-mm resector shaver into the joint and excise the stalk (when visible) along with a 1-cm portion of dorsal wrist capsule and ganglion cyst.
- Use extreme caution when resecting the ganglion stalk and capsule to avoid injury to the scapholunate ligament and intraligamentous membrane as well as the overlying extensor carpi radialis brevis and extensor digitorum communis tendons.
- Midcarpal arthroscopy is performed if indicated, but routine inspection is not necessary when treating a dorsal wrist ganglion cyst.
- The portal sites are typically closed with a removable monofilament suture.
- A light hand dressing is applied with a plaster palmar splint, which is left in place for about 5 to 7 days.

EXCISION OF A GIANT CELL TUMOR OF THE TENDON SHEATH

- The standard treatment is complete surgical removal.
- Careful surgical dissection is performed under loupe magnification (TECH FIG 5A).
- After initial exposure, isolate the neurovascular bundle proximal and distal to the lesion (TECH FIG 5B).
- Once the pseudocapsule is identified, it can be bluntly dissected or teased away from underlying structures with a Freer elevator, with care taken not to seed the surrounding tissues.6 Alternatively, a small portion of the tendon sheath may be excised with the tumor origin and the area cauterized with bipolar electrocautery12 (TECH FIG 5C,D).
- Carefully examine the local tissues for satellite lesions, which may be only a few millimeters in size. These lesions need to be completely excised (TECH FIG 5E).
- If the extensor tendon is involved, surgical excision of a portion of the tendon may be required. In rare cases, tendon reconstruction may be necessary. Lesions eroding into bone may require local curettage.
- If the tumor appears to arise from an underlying joint, it is important to perform a capsulotomy to inspect the joint and débride any pigmented tissue.11
- Arthrodesis of the distal interphalangeal joint may be necessary to completely excise some lesions.
TECHNIQUES

TECH FIG 5 • A. Careful surgical dissection of the subcutaneous tissues through a Brunner incision. B. The digital nerve is identified distal to the lesion and protected throughout the procedure. C. The tumor should be carefully removed from surrounding soft tissues. D. Excision demonstrates a firm multinodular lesion. E. Any satellite lesions should be carefully identified and removed.

MARGINAL EXCISION OF AN EPIDERMAL INCLUSION CYST

- Careful surgical dissection is undertaken under loupe magnification.
- After initial exposure, isolate the neurovascular bundles in the area of the lesion.
- Once the capsule is identified, it can be sharply dissected from overlying skin and bluntly dissected from deeper soft tissues (TECH FIG 6).
- Take care to remove the entire capsule.
- Lesions eroding into bone may require local curettage and bone graft.
- In rare cases with advanced bony destruction, amputation is an alternative.

TECH FIG 6 • A. Through a small longitudinal incision directly over the lesion, the cyst is bluntly excised from surrounding soft tissues. B. Excision of the lesion demonstrates a firm, white, encapsulated mass.

PEARLS AND PITFALLS

Dorsal ganglion cysts
- The scapholunate ligament is just distal to the tubercle of Lister. Dorsal ganglion cysts almost always arise from the distal margin of the dorsal scapholunate intraosseous membrane, just proximal to the dorsal scapholunate ligament.
- Excise the cyst at the base of the stalk, which is the site of origin.
- Cauterize the site of origin with a bipolar cautery to decrease the chances of recurrence.
- Take care to avoid injury to the dorsal scapholunate ligament.
- If the ganglion cyst recedes in size before surgery, dissect to identify the scapholunate ligament, which will often reveal the cyst.
## POSTOPERATIVE CARE

### Ganglion Cysts of the Wrist
- The splint and sutures are removed about 1 week postoperatively and Steri-Strips applied to the wound.
- Range-of-motion exercises and light use of the hand are initiated at 1 week, with gradual advancement of activities as tolerated.
- Scar massage is encouraged at 2 weeks.

### Ganglion Cyst of Tendon Sheath and Degenerative Mucous Cyst
- Patients are instructed to remove their postoperative dressing 4 to 5 days after surgery. We prefer to have the patients clean their wound at least twice daily with antibacterial soap and water. The wound is redressed with light gauze or an adhesive bandage.
- Sutures are generally removed at 1 week and Steri-Strips applied to the wound.
- Range-of-motion exercises and light use of the hand are initiated, with gradual advancement of activities as tolerated.
- Scar massage is encouraged at 2 weeks.

### Intraosseous Ganglion Cysts
- Postoperative dressing and sutures are removed at 1 week and Steri-Strips applied to the wound.
- We generally apply a short-arm cast for 3 to 5 weeks. The cast is removed and range-of-motion exercises and light hand use are initiated.
- Incorporation of the bone graft is monitored with use of serial radiographs. If the intraosseous ganglion cyst has weakened the bone, a protective splint may be used once the cast is removed until incorporation of the bone graft.

### Giant Cell Tumors and Epidermal Inclusion Cysts
- Patients should be instructed about the high rate of recurrence of giant cell tumors.
- Range-of-motion exercises and antiedema techniques should be started immediately after surgery.
- Sutures can be removed at 8 to 10 days.

## OUTCOMES

### Ganglion Cysts
- Symptomatic relief is often accomplished after excision of most ganglion cysts.
- Recurrence rates after ganglion cyst surgery have been reported to range from 4% to 40%. With adherence to the above principles, however, the recurrence rate in our experience is less than 5%.
- Complications of ganglion cyst removal are infrequent.
- The recurrence rate of giant cell tumors has varied from 5% to 50%. The high rate of recurrence is due to incomplete excision or satellite lesions.  
- Recurrence rates are even higher after excision of a recurrent tumor.
- In contrast, the recurrence rate after epidermal inclusion cyst excision, even with bony involvement, is low.

## COMPLICATIONS
- Wound complications (e.g., painful or unsightly scar), infection, digital neurapraxia, or recurrence can occur.
- Ganglion cyst excision can result in a neurovascular injury. This complication is rare with adherence to good surgical technique and a good understanding of the local anatomy. Volar wrist ganglion cysts are adherent to the radial artery and can be difficult to dissect free from the artery. If necessary, a cuff of the cyst is left attached to the artery. If injury to the artery does occur, a repair should be performed.
- Stiffness is a complication of ganglion cyst excision. Avoiding direct capsular closure reduces the risk of this complication.
- Complications associated with degenerative mucous cysts include extensor lag, joint stiffness, infection, nail plate deformity, and distal interphalangeal joint deformity.

## REFERENCES
DEFINITION
- Nerve tumors make up less than 5% of tumors about the hand and wrist.11
- Most nerve tumors are benign and grow without causing neural dysfunction. As a result, the neural origin of a mass is often not anticipated and unexpected loss of function may occur after surgery.
- The key is to prepare for excision of any mass by discussing the possibility of a nerve tumor with the patient, by recognizing patients and masses with a high likelihood of a nerve tumor, and by being familiar with surgical techniques that allow preservation or, if necessary, reconstruction of the affected nerve.

ANATOMY
- Peripheral nerves consists of axons surrounded by a nerve sheath (FIG 1).
- The epineurium is a thin outer layer of connective tissue containing blood vessels that supply the nerve.
- Perineural cells form a strong cellular layer, the perineurium, surrounding each fascicle (bundle) of axons.
- An endoneurial layer of protective Schwann cells surrounds each individual axon.

PATHOGENESIS
- Tumors of the peripheral nerve arise from and resemble components of the nerve sheath.
- Most nerve tumors arise from the Schwann cell and are informally called schwannomas (or neurilemomas) and neurofibromas, depending on the pattern of growth and histology.
- Other benign peripheral nerve sheath tumors (BPNSTs) include the granular cell tumor, neurothekeoma, nerve sheath myxoma, and perineurioma. Electron microscopy and immunohistochemistry may be necessary to determine the type of tumor and cell of origin in some cases.³
- Malignant peripheral nerve sheath tumors (MPNSTs) arise de novo or from malignant change within a BPNST.
- About half of MPNSTs occur in patients with neurofibromatosis (NF) type I (von Recklinghausen disease).
- The incidence of a MPNST in patients with NF type I is 2%,7 although the lifetime risk rises to 13%.²

NATURAL HISTORY
- Upper extremity BPNSTs are usually solitary, and most occur in middle-aged adults.⁴,⁶
- Pediatric nerve tumors are uncommon.¹
- BPNSTs are typically painless and slow-growing, with malignant degeneration being exceedingly rare. Most tumors are relatively small (less than 2.5 cm), although they may cause nerve dysfunction due to focal impingement on the adjacent axons.
- Patients with NF type I often have multiple schwannomas, neurofibromas, or both of major upper extremity nerves. Thick tortuous “plexiform” neurofibromas are common in NF type I and have a high risk of progression to malignancy.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history should include the duration, growth characteristics, and local effects of the mass. Mild discomfort is common with nerve tumors but paresthesias are the exception rather than the rule. Hence, the possibility of a nerve tumor must often be entertained for the sake of completeness alone. Similarly, physical examination may suggest but cannot definitively diagnose a nerve tumor.
- A complete examination of a distal upper extremity soft tissue mass should evaluate other nonneural possibilities within the differential diagnosis.
- Ganglia: Arise from joint and tendon sheaths in characteristic locations. The mass will typically transilluminate and the diagnosis can be confirmed by aspiration of highly viscous mucinoid material. Ganglia may mimic nerve tumors by causing compression of an adjacent nerve (eg, a ganglion in the canal of Guyon may cause ulnar neuropathy) (FIG 2).
- Giant cell tumors (GCTs) of the tendon sheath: Reactive lesions of synovium that occur about the palm and fingers in similar locations to nerve tumors. GCTs are often palpably nodular, compared to the smooth margins of a nerve tumor.
- Lipomas: These fatty tumors are usually more superficial and mobile than a nerve tumor. Rarely, lipomas grow in the carpal canal, causing median neuropathy.
- Epidermal inclusion cysts: Should be suspected when examination reveals evidence of prior penetrating trauma. Unlike neurites, these cysts do not cause nerve symptoms and a Tinel sign is not present.
- Nodular fasciitis: A firm, reactive soft tissue proliferation that may grow rapidly on the volar surface of the forearm.
or hand. The location may suggest a nerve tumor and the aggressive spread mimics sarcoma. While most nerve tumors are mobile in the transverse plane, palpation of nodular fasciitis reveals dense adhesions to the adjacent subcutaneous tissue.

- Patients with NF type I may have multiple nerve tumors, along with features such as café-au-lait spots, freckling in the axilla or groin, optic pathway tumors, iris hamartomas, and bone dysplasias. In patients with NF type 1, rapid growth of a neurofibroma, severe pain, and a new neurologic deficit often herald malignant degeneration.

- Examination techniques include the following:
  - Palpation: The examiner moves the mass transversely and longitudinally. Nerve tumors may be translated transversely but are tethered in the longitudinal plane.
  - Sensory testing using Semmes-Weinstein monofilament. Early nerve compression increases threshold while innervation density (two-point) remains normal. In a busy clinical practice, light moving touch may be as reliable (Stauch).
  - The examiner assesses visible atrophy and weakness in motor units innervated by the affected nerve. Manual strength testing is usually normal.
  - Direct pressure is applied over the nerve just proximal to the mass. Nerves under compression by a mass are sometimes sensitive to touch and may produce paresthesias when manipulated.
  - The nerve is percussed immediately adjacent to the mass. A positive result is paresthesias in the cutaneous distribution of the nerve. The Tinel sign is positive only when an injured nerve is attempting to regenerate. Most nerve tumors do not have a positive Tinel sign.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs should be obtained to look for intraleisonal calcification or invasion of adjacent bony architecture.
- Intraleisonal calcification is rarely seen in BPNST and should alert the surgeon to the more likely possibility of a lipoma, hemangioma, giant cell tumor of tendon sheath, synovial chondromatosis, calcific tendonitis, myositis ossificans, or synovial sarcoma.
- A malignant nerve tumor may invade nearby osseous structures.
- An MRI is useful for evaluating tumor characteristics, delineating the surrounding anatomy, and planning a surgical approach.
- Localization of the tumor to the vicinity of a large nerve trunk suggests a peripheral nerve tumor (**FIG 3A**).
- MRI may also occasionally demonstrate subtle muscle atrophy of the distally innervated musculature. Tumor margins are smooth and there is mild intraleisonal inhomogeneity.
- Nerve tumors have intermediate signal intensity on T1-weighted images secondary to intermingled adipose tissue (**FIG 3B**).
- BPNSTs are bright on T2-weighted images.\(^1\) These MRI features are similar to those of other soft tissue neoplasms and are not diagnostic.\(^5\)
- Irregular margins may be seen with plexiform neurofibromas or malignant tumors.
- Other characteristics of a malignant neoplasm include size more than 5 cm, invasion into adjacent tissues, and tumor necrosis.
- Electrodiagnostic studies are most useful in the rare case of a clinically significant preoperative nerve deficit. Slowing of the nerve conduction velocity at the site of the tumor manifests as increases in the distal motor and sensory latencies, while electromyography will detect subtle muscle denervation.

**DIFFERENTIAL DIAGNOSIS**

- Neuroma
- Lipofibromatous hamartoma (fibrofatty infiltration)
- Nerve sheath ganglion
- Intraneural tumors of nonneural origin
  - Intraneural lipoma
  - Intraneural hemangioma

**NONOPERATIVE MANAGEMENT**

- In the absence of rapid growth, pain, or nerve dysfunction it is reasonable to observe a distal upper extremity mass. An MRI may be obtained to identify features consistent with a BPNST and to exclude signs of malignancy (see above).
Patients with NF type I often have multiple neurofibromas, including dermal and plexiform types.

- Dermal neurofibromas grow through the dermis and subcutaneous tissue to form plaque-like swellings. While sometimes unsightly, these tumors are routinely observed as the surgical defects are no more cosmetically pleasing.
- Plexiform neurofibromas are visible as nodular masses lying longitudinally along the course of peripheral nerves. These tumors must be carefully followed as progression to a MPNST (neurofibrosarcoma) is common.
- Pain is the most predictive symptom of malignant change. If there is no concern for malignancy, surgical excision is generally avoided as it frequently results in nerve deficits postoperatively.
- Children and young adults may develop masses of fibrofatty tissue infiltrating major nerves and their branches, particularly the median nerve.
- These lipofibromatous hamartomas cause slow progressive nodular swelling and, at times, distal soft tissue overgrowth (macrodactyly).

- When asymptomatic, nonoperative management may be preferred, particularly if MRI shows pathognomonic features of this lesion.13
- Carpal tunnel symptoms may be treated with limited surgery, including an open carpal tunnel release and a definitive biopsy of a small cutaneous branch of the nerve.

**SURGICAL MANAGEMENT**

- An isolated distal upper extremity mass is treated surgically for definitive diagnosis, to control symptoms, or to exclude malignancy.

**Preoperative Planning**

- MRI is reviewed to confirm characteristics of a BPNST and to plan a surgical approach.
- Nerve reconstruction options are discussed with the patient.
- We consider synthetic absorbable nerve conduits for defects of up to 2 cm, particularly in the palm.
- We avoid conduits when there is any concern of extrusion (eg, about joints in the digits) or in superficial sites where foreign body reaction may be confused with a tumor recurrence.
- The medial antebrachial cutaneous nerve (MABC) is a suitable graft for the common and proper digital nerves.
- A sural nerve cable graft may be necessary for major peripheral nerve defects.
- If significant nerve dysfunction is present before surgery (or is expected afterward), consideration should be given to performing concomitant tendon transfers, particularly in adults.

**Positioning**

- The patient is positioned supine with the affected extremity placed on a hand table. A brachial tourniquet is applied proximally, allowing access to the medial elbow for MABC nerve harvest if necessary.
- If sural nerve harvest is considered a possibility, we place a proximal thigh tourniquet and prepare and drape the contralateral lower extremity so that a second team may operate unencumbered.

**Approach**

- The surgical approach varies with tumor location.
  - A midlateral approach to digital nerve lesions allows excellent visualization of the tumor, protection of the adjacent digital artery, and good soft tissue coverage of the adjacent flexor tendon sheath.
  - Lesions in the palm are approached with a Brunner zigzag type of skin incision, which provides excellent visualization and minimizes restrictive postoperative longitudinal scar formation.
  - An open carpal tunnel approach is included for tumors close to the median nerve to decrease nerve compression from postoperative edema.
- Any suspected malignancy is managed according to the principles described in the oncology section of this text: a biopsy incision must allow optimal definitive resection options later. For example, a biopsy of a possible neurofibrosarcoma of the radial sensory nerve should be made through the mobile wad compartment as opposed to the more familiar Henry approach to this region.
ENUCLEATION

- Most isolated BPNSTs are schwannomas and arise eccentrically from the nerve sheath (TECH FIG 1A). The tumor is encapsulated and can be safely enucleated without removing nerve fascicles.
- The nerve is exposed and fascicles are seen to drape over the mass, sometimes with a pedicled or multilobulated appearance. Inspect the nerve circumferentially for the window of splayed fascicles that affords the best resection plane (TECH FIG 1B).
- Incise the nerve sheath longitudinally, preserving the vessels running in the epineurium. Expand the window by carefully peeling away the fascicles and, ultimately, delivering the tumor out of the nerve (TECH FIG 1C).
- The resected specimen contains no nerve fascicles (TECH FIG 1D).

NERVE REPAIRS, GRAFTS, AND CONDUITS

- Surgical exploration of a nerve tumor may reveal a centrally placed expansile lesion with characteristic incorporation of nerve fascicles within the mass—the neurofibroma (TECH FIG 2A). While poorly encapsulated within the nerve, these tumors are typically free of adhesions to the adjacent soft tissues. Complete excision may require resection of the involved section of the nerve.
- The neurofibroma is exposed similar to the schwannoma. In this case, fusiform expansion of the posterior interosseous nerve is identified. Fascicles are seen entering the lesion at its proximal and distal extent, confirming the diagnosis of a neurofibroma (TECH FIG 2B).
- A microscope may allow identification of a prominent fascicular group that can be microdissected from the adjacent normal fascicles. If no prominent fascicular group or groups can be identified, then tumor resection will require nerve transection through normal fascicles at each end of the mass.
- Direct reapproximation of the nerve ends is optimal but should be done only with minimal joint flexion and tension. Direct repairs done with significant joint flexion or high tension have poor results.
- The MABC is harvested if an autologous nerve graft is required (TECH FIG 2C). The nerve exits the brachial fascia adjacent to the basilic vein at the junction of the middle and distal third of the forearm.
- The length of the nerve may be harvested for a nerve cable graft if a major peripheral nerve has been sacrificed.
- The small anterior branch of the MABC may be harvested an inch anterior and distal to the medial epicondyle. The anterior branch is generally a good size match for a digital nerve, as seen in this case of a nerve tumor with iatrogenic soft tissue loss (TECH FIG 2D).
- Alternatively, a nerve tube may be used to bridge an intercalary nerve defect (TECH FIG 2E).
- A digital neurofibroma can be resected and the defect bridged with a nerve tube (TECH FIG 2F). Studies suggest that nerve conduits are best suited for defects of 2 cm or less.
Digital nerve schwannomas may sometimes require microdissection to preserve axons. The nerve is isolated under loupe magnification. The operating microscope facilitates identification of normal nerve fibers proximally. These axon bundles are traced distally and carefully dissected free of the mass. Occasionally, microdissection will allow the surgeon to identify and preserve normal fascicles from a neurofibroma of a large peripheral nerve.
LIPOFIBROMATOUS HAMARTOMA: LIMITED RESECTION AND SURAL NERVE GRAFTING

- A lipofibromatous hamartoma of the median nerve is most apparent about the proximal and distal extent of the transverse carpal ligament (TECH FIG 3A). The contained space of the carpal canal limits outward expansion of the hamartoma causing compression of nerve fascicles. Open carpal tunnel release may improve pain and nerve dysfunction. However, a mass that continues to grow, causing pain and nerve dysfunction, may need to be resected. Nerve grafts should be considered, especially in young patients. Management in adults is controversial.

- Sagittal-plane MRI images will show the extent of the lesion (TECH FIG 3B).
- Surgical exposure begins with an open carpal tunnel release to identify the transition zone between normal and abnormal nerve. The incision is carried distally in a Brunner zigzag type of fashion to find the end of the lesion (TECH FIG 3C).
- The hamartoma is excised en bloc at healthy-appearing fascicular margins (TECH FIG 3D).
- A sural nerve is harvested and interposed as a cable graft (TECH FIG 3E).
### PEARLS AND PITFALLS

| Diagnosis | A nerve tumor must be part of the differential diagnosis for any distal upper extremity mass.  
| Nonsurgical management | Watch for signs of malignancy, including increasing nerve dysfunction, rapid growth, and pain.  
| Surgical approach | Masses should be resected through an extensile approach; avoid transverse incisions.  
| Tumor resection | A microscope should be available should microdissection or nerve resection and reconstruction become necessary (neurofibroma).  

### POSTOPERATIVE CARE

- At a minimum, short arcs of joint motion are initiated early to discourage adhesion formation between the cutaneous scar and the underlying nerve.
- If necessary, the end range of motion may be avoided for up to 1 month to protect nerve repairs or reconstructions.
- When axons have been injured, a hand therapist may assist with desensitization or sensory re-education.
- A Tinel sign may be followed for reinnervation along the course of the affected nerve.
- Late changes in nerve function or swelling suggest the possibility of recurrence.

### OUTCOMES

- Transient paresthesias are common after enucleation of a schwannoma; however, long-term nerve function is generally the same as or improved compared to the preoperative state. Tumor recurrence is rare.
- Permanent neurologic deficits follow en bloc resection of a neurofibroma, thus limiting the surgical indications for this procedure. Microdissection preserves nerve function but likely has an increased risk of recurrence.
- Resection of a lipofibromatous hamartoma of the median nerve (including partial excision or interfascicular dissection) often results in permanent nerve deficits. There is limited long-term follow-up for nerve grafting of these lesions.

### COMPLICATIONS

- Loss of nerve function after tumor resection
- Loss of motion due to prolonged immobilization
- Neuroma formation at a nerve donor site (eg, MABC neuroma)
- Wound breakdown over a nerve conduit, especially in the digits

### REFERENCES

DEFINITION

- Enchondromas are benign cartilaginous neoplasms that are commonly seen in the medullary cavity of phalanges and metacarpals and less commonly the radius and ulna. Enchondroma is the most common neoplasm of bone arising in the hand.
- Unicameral bone cysts are benign endothelial-lined fluid-filled cavities arising in metaphyseal bone; they are occasionally seen in the distal radius and rarely seen in the hand.
- Giant cell tumor of bone is an uncommon benign neoplasm of bone, which is locally aggressive and can metastasize. While its histology suggests a benign process, behaves as a low-grade malignancy.

ANATOMY

- Enchondroma most commonly arises in the proximal phalanx or metacarpal when seen in the hand (FIG 1A). It can be seen in metaphyseal and epiphyseal regions and is typically confined to the bone. The enchondroma may distend the bone and pathologic fracture may be seen.
- Unicameral bone cysts are rarely seen in the hand. When presenting in the radius they are often metaphyseal and may be in continuity with the distal radial physis (FIG 1B). Unicameral bone cysts are typically confined to bone and pathologic fracture may be seen.
- Giant cell tumor of bone most commonly arises in the epiphyseal region except in the skeletally immature patient, in whom it may arise in the metaphysis. The distal radius is the third most frequent location for these tumors (FIG 1C), after the distal femur and the proximal tibia. Hand lesions account for 2% of giant cell tumors of bone.

PATHOGENESIS

- The pathogenesis of enchondroma, unicameral bone cyst, and giant cell tumor of bone is uncertain. Enchondroma and unicameral bone cysts may be associated with bone development and growth.
- Enchondroma, unicameral bone cyst, and giant cell tumor of bone can weaken the bone and predispose the patient to pathologic fracture.

NATURAL HISTORY

- Enchondromas are most commonly identified incidentally during unrelated evaluation. They also can present after pathologic fracture. On occasion, a patient may complain of painful swelling in the bone.
- Enchondromas found incidentally and not causing considerable mechanical weakness may be observed if typical radiographic findings are seen.
- Enchondromas causing substantial fracture risk and those presenting after pathologic fracture can be treated surgically with a low risk of recurrence.
- Enchondroma can extremely rarely transform to chondrosarcoma.
- Unicameral bone cysts are most commonly seen during adolescence or childhood. They are most commonly identified after pathologic fracture. Proximal humerus lesions may be seen.
- Unicameral bone cysts with a low risk of fracture may be observed with activity modification.
- Unicameral bone cysts causing substantial weakness and fracture risk may be treated with surgery or injection.
- Suspected unicameral bone cysts in the bones of the hand are sufficiently rare that strong consideration should be given to biopsy when this lesion is suspected.

FIG 1 • A. Enchondroma of the proximal phalanx. B. Unicameral bone cyst of the distal radius. C. Giant cell tumor of the distal radius.
Giant cell tumor of bone is locally aggressive. Patients may present with pain and swelling or after pathologic fracture. Giant cell tumor of bone metastasizes 2% to 10% of the time, with metastasis more frequently seen with distal radius and hand lesions.\(^1,2,4,5\) Metastasis most frequently occurs concurrent with or after a local recurrence. Patients with giant cell tumor of bone require systemic staging, treatment, and long-term surveillance, as recurrence may be seen late.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- Enchondroma is most often an incidental finding and is asymptomatic. Pain and deformity can be seen after pathologic fracture. On occasion there will be bone distention and tenderness with palpation.
- Unicameral bone cysts are most commonly seen after pathologic fracture. On occasion there will be swelling and tenderness.
- Giant cell tumor of bone may cause swelling, pain, tenderness, and a sense of weakness. Loss of range of motion is common as these lesions are typically periarticular. Pathologic fracture may be seen.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Plain radiographs are indispensable in the initial evaluation of primary bone tumors (**FIG 2A**).

MRI is useful when an aggressive lesion or soft tissue extension is suspected. MRI may allow better identification of the local extent of disease and may assist in operative planning (**FIG 2B**).
- Campanacci et al’s\(^3\) grading system may be used:
  - Grade 1 lesions are confined to the intramedullary cavity without distention or distortion of the cortex.
  - Grade 2 lesions distend the cortex but do not extend into the surrounding soft tissues.
  - Grade 3 lesions destroy the cortex and extend into the surrounding soft tissues.
- Total body bone scan and lung CT scan are required for staging patients with giant cell tumor of bone.
- Incision or needle biopsy may be required when radiographs and MRI are not diagnostic.

**DIFFERENTIAL DIAGNOSIS**
- Enchondroma
- Chondromyxoid fibroma
- Chondrosarcoma
- Unicameral bone cyst
- Infection
- Aneurysmal bone cyst
- Giant cell tumor of bone
- Primary malignant bone neoplasms
- Acrometastasis

**NONOPERATIVE MANAGEMENT**
- Enchondroma and unicameral bone cyst may be observed provided radiographic assessment is diagnostic or the differential is limited to benign, nonaggressive lesions with an indolent natural history. The assessment of risk of pathologic fracture is paramount. Lesions with a substantial risk of pathologic fracture in the context of the patient’s activity level are best treated operatively.
- The rare risk of malignant degeneration of enchondromas should be considered and discussed with the patient.
- Suspected giant cell tumor of bone requires biopsy. Rarely these can be treated with radiation alone; however, this approach is the exception and should not be considered first-line treatment. Radiation is associated with a risk of subsequent true malignant degeneration to a highly malignant giant cell tumor of bone.

**SURGICAL MANAGEMENT**
- All suspected giant cell tumors of bone and those enchondromas and unicameral bone cysts with a high risk of fracture are best treated surgically.

**Preoperative Planning**
- The radiographic extent of disease must be assessed.
- The approach will vary depending on the anatomic location.
- Bone graft source (autologous or allograft) must be considered.
- Precautions to prevent donor-site cross-contamination must be considered and reviewed with the operating room team.
- The surgeon must determine the anticipated need for frozen section and discuss this with the pathologist and review radiographs before any anticipated frozen section.

**FIG 2 • A.** Radiograph showing giant cell tumor of the metacarpal. B. MRI axial image of grade 3 giant cell tumor of the distal radius (arrow).
• The surgeon must secure and confirm the availability of any necessary grafting materials, instruments, implants, or adjuvants (ie, liquid nitrogen).
• The surgeon must confirm the availability of intraoperative imaging. Radiographs will give better resolution than fluoroscopy.

Positioning
• Surgery is typically done in the supine position with the arm extended on a radiolucent armboard.
• Proximal humerus lesions may be approached in a modified beach-chair position.

Approach
• Phalanx lesions may be approached from the dorsal or lateral approach.

**TECHNIQUES**

**CURETTAGE AND EXCISION OF PROXIMAL PHALANGEAL ENCHONDROMA**

- The mid-axial approach from the ulnar side is preferred whenever possible (**TECH FIG 1A**).
- After making the incision under tourniquet control, identify the lateral band and retract it dorsally.
- Reflect the periosteum and create a bone window using curettes, rongeur, or drill (**TECH FIG 1B**).
- Curette the lesion in its entirety. The use of flexible fiberoptic lights may improve visualization.
- Pack the cavity with preferred bone grafting material.
- Obtain plain radiographs in the operating room to confirm complete excision and appropriate grafting.

**CURETTAGE AND EXCISION OF METACARPAL ENCHONDROMA**

- Metacarpal lesions are approached dorsally through longitudinal incisions.
- Reflect the periosteum and create a bone window using curettes, rongeur, or drill.
- Curette the lesion in its entirety. Ensure adequate visualization through a longitudinal bone trough.
- Pack the cavity with preferred bone grafting material.
- Obtain plain radiographs in the operating room to confirm complete excision and appropriate grafting.
CURETTAGE, CRYOSURGERY, AND CEMENTATION OF DISTAL RADIUS GIANT CELL TUMOR OF BONE

- Preoperative preparation includes confirming the availability of liquid nitrogen, proper storage containers, cryosurgery instruments, and trained operative staff.
- Grade 1, 2, or 3 lesions with a single plane of palmar perforation can be approached from a palmar radial incision between the first dorsal compartment and the radial artery (TECH FIG 2A,B).
  - A branch of the superficial radial nerve may be encountered and should be retracted and protected.
  - The radial 50% of the pronator quadratus is exposed.
- When palmar soft tissue perforation is present it will commonly be contained by the pronator quadratus. The pronator overlying the region of perforation should be excised en bloc with the bone window, effectively converting a grade 3 lesion to a grade 2 lesion with a palmar bone window.
- Wide exteriorization of the lesion with a window roughly two-thirds the maximum dimension of the lesion is needed to ensure adequate visualization.
- Thoroughly curette the lesion. Fiberoptic lighting may assist in viewing the extent of radial styloid involvement.
- Burr the endosteal surface if it is sufficiently thick. Irrigate and dry the cavity.
- The argon beam coagulator may be used to achieve hemostasis in the cavity and may have a beneficial effect as an adjuvant causing surface necrosis.
- Perform cryosurgery using three separate freeze–thaw cycles with either the direct pour technique or the spray gun (TECH FIG 2C).
- Fill the cavity with polymethylmethacrylate bone cement. Reinforcing Rush pins (Rush Pin, Meridian, MS) may be used (TECH FIG 2D).
- Apply a bulky compressive bandage and volar splint.

TECH FIG 2 • A. The right radius is approached from the palmar radial aspect between the first dorsal compartment and the radial artery. B. The radial border of the pronator quadratus is exposed to gain access to the lesion for creation of the bone window. C. Cryosurgery is performed after wide retraction and soft tissue protection. D. The defect is filled with bone cement.
**WIDE EN BLOC EXTRA-ARTICULAR DISTAL RADIUS RESECTION**

- Wide extra-articular excision of the distal radius may be indicated for grade 3 giant cell tumors with extensive cortical destruction, recurrent lesions, and those with pathologic fracture into the radiocarpal articulation.
- A dorsal approach maximizes exposure and facilitates subsequent intercalary arthrodesis.
- Finger extensors are released from the retinaculum while wrist extensors and often thumb extensors or abductors may need to be sacrificed.
- Cut the radius proximal to the tumor. Cut the ulna proximal to the distal radioulnar joint, away from the ulnar extent of the lesion (*TECH FIG 3A*).
- “Evert” the radius and ulna into the wound while the interosseous membrane is transected (*TECH FIG 3B*).

Dissect the flexor pollicis longus and the radial artery away from the tumor-bearing segment.
- Mobilize the flexor tendons, median nerve, and ulnar nerve away from the tumor-bearing segment.
- The midcarpal articulation can be disarticulated initially from a dorsal approach and then circumferentially to complete the resection (*TECH FIG 3C*).
- Alternatively, the midcarpal articulation can be excised en bloc with the tumor-bearing segment by cutting with an oscillating saw from dorsal to palmar through the distal aspect of the distal carpal row bones.
- Reconstruction is readily accomplished by means of a vascularized or nonvascularized fibula graft (*TECH FIG 3D*). Spanning rigid internal fixation with a 3.5-mm dynamic compression plate lowers the risk of nonunion.

*TECH FIG 3* • **A.** Dorsal exposure of the distal radius and ulna with transection of the radius and ulna proximally. **B.** The radius and ulna are everted into the dorsal wound to allow palmar exposure and dissection of palmar soft tissues. **C.** The resection specimen, demonstrating the midcarpal articulation of the proximal carpal row. **D.** Reconstruction is by means of an osteoseptocutaneous vascularized fibula graft for intercalary arthrodesis. A spanning 3.5-mm compression plate is used for fixation.
PEACE AND PITFALLS

“Exteriorization”
- Make the bone window to the lesion two-thirds the greatest dimension of the lesion to allow adequate visualization of the cavity.

Pathology consultation
- Consult the pathologist in advance. Frozen section analysis of cartilaginous lesions is notoriously difficult.

Approach
- A lateral approach to phalanx lesions provides more rapid return to normal motion and a better appearance. A volar radial approach for distal radius grade 1 and 2 giant cell tumors of bone allows excellent visualization and limits local contamination risk.
- The dorsal approach for large grade 3 giant cell tumor distal radius lesions is best when wide excision and reconstruction or arthrodesis is anticipated.

Monitoring
- Surveillance monitoring is mandatory, particularly for giant cell tumor of bone, which can recur late and metastasize.

POSTOPERATIVE CARE
- Phalanx or metacarpal enchondroma
  - Bulky protective dressings are applied and range of motion is initiated at the first dressing change, usually 8 to 10 days postoperatively.
  - Protective splinting is continued for 6 weeks after surgery. High-risk activities are restricted for 12 to 16 weeks.
  - Periodic surveillance continues for 3 to 5 years.
  - Curettage, cryosurgery, and cementation of distal radius giant cell tumor of bone
    - Dressings are changed 10 days postoperatively. Sutures are removed and the patient is fitted with a removable splint.
    - Active range-of-motion exercises are initiated. Active-assisted and passive range-of-motion exercises are added at week 6.
    - Activities are gradually increased, with high-risk activities being restricted for up to 2 years due to cryonecrosis of bone caused by cryosurgery.
- Wide en bloc extra-articular distal radius resection
  - Patients are dressed in a bulky compressive dressing, most commonly with a volar splint.
  - Elevation is encouraged for the first 48 hours and digit range of motion is encouraged.
  - Formal supervised therapy is initiated at the first dressing change, typically 8 to 10 days after surgery.
    - At that time bandages are removed and sutures can be removed.
    - Most commonly, active and active-assisted range-of-motion exercises are initiated. When not exercising, patients are asked to use a protective splint for an additional month. Activities are progressively increased as soft tissue and bone healing allows.
    - Range-of-motion exercises are initiated no later than 10 days after surgery.
    - Protective splinting continues a total of 6 weeks minimum after intralesional procedures and until bone healing is confirmed after arthrodesis.
    - Sporting activities are typically restricted for 12 to 18 weeks. High-risk activities are avoided for longer periods.
    - Surveillance for local recurrence should continue for 5 years for benign lesions and 10 years for giant cell tumor of bone.

OUTCOMES
- Local recurrence
  - The local recurrence rate after curettage and bone grafting of enchondromas is about 5%. When recurrence is seen, the question of malignant transformation should be considered.
  - The local recurrence rate after curettage and bone grafting of giant cell tumor of bone in the distal radius is about 50%, and adjuvants such as liquid nitrogen can lower this to about 20%. Intralesional treatment (curettage) is best reserved for lesions without soft tissue extension (grade 1 and 2 lesions).
  - Wide excision of distal radius lesions is associated with local recurrence rates of less than 10%; however, reconstruction in the form of articular allograft or intercalary arthrodesis results in inferior function, motion, and strength and higher levels of pain.
  - The local recurrence rate after curettage and bone grafting of giant cell tumor of bones of the hand is about 80%. Isolated curettage without the use of adjuvants cannot be advocated in this setting. There are several successful examples of curettage cryosurgery and cementation of giant cell tumor of the small bones of the hand. This type of procedure is best done at a tumor referral center.
  - Wide excision or amputation has been advocated for giant cell tumor of bone when it arises in the phalanges or metacarpals. Local recurrence may still be seen, but the rate is probably less than 10%.
  - The local recurrence rate after curettage of enchondromas arising in the hand is about 5%.
  - The local recurrence rate after wide excision or amputation for giant cell tumor of the bones of the hand is less than 10%.
  - The local recurrence rate after curettage, cryosurgery, and cementation of distal radius giant cell tumor of bone is about 20% to 25% and correlates with soft tissue extension.
  - The local recurrence rate after wide excision of distal radius giant cell tumor of bone is likely less than 10%.
- Metastasis
  - Benign giant cell tumor of bone metastasizes in 2% to 8% in general case series.
  - Motion and strength
    - Range of digit motion is typically excellent after curettage for enchondroma.
    - Range of motion of the wrist may be slightly diminished after curettage of enchondromas in the distal radius.
    - Grip strength is reduced to 60% of normal after wide excision of the distal radius for giant cell tumor with intercalary segmental arthrodesis. Forearm rotation is typically preserved.
COMPLICATIONS

- Infection, hematoma, nerve injury, intraoperative fracture, postoperative fracture, nonunion, limited range of motion, and tendon gliding problems may be seen after treatment of enchondroma or giant cell tumor of bone when arising in the upper extremity.
- Delayed complications include extensor tendon rupture due to prominent residual ulna, nonunion, and fracture after hardware removal.

OVERVIEW OF SHOULDER AND ELBOW SURGERY

- In order to diagnose and treat problems of the shoulder and elbow, one must fully understand the anatomy of the region and appreciate how this translates to functional rearrangements.
- There is no line of demarcation between the shoulder and elbow regions. Pain in the arm may originate at the neck or shoulder and refer down the arm. Less often pain noted by patients at the elbow or forearm have local origin. If the slightest doubt exists as to the etiology of the pain, the patient is examined from neck to fingers.
- The upper extremity functions to position and move the hand in space. The upper extremities are attached to the body by the sternoclavicular joint. Otherwise, they are suspended from the neck and held fast to the torso by soft tissues (muscles and fascia).
- The upper extremity gains leverage against the posterior aspect of the thorax by virtue of the broad, flat body of the scapula.
- The elbow along the upper extremity is a complex modified hinge articulation. Unlike the shoulder, the elbow has a much more intrinsic stability based on its bony architecture. The primary purpose of the elbow is to position the hands in space. The elbow joint is perhaps the main joint responsible for communicating the actions of the hand to the trunk.
- The surgical management of major shoulder and elbow conditions has rapidly progressed over the last 30 years as our understanding of the pathoanatomy and biomechanics has greatly enhanced our ability to treat certain problems. Consequently, new surgical techniques have allowed the surgeon to more effectively treat many disorders.
- Arthroscopic surgery in particular has significantly increased our ability to surgically manage conditions and reduce morbidity. The sports medicine portion of this textbook handles the arthroscopic management of shoulder and elbow disorders.
- The art of any surgery lies in the reconstruction of diseased or injured tissues with minimal additional destruction. Skillful handling of the soft tissues is the hallmark of all upper extremity surgery, including the shoulder and elbow. Knowledge of anatomy defines the precision and safety of surgery. Approaches to any joint in the body are developed on this foundation, with particular emphasis on the exploitation of internervous planes. Familiarity with the intricate anatomy and multiple approaches to the shoulder and elbow allows the surgeon to confidently embark on the repair or reconstruction of the injury or disorder of the joint.

OSTEOLOGY

Clavicle

- This is a relatively straight bone when viewed anteriorly, whereas in the transverse plane, it resembles an italic S (FIG 1).
- There are three bony impressions for ligament attachment to the clavicle:
  - On the medial side is an impression for the costoclavicular ligament, which at times may be a rhomboid fossa.
  - At the lateral end of the bone is the conoid tubercle.
  - Just lateral to the conoid tubercle is the trapezoid tubercle.
- Muscles that insert on the clavicle are the trapezius on the posterosuperior surface of the distal end and the subclavius muscle, which has an insertion on the inferior surface of the middle third of the clavicle.
- Functionally, the clavicle acts mainly as a point of muscle attachment.
- Some of the literature suggests that with good repair of the muscle, the only functional consequences of surgical removal of the clavicle are with heavy overhead and that, therefore, its function as a strut is less important.
- Four muscles take origin from the clavicle: deltoid, pectoralis major, sternocleidomastoid, and sternohyoid.
- Important relations to the clavicle are the subclavian vein and artery and the brachial plexus posteriorly.

Scapula

- This is a thin sheet of bone that functions mainly as a site of muscle attachment (FIG 2A).
- It is thicker at its superior and inferior angles in its lateral border, where some of the more powerful muscles are attached.
Chapter 1
ANATOMY OF THE SHOULDER AND ELBOW

The acromion is the most studied process of the scapula because of the amount of pathology involving the acromion and the rotator cuff.

Three types of acromion morphologies have been defined by Bigliani and Morrison (FIG 3).

Type 1, with its flat surface, provided the least compromise of the supraspinatus outlet, whereas type 3, which has a hook, was associated with the highest rate of rotator cuff pathology in a series of cadaver dissections.

The glenoid articular surface is within 10 degrees of being perpendicular to the blade of the scapula, with the mean being 6 degrees of retroversion.

More caudad portions face more anteriorly than cephalad.

Three processes—the spine, the coracoid, and the glenoid—create two notches in the scapula.

Suprascapular notch is at the base of the coracoid.

Spinoglenoid, or greater scapular notch, is at the base of the spine.

Major ligaments that take origin from the scapula are:

- Coracoclavicular
- Coracoacromial
- Acromioclavicular
- Glenohumeral
- Coracohumeral

Blood supply to the scapula derives from vessels in the muscles that take fleshy origin from the scapula.

Vessels cross these indirect insertions and communicate with bony vessels.

**Humerus**

The articular surface of the humerus at the shoulder is spheroid, with a radius of curvature of about 2.25 cm.

With the arm in the anatomic position (ie, with the epicondyles of the humerus in the coronal plane), the head of humerus has retroversion of about 30 degrees, with a wide range of normal values.

The intertubercular groove lies about 1 cm lateral to the midline of the humerus (FIG 4).

The axis of the humeral head crosses the greater tuberosity at about 9 mm posterior to the bicipital groove.

The lesser tuberosity lies directly anterior, and the greater tuberosity lines up on the lateral side.

The lesser tuberosity is the insertion for the subscapularis tendon.

The greater tuberosity bears the insertion of the supraspinatus, infraspinatus, and teres minor in a superior to inferior order.
Greater and lesser tuberosities make up the boundaries of the intertubercular groove through which the long head of the biceps passes from its origin on the superior lip of the glenoid. The intertubercular groove has a peripheral roof referred to as the intertubercular ligament or the transverse humeral ligament, which has varying degrees of strength. In the coronal plane, the head–shaft angle is about 135 degrees. The space between the articular cartilage and the ligamentous and tendon attachments is referred to as the anatomic neck of the humerus. Below the level of the tuberosities, the humerus narrows in a region that is referred to as the surgical neck of the humerus because of the frequent occurrence of fractures at this level.

**STERNOCLAVICULAR JOINT**
- This is the only skeletal articulation between the upper limb and the axial skeleton.

**Ligaments**
- The major ligaments of the sternoclavicular joint are the anterior and posterior sternoclavicular ligaments.
- The most important ligament of this group, the posterior sternoclavicular ligament, is the strongest.

**Blood Supply**
- Blood supply of the sternoclavicular joint derives from the clavicular branch of the thoracoacromial artery, with additional contributions from the internal mammary and the suprascapular arteries.

**Nerve Supply**
- Innervation of the joint is supplied by the lateral pectoral, axillary, and suprascapular nerves.

**ACROMIOCLAVICULAR JOINT**
- Only articulation between the clavicle and the scapula

**Ligaments**
- Ligaments about the acromioclavicular articulation are the trapezoid and the conoid ligaments (FIG 5).
- The anteroposterior stability of the acromioclavicular joint is controlled by the acromioclavicular ligaments, and the vertical stability is controlled by the coracoclavicular ligaments.

**Blood Supply**
- Blood supply derives mainly from the acromial artery, a branch of the deltoid artery of the thoracoacromial axis.

There are rich anastomoses between the thoracoacromial artery, suprascapular artery, and posterior humeral circumflex artery. The acromial artery comes on to the thoracoacromial axis anterior to the clavipectoral fascia and perforates back through the clavipectoral fascia to supply the joint.

**Nerve Supply**
- Innervation of the joint is supplied by the lateral pectoral, axillary, and suprascapular nerves.

**SHOULDER LIGAMENTS: CAPSULOLIGAMENTOUS AND LABRAL ANATOMY (FIG 6)**

**Superior Glenohumeral Ligament (SGHL)**
- Arises near the origin of the long head of the biceps brachii
- If the glenoid had the markings of a clock, with the 12-o’clock position superiorly and the 3-o’clock position anteriorly, the origin of the superior glenohumeral ligament would correspond to the area from the 12-o’clock to the 2-o’clock positions.
- SGHL runs inferiorly and laterally to insert on the humerus, superior to the lesser tuberosity.

**Middle Glenohumeral Ligament (MGHL)**
- Usually arises from the neck of the glenoid just inferior to the origin of the SGHL and inserts into the humerus just medial to the lesser tuberosity
- Presence of the MGHL most variable of any shoulder ligament

**Inferior Glenohumeral Ligament (IGHL)**
- Most important ligament for providing anterior and posterior shoulder stability
- IGHL has been described as having an anterior and posterior band, with an axillary pouch between the bands.
With abduction and external rotation, the anterior band fans out and the posterior band becomes cordlike.

Likewise, with internal rotation, the posterior band fans out and the anterior band appears cordlike.

Anterior band of the IGHL arises from various areas corresponding to the 2- to 4-o’clock positions on the glenoid.

Insertion site of this ligament has two attachments, one to the glenoid labrum and the other directly to the anterior neck of the glenoid.

Posterior band originates at the 7-o’clock to 9-o’clock positions.

With the arm at the side, both the anterior and the posterior bands pass through a 90-degree arc and insert on the humerus.

Labrum

Surrounds the periphery of the glenoid and is a site of attachment of the capsuloligamentous structures.

It is composed of dense fibrous connective tissue, with a small fibrocartilaginous transition zone at the anteroinferior attachment of the osseous glenoid rim.

The labrum acts as a load-bearing structure for the humeral head and serves to increase the surface area of the glenoid.

Howell and Galinat showed that the labrum deepened the glenoid socket by nearly 50%.

Lippett and coworkers have shown that removal of the labrum decreases the joint’s stability to sheer stress by 20%.

Triangular cross-section of the labrum allows it to act as a chock-block to help prevent subluxation.

SCAPULOTHORACIC MUSCLES

Trapezius

Largest and most superficial of scapulothoracic muscles

Takes origin from spinous process of C7 through T12 vertebrae

Insertion of the upper fibers is over the distal one third of the clavicle.

Lower cervical and upper thoracic fibers of the trapezius have their insertion over the acromion and spinous scapula.

Lower portion of the muscle takes insertion at the base of the scapular spine.

Acts as a scapular retractor, with the upper fibers used mostly for elevation of the lateral angle

Spinal accessory nerve is the motor supply.

Arterial supply is derived from transverse cervical artery.

Rhombooids

Similar in function to the midportion of the trapezius, with origin from the lower ligamentum nuchae, C7 and T1 for the rhomboid minor and T2 through T5 for the rhomboid major

Rhomboind minor inserts on the posterior portion of the medial base of the spine of the scapula.

Rhomboind major inserts to the posterior surface of the medial border, from where the minor leaves off down to the inferior angle of the scapula.

Action of the rhomboids is retraction of the scapula, and because of their oblique course they also participate in elevation of the scapula.

Innervation is the dorsal scapular nerve (C5), which may arise off the brachial plexus in common with the nerve to the subclavius or with the C5 branches of the long thoracic nerve.

Dorsal scapular artery provides arterial supply to the muscles through their deep surfaces.

levator Scapula and Serratus Anterior

The levator scapula and the serratus anterior are often discussed together because of their close relationship anatomically and functionally.

The levator scapula takes origin from the posterior tubercles of the transverse process from C1 through C3 and sometimes C4.

Inserts on the superior angle of the scapula

Acts to elevate the superior angle of the scapula

In conjunction with the serratus anterior, produces upward rotation of the scapula

Innervation is from the deep branches of C3 and C4.

Serratus anterior takes origin from the ribs on the anterior lateral wall of the thoracic cage.

Bounded medially by the ribs and intercostal muscles and laterally by the axillary space

Protracts the scapula and participates in upward rotation of the scapula

More active in flexion than in abduction because straight abduction requires some retraction of the scapula

Absence of serratus activity, usually because of paralysis, produces a winging of the scapula with forward flexion of the arm and loss of strength in that motion.

Innervation is supplied by the long thoracic nerve (C5, C6, and C7).

Blood supply is from the lateral thoracic artery, with a large contribution from the thoracodorsal artery.

pectoralis Minor

Takes fleshy origin anteriorly on the chest wall, and second through fifth ribs, and has its insertion onto the base of the medial side of the coracoid.
Function is protraction of the scapula if the scapula is retracted and depression of the lateral angle or downward rotation of the scapula if the scapula is upwardly rotated.

Innervation is from the medial pectoral nerve (C8 and T1).

Blood supply is through the pectoral branch of the thoracoacromial artery.

GLENOHUMERAL MUSCLES (FIG 7)

Deltoid

Largest and most important of the glenohumeral muscles, consisting of three major sections:

- Anterior deltoid takes origin off the lateral third of the clavicle, middle third of the deltoid takes origin off the acromion, and posterior deltoid takes origin from the spine of the scapula.
- The deltoid is supplied by the axillary nerve (C5 and C6), which enters the posterior portion of the shoulder through the quadrilateral space and innervates the teres minor in this position.
- Nerves to the posterior third of the deltoid enter the muscle very close to their exit from the quadrilateral space, traveling in the deltoid muscle along the medial and inferior borders of the posterior deltoid.
- Branch of the axillary nerve that supplies the anterior two thirds of the deltoid ascends superiorly and then travels anteriorly, about 2 inches inferior to the rim of the acromion.
- Vascular supply to the deltoid is largely derived from the posterior humeral circumflex artery, which travels with the axillary nerve through the quadrilateral space of the deep surface of the muscle.
- Deltoid is also supplied by the deltoid branch of the thoracoacromial artery.

Supraspinatus

- Lies on the superior portion of the scapula
- It takes origin from the supraspinatus fossa and overlying fascia and inserts into the greater tuberosity.
- Its tendinous insertion is in common with the infraspinatus posteriorly.
- It is active in any motion involving elevation.
- It exerts maximum effort at about 30 degrees of elevation.
- Innervation of the supraspinatus is supplied by the suprascapular nerve (C5, C6).
- Arterial supply is the suprascapular artery.
- Nerve comes through the suprascapular notch and is bound above by the transverse scapular ligament.
- Artery travels above this ligament.
- Suprascapular vessels and nerve supply the deep surface of the muscle.

Infraspinatus

- Second most active rotator cuff muscle
- Its tendinous insertion is in common with the supraspinatus anterosuperiorly and the teres minor inferiorly at the greater tuberosity.
- One of the two main external rotators of the humerus and accounts for as much as 60% of external rotation force
- Also functions as a depressor of the humeral head
- Even in a passive state, it is an important stabilizer against posterior subluxation.
- Innervated by the suprascapular nerve
- Blood supply is from two large branches of the suprascapular artery.

Teres Minor

- One of the few external rotators of the humerus
- It provides up to 45% of the external rotation force.
- It is important in controlling stability in the anterior direction.
- Innervated by the posterior branch of the axillary nerve (C5 and C6)
- Blood supply is derived from several vessels in the area, especially the posterior humeral scapular circumflex artery.

Subscapularis
- Makes up the anterior portion of the rotator cuff
- Takes origin from the subscapularis fossa, which covers most of the anterior surface of the scapula
- Its upper 60% inserts through a cartilaginous tendon into the lesser tuberosity of the humerus, and its lower 40% has a flimsy insertion into the humerus below the lesser tuberosity cupping the head and neck.
- Functions as an internal rotator and passive stabilizer to anterior subluxation and serves in its lower fibers to depress the humeral head
- Innervation usually supplied by two sources:
  - Upper subscapular nerve (C5) and lower subscapular nerves (C5 and C6)
  - Upper subscapular nerves usually come off the posterior cord.
- Blood supply originates from the axillary and subscapular arteries.

Teres Major
- Takes origin from the posterior surface of the scapula along the inferior portion of the lateral border
- It has a muscular origin and a common tendinous insertion with the latissimus dorsi into the humerus along the medial lip of the bicipital groove.
- In their course, both the latissimus dorsi and the teres major undergo a 180-degree spiral; thus, the formerly posterior surface of the muscle is represented by fibers on the anterior surface of the tendon.
- Function is internal rotation, adduction, and extension of the arm.
- Innervation is supplied by the lower subscapular nerve C5 and C6.
- Blood supply is derived from the subscapular artery.

Coracobrachialis
- Originates from the coracoid process, in common with and medial to the short head of the biceps, and inserts onto the anteromedial surface in the midportion of the humerus
- Action is flexion and adduction of the glenohumeral joint.
- Innervation supplied by small branches from the lateral cord and the musculocutaneous nerve
- Because the larger musculocutaneous nerve’s entrance to the muscle may be situated as high as 1.5 cm from the tip of the coracoid to as low as 7 to 8 cm, it must be protected during certain types of repair.
- Major blood supply is usually off the axillary.

MULTIPLE JOINT MUSCLES

Pectoralis Major
- Consists of three portions:
  - Upper portion takes origin from the medial one half to two thirds of the clavicle and inserts along the lateral lip of the bicipital groove.
  - Middle portion takes origin from the manubrium and upper two thirds of the body of the sternum and ribs 2 through 4.
  - It inserts directly behind the clavicular portion and maintains a parallel fiber arrangement.
  - Inferior portion of the pectoralis major takes origin from the distal body of the sternum, the fifth and sixth ribs, and the external oblique muscle fascia.
- Action
  - Clavicular portion participates somewhat in flexion with the anterior portion of the deltoid while the lower fibers are antagonistic.
  - Is active in internal rotation against resistance and will extend the shoulder from flexion until the neutral position is reached.
  - Powerful adductor of the glenohumeral joint.
- Innervation is supplied by two sources:
  - Lateral pectoral nerve (C5, C6, and C7) innervates the clavicular portion of the muscle.
  - Loop contribution from the lateral to the medial pectoral nerve carrying C7 fibers into the upper sternal portion.
- Major blood supply derives from two sources:
  - The deltoïd branch of the thoracodorsal artery supplies the clavicular portion and the pectoral artery supplies the sternocostal portion of the muscle.

Latissimus Dorsi
- Takes origin by the large and broad aponeurosis from the dorsal spines of T7 through L5, a portion of the sacrum, and the crest of the ilium.
- Wraps around the teres major and inserts into the medial crest and floor of the bicipital or intertubercular groove.
- Actions are inward rotation and abduction of the humerus, shoulder extension, and indirectly through its pull on the humerus downward rotation of the scapula.
- Innervation is through the thoracodorsal nerve (C6 and C7).
- Major blood supply is derived from the thoracodorsal artery.

Biceps Brachii
- There are two origins of the biceps muscle in the shoulder:
  - The long head takes origin from the bicipital tubercle at the superior rim of the glenoid.
  - The short head takes origin from the coracoid tip lateral.
- Has two distal tendinous insertions:
  - Lateral insertion is to the posterior part of the tuberosity of the radius.
  - Medial insertion is aponeurotic (lacertus fibrosus), passing medially across and into the deep fascia of the muscles of the volar forearm.
- Loss of the long head attachment expresses itself mainly as loss of supination strength (20%), with a smaller loss (8%) of elbow flexion strength.
- Actions of the biceps are flexion and supination at the elbow.
- Main action is at the elbow rather than the shoulder.
- Innervation is supplied by branches of the musculocutaneous nerve (C5 and C6).
- Blood supply derives from a single large bicipital artery from the brachial artery (35%), multiple very small arteries (40%), or combination of two types.

Triceps Brachii
- Long head takes origin from the infraglenoid tubercle.
- Major action of the muscle is extension at the elbow.
Innervation is supplied by the radial nerve with root innervation C6 to C8.
Arterial supply is derived mainly from the profunda brachial artery and the superior ulnar collateral artery.

**BRACHIAL PLEXUS**

- The standard brachial plexus is made up of distal distribution of the anterior rami of spinal nerve roots C5, C6, C7, C8, and T1. The plexus has contributions from C4 and T1 (FIG 8).

**Trunks, Divisions, and Cords**

- The roots combine to form trunks: C5 and C6 form the superior trunk; C7 forms the middle trunk; and C8 and T1 form the inferior trunk.
- The trunks then separate into anterior and posterior divisions.
- The posterior divisions combine to form the posterior cord, the anterior division of the inferior trunk forms the medial cord, and the anterior division of the superior and middle trunks forms the lateral cord.
- These cords give off the remaining largest number of the terminal nerves of the brachial plexus, and roots from the lateral and medial cords come together to form the median nerve.
- The brachial plexus leaves the cervical spine and progresses through the interval between the anterior and middle scalene muscles.
- The subclavian artery follows the same course. The plexus splits into cords at or before it passes below the clavicle.
- As the cords enter the axilla, they become closely related to the axillary artery, attaining positions relative to the artery indicated by their names: lateral, posterior, and medial.

**Terminal Branches**

- Plexus gives off some terminal branches above the clavicle.
- The dorsal scapular nerve comes off C5 with some C4 fibers and penetrates the scalenus medius and the levator scapulae, sometimes contributing with C4 fibers to the latter.
- The dorsal scapular nerve accompanies the deep branch of the transverse cervical artery or the dorsal scapular artery on the undersurface of the rhomboids and innervates them.
- Rootlets of the nerves C5, C6, and C7 immediately adjacent to the intravertebral foramina contribute to the formation of the long thoracic nerve, which immediately passes between the middle and posterior scalene muscles or penetrates the middle scalene.
- Next most proximal nerve is the suprascapular nerve.
- It arises from the superolateral aspect of the upper trunk shortly after its formation at Erb’s point.
- The lateral cord generally contains fibers of C5, C6, and C7 and gives off three terminal branches:
  - Musculocutaneous
  - Lateral pectoral
  - Lateral root of the median nerve
- Posterior cord supplies most of the innervations of the muscles of the shoulder, in this order:
  - Upper subscapularis, thoracodorsal, lower subscapular, axillary, and radial
- Medial cord has five branches, in the following order:
  - Medial pectoral nerve, medial brachial cutaneous, medial antebrachial cutaneous, medial root of the median nerve, and ulnar nerve

![The brachial plexus](FIG 8 - The brachial plexus.)
**ARTERIES**

Subclavian Artery
- Blood supply to limb begins with the subclavian artery, which ends at the lateral border of the first rib.
- Divided into three portions in relation to the insertion of the scalenus anterior muscle.
- Vertebral artery takes origin in the first portion, and the costocervical trunk and thyrocervical trunk take origin in the second portion.
- There are usually no branches in the third portion of the artery.
- Two vessels encountered more frequently by the shoulder surgeon are the transverse cervical artery and the suprascapular artery.
  - Come off the thyrocervical trunk in 70% of dissections.
  - In the remaining cases, they come off directly, or in common from the subclavian artery.

Axillary
- Is the continuation of the subclavian artery.
- It begins at the lateral border of the first rib and continues along the inferior border of the latissimus dorsi, at which point it becomes the brachial artery.
- This artery is traditionally divided into three portions:
  - First portion is above the superior border of the pectoralis minor.
  - Second portion is deep to the pectoralis minor.
  - Third portion is distal to lateral border of the pectoralis minor.
- Usual number of branches for each of the three sections corresponds to the name of the section: one branch in the first portion, two in the second, and three in the third.
  - First section gives off the superior thoracic artery.
  - Second portion gives off the thoracoacromial artery and the lateral thoracic artery.
  - Third portion gives off the following:
    - Largest branch is the subscapular artery, and this is the largest branch of the axillary.
    - Next branch is the posterior humeral circumflex artery, and the third branch is the anterior humeral circumflex artery.
    - Anterior humeral circumflex artery is an important surgical landmark because it travels laterally at the inferior border of the subscapularis tendon, marking the border between the upper tendinous insertion of the subscapularis and the lower muscular insertion.

**VEINS**

Axillary Vein
- Begins at the inferior border of the latissimus dorsi as the continuation of the basilic vein, continues along the lateral border of the first rib, and becomes the subclavian vein.

Cephalic
- Cephalic vein is the superficial vein in the arm that lies deep to the deep fascia after reaching the deltopectoral groove and finally pierces the clavipectoral fascia, emptying into the axillary vein.

**OSTEOMETRY**

Distal Humerus
- The distal humerus consists of two condyles, which form the articular surfaces of the trochlea and capitellum (FIG 9A).

Trochlea
- Hyperbolic, pulley-like surface that articulates with the semilunar notch of the ulna, covered by articular cartilage over an arc of 300 degrees.
- Medial margin is large and projects more distally than does the lateral margin.
- The prominent medial and lateral margins are separated by a groove that courses in a helical manner from an anterolateral to the posteromedial direction.

Capitellum
- Capitellum is almost spheroidal in shape and is covered with hyaline cartilage, which is about 2 mm thick anteriorly.
- Postero-medial limit of the capitellum is marked by a prominent tubercle.
- A groove separates the capitellum from the trochlea, and the rim of the radial head articulates with this groove throughout the arc of flexion and during pronation and supination.

Joint Surface Orientation
- In the lateral plane, the orientation of the articular surface of the distal humerus is located anteriorly about 30 degrees with respect to the long axis of the humerus (FIG 9B).
- The center of the concentric arc formed by the trochlea and capitellum is on a line that is coplanar with the anterior and distal cortex of the humerus.
- In the transverse plane, the articular surface is rotated inwardly about 5 degrees, and in the frontal plane, it is tilted about 6 degrees in valgus (FIG 9C).

Epicondyles of Humerus
- Medial epicondyle serves as the source of attachment of the ulnar collateral ligament and the flexor pronator group of muscles.
- Lateral epicondyle is located just above the capitellum and is much less prominent than the medial epicondyle.
- The lateral collateral ligament and the supinator extensor muscle group originate from the flat, irregular surfaces of the lateral epicondyle.

Anterior Surface of Humerus
- Anteriorly, the radial and coronoid fossae accommodate the radial head and coronoid, respectively, during flexion.

Posterior Surface of Humerus
- Posteriorly, the olecranon fossa receives the tip of the olecranon in extension (FIG 9D).

Radius
- The proximal radius includes the radial head, which articulates with the capitellum and exhibits a cylindrical depression in the midportion to accommodate the capitellum.
- Hyaline cartilage covers the depression of the radial head. The outside circumference of the radial head articulates with the ulna at the lesser sigmoid notch.
- About 240 degrees of the circumference of the radial head is covered with cartilage. With the arm in neutral rotation, the anterolateral third of the circumference of the radial head is void of cartilage.
- This part of the radial head lacks subchondral bone, and thus is not as strong as the part that supports the articular cartilage.
- This part has been demonstrated to be the portion most often fractured.
- The disc-shaped head is held against the ulna by the annular ligament distal to the radial head.
- The head and neck of the radius are not colinear with the rest of the bone. The head and neck are offset by an angle of about 15 degrees with respect to the shaft of the radius opposite to the radial tuberosity (FIG 10).
- The neck of the radius is tapered, and the angular relationship between the head and neck has been implicated in the etiology of radial neck fractures.

**Ulna**
- The proximal ulna provides the major articulation of the elbow that is responsible for its inherent stability (FIG 11A,B).
- The broad, thick proximal aspect of the ulna consists of the greater sigmoid notch (incisura semilunaris), which articulates with the trochlea of the humerus.
- The sloped cortical surface of the coronoid process serves as the site of insertion of the brachialis muscle.
- The olecranon comprises the posterior portion of the articulation of the ulnohumeral joint and is the site of attachment for the triceps tendon.
- On the lateral aspect of the coronoid process, the lesser sigmoid or radial notch articulates with the radial head and is oriented roughly perpendicular to the long axis of the bone.
- On the lateral aspect of the proximal ulna, a tuberosity, the crista supinatoris, is the site of the insertion of the lateral ulnar collateral ligament (FIG 11C).
- This stabilizes the humeroulnar joint to resist varus and rotational stresses.
- The medial aspect of the coronoid process (sublime tubercle) serves as the site of attachment of the anterior bundle of the medial collateral ligament.
SURVEY OF TOPICAL ANATOMY

Landmarks

Lateral Landmark
- The tip of the olecranon, the lateral epicondyle, and the radial head form an equilateral triangle, providing an important landmark for entry into the elbow for such things as joint aspiration.

Flexion Crease
- The flexion crease of the elbow is in line with the medial and lateral epicondyles. It is actually 1 to 2 cm proximal to the joint line when the elbow is extended.

Antecubital Fossa
- Inverted triangular depression on the anterior aspect of the elbow that is just distal to the epicondyles

Topographical Regions of the Elbow and Corresponding Musculature

Lateral Margin of Antecubital Fossa
- Extensor forearm musculature originates from the lateral epicondyle and has been termed the mobile wad.
- This forms the lateral margin of the antecubital fossa and the lateral contour of the forearm and comprises the brachioradialis and the extensor carpi radialis longus and brevis muscles.

Medial Margin of the Antecubital Fossa
- Muscles making up the contour of the medial anterior forearm include the pronator teres, flexor carpi radialis, palmaris longus, and flexor carpi ulnaris.

Dorsum
- The dorsum of the forearm is contoured by the extensor musculature, consisting of the anconeus, extensor carpi ulnaris, extensor digitorum quinti, and extensor digitorum communis.

Cutaneous Innervation

Proximal Elbow
- Skin about the proximal elbow is innervated by the lower lateral cutaneous (C5, C6) and the medial cutaneous (radial nerve, C8, T1, and T2) nerves of the arm.

Forearm
- Forearm skin is innervated by the medial (C8, T1), lateral (musculocutaneous, C5, C6), and posterior (radial nerve, C6 through C8) cutaneous nerves of the forearm.

Elbow Joint Structure

Joint Articulation
- The elbow joint consists of two types of articulations:
  - The ulnohumeral joint resembles a hinge (ginglymus), allowing flexion and extension.
  - The radiohumeral and the proximal radioulnar joint allow actual rotation or pivoting type of motion.
- Because of this joint articulation, the elbow is classified as a trochoginglymoid joint and is one of the most congruent joints of the body.

Carrying Angle
- Angle formed by the long axis of the humerus and the ulna with the elbow fully extended
  - In males, mean carrying angle is 11 to 14 degrees.
  - In females, mean carrying angle 13 to 16 degrees.

Joint Capsule
- The anterior capsule inserts proximally above the coronoid and radial fossae.
- Distally, the capsule attaches to the anterior margin of the coronoid medially as well as to the annular ligament laterally.
- Posteriorly, the capsule attaches just above the olecranon fossa, distally along the supracondylar bony columns, and then down along the medial and lateral margins of the trochlea.
- Distally, the attachment is along the medial and lateral articular margin of the sigmoid notch; laterally, it occurs along the lateral aspect of the sigmoid notch and blends with the annular ligament.
- Normal capacity of the fully extended joint capsule is 25 to 30 mL.
- The joint capsule is innervated by branches from all major nerves crossing the joint, including contributions from the musculocutaneous nerve.

LIGAMENTS OF THE ELBOW
- Ligaments of the elbow consist of specialized thickening of the medial and lateral capsule that forms medial and lateral collateral ligament complexes.

Medial Collateral Ligament Complex
- The medial collateral ligament consists of three parts: anterior, posterior, and transverse segments.
- Anterior bundle is the most discrete component.
- The posterior portion, being a thickening of the posterior capsule, is well defined only in about 90 degrees of flexion.
- The transverse component appears to contribute a little or nothing to elbow stability.
- Clinically and experimentally, the anterior bundle is clearly the major portion of the medial ligament complex.

Lateral Collateral Ligament Complex
- Unlike the medial collateral ligament complex, with a rather consistent pattern, the lateral ligaments of the elbow joint are less discrete and some individual variation is common.
- Several components make up the lateral ligament complex: radial collateral ligament, the annular ligament, a variably present accessory lateral collateral ligament, and the lateral ulnar collateral ligament.

Lateral Ulnar Collateral Ligament
- This structure originates from the lateral epicondyle and blends with the fibers of the annular ligament, but arching superficial and distal to it.
- Insertion is through the tubercle of the crest of the supinator on the ulna.
- The function of this ligament is to provide stability to the ulnohumeral joint; it was shown to be deficient in posterolateral rotary instability of the joint.
- This ligament represents the primary lateral stabilizer of the elbow and is taut on flexion and extension.

Accessory Lateral Collateral Ligament
- Its function is to further stabilize the annular ligament during varus stress.

VESSELS

Brachial Artery and Its Branches
- The brachial artery descends in the arm, crossing in front of the intramuscular septum to lie anterior to the medial aspect of the brachialis muscle.
- The median nerve crosses in front of and medial to the artery at this point, near the middle of the arm. The artery continues distally at the medial margin of the biceps muscle and enters the antecubital space medial to the biceps tendon and lateral to the nerve.
- At the level of the radial head, it gives off its terminal branches, the ulnar and radial arteries, which continue into the forearm.

Radial Artery
- Usually the radial artery originates at the level of the radial head, emerges from the antecubital fossa between the brachioradialis and the pronator teres muscle, and continues down the forearm under the brachioradialis muscle.

Ulnar Artery
- The ulnar artery is the larger of the two terminal branches of the brachial artery.
- The artery traverses the pronator teres between its two heads and continues distally and medially behind the flexor digitorum superficialis muscle.
- It emerges medially to continue down the medial aspect of the forearm under the cover of the flexor carpi ulnaris.

**NERVES**

**Musculocutaneous Nerve**
- Originates from C5 through C8 nerve roots and is a continuation of the lateral cord.
- Innervates the major elbow flexors and the biceps and brachialis and continues through the brachial fascia lateral to the biceps tendon, terminating as the lateral antebrachial cutaneous nerve.
- Motor branch enters the biceps about 15 cm distal to the acromion; it enters the brachialis about 20 cm below the tip of the acromion.

**Median Nerve**
- Median nerve arises from C5 through C8 and T1 nerve roots.
- The nerve enters the anterior aspect of the brachium, crossing in front of the brachial artery as it passes across the intramuscular septum.
  - It follows a straight course into the medial aspect of the antecubital fossa, medial to the biceps tendon and the brachial artery.
  - It then passes under the bicipital aponeurosis.
- There are no branches of the median nerve in the arm.
- The first motor branch is given to the pronator teres, through which it passes.
- In the antecubital fossa, a few small articular branches are given off before the motor branches to the pronator teres, the flexor carpi radialis, the palmaris longus, and the flexor digitorum superficialis.

**Anterior Interosseous Nerve**
- Arises from the median nerve near the inferior border of the pronator teres and travels along the anterior aspect of the interosseous membrane in the company of the anterior interosseous artery.
- Innervates the flexor pollicis longus and the lateral portion of the flexor digitorum profundus.

**Radial Nerve**
- Is a continuation of the posterior cord and originates from the C6, C7, and C8 nerve roots, with variable contributions of the C5 and T1 roots.
- In the midportion of the arm, the nerve courses laterally just distal to the deltoid insertion to occupy the groove in the humerus that bears its name.
- It then emerges in a spiral path inferiorly and laterally to penetrate the lateral intramuscular septum.
- Before entering the anterior aspect of the arm, it gives off the motor branches to the medial and lateral heads of the triceps, accompanied by the deep branch of the brachial artery.
- After penetrating the lateral intramuscular septum in the distal third of the arm, it descends anterior to the lateral epicondyle behind the brachioradialis.
- It innervates the brachioradialis with a single branch to this muscle.
- In the antecubital space, the nerve divides into the superficial and deep branches. The superficial branch is the continuation of the radial nerve and extends into the forearm to innervate the mid-dorsal cutaneous aspect of the forearm.
- Motor branches of the radial nerve are given off to the triceps above the spiral groove, except for the branch to the medial head of the triceps, which originates at the entry to the spiral groove.
- This branch continues distally through the medial head to terminate as a muscular branch to the anconeus.
- In the antecubital space, the recurrent radial nerve curves around the posterolateral aspect of the radius, passing deep through supinator muscle, which it innervates. During its course through the supinator muscle, the nerve lies over the bare area, which is distal to and opposite to the radial tuberosity. The nerve is believed to be at risk at this site with fractures of the proximal radius. It emerges from the muscle as the posterior interosseous nerve, and the recurrent branch innervates the extensor digitorum minimi, the extensor carpi ulnaris, and occasionally the anconeus.
- The posterior interosseous nerve is accompanied by the posterior interosseous artery and sends further muscle branches distally to supply the abductor pollicis longus, the extensor pollicis longus, the extensor pollicis brevis, and the extensor indicis on the dorsum of the forearm.

**Ulnar Nerve**
- The ulnar nerve is derived from the medial cord of the brachial plexus from roots C8 and T1. In the mid-arm, it passes posteriorly through the medial intramuscular septum and continues distally along the medial margin of the triceps in the company of the superior ulnar collateral branch of the brachial artery and the ulnar collateral branch of the radial artery.
- There are no branches of this nerve in the brachium.
- The ulnar nerve may undergo compression as it passes behind the medial epicondyle, emerging into the forearm through the cubital tunnel.
- The roof of the cubital tunnel has been defined by a structure termed the cubital tunnel retinaculum.
- The first motor branch is the single nerve to the ulnar origin of the pronator and another one to the epicondylar head of the flexor carpi ulnaris. Distally, the nerve sends a motor branch to the ulnar half of the flexor digitorum profundus.
- Two cutaneous nerves arise from the ulnar nerve in the distal half of the forearm to innervate the skin of the wrist and the hand.

**MUSCLES**

**Elbow Flexors**

**Biceps**
- Covers the brachialis muscle in the distal arm and passes into the cubital fossa as the biceps tendon, which attaches to the posterior aspect of the radial tuberosity.
- Bicipital aponeurosis or lacertus fibrosus is a broad, thin band of tissue that is a continuation of the anterior, medial, and distal muscle fascia. It runs obliquely to cover the median nerve and the brachial artery and inserts into the deep fascia of the forearm and possibly into the ulna as well.
- The biceps is a flexor of the elbow that has a large cross-sectional area but an intermediate mechanical advantage because it passes relatively close to the axis of rotation.
- In the pronated position, the biceps is a strong supinator of the forearm.
Brachialis
- Largest cross-sectional area of any of the elbow flexors but suffers from a poor mechanical advantage because it crosses so close to the axis of rotation
- Origin consists of the entire anterior distal half of the humerus, and it extends medially and laterally to the respective intermuscular septa.
- Crosses the anterior capsule, with some fibers inserting into the capsule that are said to help retract the capsule during elbow flexion.
- Insertion of the brachialis is along the base of the coronoid and into the tuberosity of the ulna.
- More than 95% of the cross-sectional area is muscle tissue at the elbow joint, a relationship that may account for high incidence of trauma to this muscle with elbow dislocation.

Brachioradialis
- Has a lengthy origin along the lateral supracondylar column that extends proximally to the level of the junction of the middle and distal humerus.
- Origin separates the lateral head of the triceps and the brachialis muscle.
- Lateral border of the cubital fossa is formed by this muscle, which crosses the elbow joint with the greatest mechanical advantage of any elbow flexor. It progresses distally to insert into the base of the radial styloid.
- Protects and is innervated by radial nerve (C5 and C6) as it emerges from the spiral groove.
- Major function is elbow flexion.

Extensor Carpi Radialis Longus
- Originates from the supracondylar bony column just below the origin of the brachioradialis.
- As it continues into the midportion of the dorsum of the forearm, it becomes largely tendinous and inserts to the dorsal base of the second metacarpal.
- Innervated by the radial nerve.
- Functions as wrist extensor, and possibly an elbow flexor.

Extensor Carpi Radialis Brevis
- Originates from the lateral superior aspect of the lateral epicondyle.
- Its origin is the most lateral of the extensor group and is covered by the extensor carpi radialis longus.
- This relationship is important as the most commonly implicated site of lateral epicondylitis.
- Extensor carpi radialis brevis shares the same extensor compartment as the longus as it crosses the wrist under the extensor retinaculum and inserts into the dorsal base of the third metacarpal.
- Function of the extensor carpi radialis brevis is pure wrist extension, with little or no radial or ulnar deviation.

Extensor Digitorum Communis
- Originating from the anterior distal aspect of the lateral epicondyle, the extensor digitorum communis accounts for most of the contour of the extensor surface of the forearm.
- Extends and abducts fingers.
- Innervation is from the deep branch of the radial nerve, with contributions from the sixth through eighth cervical nerves.

Supinator
- This flat muscle is characterized by the virtual absence of tendinous tissue and has a complex origin and insertion.
- It originates from three sites above and below the elbow joint: the lateral anterior aspect of the lateral epicondyle; the lateral collateral ligament; and the proximal anterior crest of the ulna along the crista supinatoris, which is just anterior to the depression for the insertion of the anconeus.
- Form of the muscle is roughly that of a rhomboid as it runs obliquely, distally, and radially to wrap around and insert diffusely on the proximal radius, beginning lateral and proximal to the radial tuberosity and continuing distal to the insertion of the pronator teres at the junction of the proximal middle third of the radius.
- The radial nerve passes through the supinator to gain access to the extensor surface of the forearm.
- This anatomic feature is clinically significant with regard to exposure of the lateral aspect of the elbow joint and the proximal radius and in certain entrapment syndromes.
- Functions as a supinator of the forearm, but it is a weaker supinator than the biceps.
- Unlike the biceps, however, the effectiveness of the supinator is not altered by the position of the elbow flexion.
- Innervation is derived from the muscular branch given off by the radial nerve just before and during its course through the muscle.

Elbow Extensors

Triceps Brachii
- Comprises the entire musculature of the arm posteriorly.
- Two of its three heads originate from the posterior aspect of the humerus.
- The long head has a discrete origin from the infraglenoid tuberosity of the scapula.
- The lateral head originates in a linear fashion from the proximal lateral intramuscular septum on the posterior surface of the humerus.
- The medial head originates from the entire distal half of the posteromedial surface of the humerus, bounded laterally by the radial groove and medially by the intramuscular septum.
- Each head originates distal to the other with progressively larger areas of origin.
- The long and lateral heads are superficial to the deep medial head, blending in the midline of the humerus to form a common muscle that then tapers into the triceps tendon and attaches to the tip of the olecranon with Sharpey fibers.
- The tendon is usually separated from the olecranon by the subcutaneous olecranon bursa.
- Innervated by the radial nerve, the long and lateral heads are supplied by branches that arise proximal to the entrance of the radial nerve into the groove.
- The medial head is innervated distal to the groove with a branch that enters proximally and passes through the entire medial head to terminate by innervating the anconeus.

Anconeus
- This muscle has little tendinous tissue because it originates from a rather broad site on the posterior aspect of the lateral epicondyle and from the lateral triceps fascia and inserts into the lateral dorsal surface of the proximal ulna.
Innervated by the terminal branch of the nerve to the medial head of the triceps
Function of this muscle has been the subject of considerable speculation.
Some suggest that the primary role is that of a joint stabilizer.
Covers the lateral portion of the annular ligament and the radial head
For the surgeon, the major significance of this muscle is its position as a key landmark in various lateral and posterolateral exposures, and it is used for some reconstructive procedures.

**Flexor Pronator Muscle Group**

**Pronator Teres**
- There are usually two heads of origin; the larger arises from the anterosuperior aspect of the medial epicondyle and the second from the coronoid process of the ulna, which is absent in about 10% of individuals.
- Innervated by two motor branches from the median nerve

**Flexor Carpi Radialis**
- The flexor carpi radialis originates inferior to the origin of the pronator teres and the common flexor tendon at the anteroinferior aspect of the medial epicondyle.
- It continues distally and radially to the wrist, where it can be easily palpated before it inserts into the base of the second and sometimes third metacarpal.
- Innervation is from one or two branches of the median nerve.

**Palmaris Longus**
- When present, it arises from the medial epicondyle and from the septa it shares with the flexor carpi radialis and flexor carpi ulnaris.
- It becomes tendinous in the proximal portion of the forearm and inserts into and becomes continuous with the palmar aponeurosis.
- Absent in about 10% of the extremities
- Innervated by a branch of the median nerve

**Flexor Carpi Ulnaris**
- Most posterior of the common flexor tendons originating from the medial epicondyle
- Second and largest source of origin is from the medial border of the coronoid and the proximal aspect of the ulna.
- Ulnar nerve enters and innervates the muscle between these two sites of origin with two or three motor branches given off just after the nerve has entered the muscle. The muscle continues distally to insert into the pisiform, where the tendon is easily palpable, because it serves as a wrist flexor and ulnar deviator.
- With an origin posterior to the axis of rotation, weak elbow extension may also be provided by the flexor carpi ulnaris.

**Flexor Digitorum Superficialis**
- The flexor digitorum superficialis muscle is deep to those originating from the common flexor tendon but superficial to the flexor digitorum profundus; thus it is considered the intermediate muscle layer.
- Innervated by two motor branches from the median nerve

**Flexor Digitorum Profundus**
- Originates from the proximal ulna distal to the elbow joint and is involved in flexion of the distal interphalangeal joints.
SHOULDER APPROACHES

ANTERIOR APPROACH TO THE SHOULDER

Indications
- Surgical stabilization for recurrent dislocations
- Subscapularis and biceps tendon repair
- Shoulder arthroplasty
- Fracture fixation

Incisions
- Anterior shoulder can be approached through two different incisions.
  - Anterior incision: 10- to 15-cm incision along the deltopectoral interval (FIG 1A)
    - Incision begins just above the coracoid process and progresses toward the deltoid tuberosity.
  - Axillary incision
    - Vertical incision 8 to 10 cm long (FIG 1B)
    - Incision begins inferior to the tip of the coracoid and progresses toward the anterior axillary fold.

Internervous Plane
- Deltoid muscle is supplied by the axillary nerve.
- Pectoralis major muscle is supplied by medial and lateral pectoral nerves.

Surgical Dissection
- Skin flaps are developed around the deltopectoral interval.
- The deltopectoral interval, with its cephalic vein, is identified.
- The deltopectoral interval is developed by retracting the pectoralis major medially and the deltoid laterally.
  - Vein may be retracted either medially or laterally.
  - We prefer to take it laterally, as fewer tributaries are disrupted.
- The lateral border of the conjoint tendon is identified and the short head of the biceps (supplied by the musculocutaneous nerve) and coracobrachialis (supplied by the musculocutaneous nerve) are displaced medially to allow access to the anterior aspect of the shoulder joint.
  - Simple medial retraction of the conjoined tendon may be enough for a procedure such as subscapularis repair or capsular repair.
  - If more exposure is necessary, the conjoint tendon can be detached with the tip of the coracoid process.
  - The axillary artery is surrounded by cords of brachial plexus, which lie behind the pectoralis minor muscle.
  - To minimize risk for nerve injury, the arm should be kept adducted while work is being done around the coracoid process.
  - Remember, the musculocutaneous nerve enters the coracobrachialis on its medial side.
  - Overly aggressive retraction can cause a neurapraxia of the musculocutaneous nerve.
  - Behind the conjoined tendon of the coracobrachialis and the short head of biceps lies the subscapularis muscle.
  - Externally rotating the arm brings the subscapularis further into the operative field.
  - This maneuver increases the distance between the subscapularis and axillary nerve as it disappears below the lower border of the muscle.
  - Identifiable landmarks on the inferior border of the subscapularis are three small vessels (from the anterior humeral circumflex artery) that run transversely and often require ligation or cauterization.
    - These vessels run as a triad (often called the “three sisters”): a small artery with its two surrounding venae comitantes.
    - The superior border of the subscapularis muscle blends in with the fibers of the supraspinatus muscle in the rotator interval (FIG 1C).
    - The tendon of the subscapularis is tagged with stay sutures.
    - There are various ways of taking down the subscapularis as per surgeon preference.
      - Some divide the subscapularis 1 to 2 cm from its insertion onto the lesser tuberosity.
      - Some detach this insertion with a small flake of bone using an osteotome.
    - Inferior border of the subscapularis is the easiest location to allow separation between the subscapularis and capsule.
    - The capsule is incised longitudinally to enter the joint wherever the selected repair must be performed.

ANTEROSUPERIOR APPROACH TO THE SHOULDER

Indications
- Rotator cuff repair
- Subacromial decompression of the shoulder
- Acromioclavicular reconstructions
- Greater tuberosity fractures
- Removal of calcific deposits from the subacromial bursa
- Reverse shoulder replacement

Incision
- An incision is made paralleling the lateral acromion that begins at the anterolateral corner of the acromion and ends just lateral to the tip of the coracoid (FIG 2A).

Internervous Plane
- The deltoid muscle is detached proximal to its nerve supply; therefore, there is no internervous plane with this approach.

Surgical Dissection
- The incision is deepened to the deep deltoid fascia.
- Subcutaneous flaps are raised.
The location of the deltoid split depends on the pathology being managed. When the pathology requires more exposure, moving the deltoid split posteriorly will improve exposure (FIG 2B).

Subperiosteally, the anterior deltoid is elevated from the acromion and the acromioclavicular joint. Continue the detachment by sharp dissection laterally to expose the anterior aspect of the acromion.

- Bleeding will be encountered during this dissection as a result of the division of the acromial branch of the coracoacromial artery.
- The surgeon should not detach more of the deltoid than is necessary.
- The deltoid split is extended 2 to 3 cm distal to the acromion.
- Stay sutures are inserted in the apex of the split to prevent the muscle from inadvertently splitting distally during retraction and damaging the axillary nerve.

FIG 1 • A. Deltopectoral incision. B. Axillary incision beginning inferior to the tip of the coracoid and progressing toward the anterior axillary fold. C. In this dissection, the subscapularis tendon is being tagged at the superior border of the rotator interval.

FIG 2 • A. Anterosuperior approach to the shoulder. A transverse incision begins at the anterolateral corner of the acromion and ends just lateral to the coracoid. B. The posterior curve of the deltoid incision can be moved more posteriorly, as depicted here, to allow necessary exposure as dictated by the pathology.
POSTERIOR APPROACH TO THE SHOULDER

Indications
- Repair in cases of recurrent posterior dislocation or subluxation of the shoulder
- Glenoid osteotomy
- Treatment of fractures of the scapular neck
- Treatment of posterior fracture and dislocations of the proximal humerus
- Spinoglenoid notch cyst drainage

Incision
- A horizontal incision is made along the scapular spine extending to the posterolateral corner of the acromion (FIG 3A)

Internervous Plane
- Between teres minor (axillary nerve) and infraspinatus (suprascapular nerve)
- The suprascapular nerve passes around the base of the spine of the scapula as it runs from the supraspinatus fossa to the infraspinatus fossa.

Surgical Dissection
- The origin of the deltoid is identified on the scapular spine. There are three ways to manage the deltoid during posterior exposures:
  - Detach the origin on the scapular spine
  - Split the deltoid muscle along the length of its fibers
  - Elevate the deltoid from the inferior margin
- The plane between the deltoid muscle and the underlying infraspinatus muscle is identified.
- The plane is easier to locate at the lateral end of the incision.
- The internervous plane between the infraspinatus and teres minor muscles is identified (FIG 3B).
- The axillary nerve runs longitudinally in the quadrangular space beneath the teres minor.
- The posterior circumflex humeral artery runs with the axillary nerve in the quadrangular space between the inferior borders of the teres minor muscle.
- The infraspinatus is retracted superiorly and the teres minor inferiorly to reach the posterior regions of the glenoid cavity and the neck of the scapula.
- The posteroinferior corner of the shoulder joint capsule should be visible.

HUMERUS APPROACHES

ANTERIOR APPROACH TO THE HUMERUS

Indications
- Internal fixation of fractures of the humerus
- Management of humeral nonunions
- Osteotomy of the humerus

Incision
- A longitudinal incision is made over the tip of the coracoid process of the scapula; it runs distally and laterally in the line of the deltopectoral interval to the insertion of the deltoid muscle on the lateral aspect of the humerus, about halfway down its shaft.
- The incision should be continued distally as far as necessary, following the lateral border of the biceps muscle (FIG 4A).

Internervous Plane
- Between teres minor (axillary nerve) and pectoralis major muscle (supplied by medial and lateral pectoral nerves) (FIG 4B).
- Distally, the plane lies between the medial fibers of the brachialis muscle (musculocutaneous nerve) and the lateral fibers of the brachialis muscle (radial nerve) (FIG 4C).

Surgical Dissection

Proximal Humeral Shaft
- The deltopectoral interval is identified using the cephalic vein as a guide and the two muscles are separated, retracting the cephalic vein either medially with the pectoralis major or laterally with the deltoid.
FIG 4 • A. Patient prepared for an anterior approach to the humerus. B. The internervous plane between the deltoid muscle and the pectoralis major muscle. C. Further distally, one can appreciate the internervous plane between the medial fibers of the brachialis (musculocutaneous nerve) medially and the lateral fibers of the brachialis (radial nerve) laterally. D. Deltopectoral incision: developing the interval between the deltoid and pectoralis major. The cephalic vein can be seen separating these two structures. E. With deeper dissection, the biceps tendon is seen running in the rotator interval. F. Further distal dissection reveals the musculocutaneous nerve passing along the medial border of the biceps muscle. G. To expose the distal third of the humerus, the fibers of the brachialis are split. Flexion of the elbow will relieve the tension off the brachialis, making the exposure easier. (A: Courtesy of Matthew J. Garberina, MD, and Charles L. Getz, MD.)
The muscular interval is developed distally down to the insertion of the deltoid into the deltoid tuberosity and the insertion of the pectoralis major into the lateral lip of the bicipital groove (FIG 4D,E).
- To expose the bone fully, the surgeon may need to detach part or all of the insertion of pectoralis major muscle.
- The minimum amount of soft tissue should be detached to allow adequate visualization and reduction of the fracture.
- If further exposure is needed, the surgeon dissects medially in a subperiosteal manner to avoid damage to the radial nerve, which lies in the spiral groove of the humerus and crosses the back of the middle third of the bone in a medial to lateral direction.

**Distal Humeral Shaft**
- The surgeon identifies the muscular interval between the biceps brachii and brachialis.
- The interval is developed by retracting the biceps medially (FIG 4F).
- Beneath it lies the brachialis muscle, which covers the humeral shaft.
- The fibers of the brachialis are split longitudinally in the interval between the medial 2/3 and the lateral 1/3 to expose the periosteum on the anterior surface of the humeral shaft.
- The periosteum is incised longitudinally in line with the muscle dissection, and the brachialis is stripped off the anterior surface of the bone (FIG 4G).
- In the anterior compartment of the distal third of the arm, the radial nerve pierces the lateral intermuscular septum and lies between the brachioradialis and brachialis muscles.

**POSTERIOR APPROACH TO THE HUMERUS**

**Indications**
- Open reduction and internal fixation of a fracture of the humerus
- Treatment of nonunion
- Exploration of the radial nerve in the spiral groove

**Incision**
- A longitudinal incision is made in the midline of the posterior aspect of the arm, from 8 cm below the acromion to the olecranon fossa (FIG 5A).

**Internervous Plane**
- There is no true internervous plane; dissection involves separating the heads of the triceps brachii muscles, all of which are supplied by the radial nerve.
- The medial head, which is the deepest, has a dual nerve supply (radial and ulnar nerves).

**Surgical Dissection**
- The surgeon incises the deep fascia of the arm in line with the skin incision.
- The triceps muscle has two layers:
  - The outer layer consists of two heads: the lateral head arises from the lateral lip of the spiral groove, and the long head arises from the infraglenoid tubercle of the scapula (FIG 5B).
  - The inner layer consists of the medial head, which arises from the whole width of the posterior aspect of the humerus.

*FIG 5 • A. Posterior approach to the humerus, showing the longitudinal incision along the midline of the posterior aspect of the arm. B. Once the outer layer of the triceps is isolated, one can see the two heads, the lateral head and long head. (continued)*
below the spiral groove all the way down to the distal fourth of the bone.
  - The spiral groove contains the radial nerve; the radial nerve separates the origins of the lateral and medial heads (FIG 5C).
  - To avoid iatrogenic nerve injury, the surgeon should never continue dissection down to bone in the proximal two thirds of the arm until the radial nerve has been identified.

**MODIFIED POSTERIOR APPROACH TO THE HUMERUS**

**Indications**
- Open reduction and internal fixation of humeral shaft fractures
- Open reduction and internal fixation of lateral condyle fractures
- Treatment of humeral nonunion
- Exploration of the radial nerve in the spiral groove

**Incision**
- The surgeon makes a straight incision along a line between the posterolateral aspect of the acromion and the lateral edge of the olecranon.
- The length of the incision is dictated by the requirement for exposure.
- Extensile exposure is limited proximally by the axillary nerve.

**Internervous Plane**
- There is no true internervous plane, because both the medial and lateral heads of the triceps are supplied by the radial nerve.

**Surgical Dissection**
- The deep fascia is incised in line with the skin incision along the lateral aspect of the triceps.
Triceps-Splitting Approaches

Posterior Triceps-Splitting Approach (Campbell)
- Care must be exercised to maintain the medial portion of the triceps expansion over the forearm fascia in continuity with the flexor carpi ulnaris.
- Laterally, the anconeus and triceps are more stable, with less chance of disruption.

Indications
- Total elbow arthroplasty
- Distal humerus fracture
- Removal of loose bodies
- Capsulectomies
- Posterior exposure of the joint for ankylosis, sepsis, synovectomy, and ulnohumeral arthroplasty

Approach
- Skin incision begins in the midline over the triceps, about 10 cm above the joint line, and is generally placed laterally or medially across the tip of the olecranon. It continues distally over the lateral aspect of the subcutaneous border of the proximal ulna for about 5 to 6 cm (FIG 7A).
- Triceps is exposed, along with the proximal 4 cm of the ulna.
- A midline incision is made through the triceps fascia and tendon as it is continued distally across the insertion of the triceps tendon at the tip of the olecranon and down the subcutaneous crest of the ulna (FIG 7B).
- Triceps tendon and muscle are split longitudinally, exposing the distal humerus.
- Anconeus is then reflected subperiosteally laterally, while the flexor carpi ulnaris is similarly retracted medially.
- Insertion of the triceps is carefully released from the olecranon, leaving the extensor mechanism in continuity with the forearm fascia and muscles medially and laterally (FIG 7C).
- Ulnar nerve is visualized and protected in the cubital tunnel.
- Closure of the triceps fascia is required only proximal to the olecranon, but the insertion should be repaired to the olecranon with a suture passed through the ulna.
- The incision is then closed in layers.

Triceps-Splitting, Tendon-Reflecting Approach (Van Gorder)
- A variation of the technique described earlier
- Allows lengthening of the triceps if necessary
- Has been largely abandoned in favor of the triceps-reflecting techniques

Indications
- Same as those for midline-splitting approach described earlier

Approach
- A posterior midline incision begins 10 cm proximal to the olecranon and extends distally onto the subcutaneous border of the ulna between the anconeus and the flexor carpi ulnaris.
- Triceps fascia and aponeurosis are exposed along the tendinous insertion into the ulna.
■ Tendon is reflected from the muscle in a proximal to distal direction, freeing the underlying muscle fibers while preserving the tendinous attachment to the olecranon (FIG 8).
■ Triceps muscle is then split in midline, and the distal humerus is exposed subperiosteally.
■ Periosteum and triceps are elevated for a distance of about 5 cm proximal to the olecranon fossa, exposing the posterior aspect of the joint.
■ If more extensive exposure is desired, the subperiosteal dissection is extended to the level of the joint, exposing the condyles both medially and laterally.
■ Ulnar nerve should be identified and protected.
■ After the procedure, if an elbow contracture has been corrected, the joint should be maximally flexed.
■ The tendon slides distally from its initial position, and the proximal muscle and tendon are reapproximated in the lengthened relationship.

The distal part of the triceps is then securely sutured to the fascia of the triceps expansion, and the remainder of the wound is closed in layers.

**Triceps-Reflecting Approaches**

■ The triceps mechanism may be preserved in continuity with the anconeus and simply reflected to one side or the other.
■ Three surgical approaches have been described that preserve the triceps muscle and tendon in continuity with the distal musculature of the forearm fascia and expose the entire joint.

**Bryan-Morrey Posteromedial Triceps-Reflecting Approach**

■ Developed to preserve the continuity of the triceps with the anconeus

**INDICATIONS**

■ Total elbow arthroplasty
■ Interposition arthroplasty
Elbow dislocation
Distal humerus fracture
Synovial disease
Infection

**APPROACH**

- A straight posterior incision is made medial to the midline, about 9 cm proximal and 8 cm distal to the tip of the olecranon (FIG 9A).
- The ulnar nerve is identified proximally at the margin of the medial head of the triceps and, depending on the procedure, is either protected or carefully dissected to its first motor branch and transposed anteriorly.
- The medial aspect of the triceps is elevated from the posterior capsule.
- The fascia of the forearm between the anconeus and the flexor carpi ulnaris is incised distally for about 6 cm.
- The triceps and the anconeus are elevated as one flap from medial to lateral, skeletonizing the olecranon and subcutaneous border of the ulna (FIG 9B). This should be performed at 20 to 30 degrees of flexion to relieve tension on the insertion, thereby facilitating dissection.
- The collateral ligaments may be released from the humerus for exposure as needed (FIG 9C).
- If stability is important, these ligaments should be preserved or anatomically repaired at the conclusion of the surgery.
- When performing a linked total elbow replacement, it is not necessary to preserve or repair the collateral ligaments.

---

**FIG 8** Triceps-splitting, tendon-reflecting approach. The tendon is reflected from the muscle in a proximal to distal direction.

**FIG 9** The Bryan-Morrey posterior approach. **A.** Straight posterior skin incision. **B.** The ulnar nerve has been translocated anteriorly. The medial border of the triceps is identified and released and the superficial forearm fascia is sharply incised to allow reflection of the fascia and periosteum from the proximal ulna. **C.** The extensor mechanism has been reflected laterally and the collateral ligaments have been released.
Chapter 2 SURGICAL APPROACHES TO THE SHOULDER AND ELBOW

Triceps

Ulnar nerve

Anconeus

FIG 10 • Posterior view of the right elbow demonstrates a straight fascial incision to the lateral aspect of the tip of the olecranon. A. The line of release after the ulnar nerve has been identified and protected. (continued)

- The triceps attachment can be thin at the attachment to the ulna and it is not uncommon for a buttonhole to be created when reflecting the triceps.
  - To prevent this, the flap can be raised as an osteoperiosteal flap (see osteocutaneous flap approach).
  - A small osteotome is used to elevate the fascia with the petals of bone.
  - The flap is mobilized laterally, elevating the anconeus origin from the distal humerus until it can be folded over the lateral humeral condyle.
  - At this point, the radial head can be visualized.
  - The tip of the olecranon can be excised to help expose the trochlea.

Osteoanconeus Flap Approach

- This provides excellent extension and reliable healing of the osseous attachment to the olecranon.
- This approach exposes only the ulnar nerve, whereas the Mayo approach translocates the nerve.

INDICATIONS
- This is a triceps-reflecting approach similar in concept to the Bryan-Morrey triceps-reflecting approach.
- Most often used for joint replacement or distal humeral fractures

APPROACH
- A straight posterior incision is made medial to the midline, about 9 cm proximal and 8 cm distal to the tip of the olecranon.
- The ulnar nerve is identified and protected, but not translocated.
- The triceps attachment is released from the ulna by osteotomizing the attachment with a thin wafer of bone.
  - This is the essential difference from the Bryan-Morrey approach.
  - The medial aspect of the triceps, in continuity with the anconeus, is elevated from the ulna (FIG 10A,B).
  - The collateral ligaments are either maintained or released, depending on the pathology being addressed and the need for stability.
  - After the surgical procedure, the wafer of bone is secured to its bed by nonabsorbable sutures placed through bone holes (FIG 10C).
  - Interrupted sutures are used to repair the remaining distal portion of the extensor mechanism.

Extensile Kocher Posterolateral Triceps-Reflecting Approach

INDICATIONS
- Joint arthroplasty
- Ankylosis
- Distal humerus fractures
- Synovectomy
- Radial head excision
- Infection

APPROACH
- Extensile exposure from the Kocher approach
- Skin incision begins 8 cm proximal to the joint just posterior to the supracondylar ridge and continues distally over the Kocher interval between the anconeus and extensor carpi ulnaris about 6 cm distal to the tip of the olecranon
- Proximally, the triceps is identified and freed from the brachioradialis and extensor carpi radialis longus along the intramuscular septum to the level of the joint capsule.
- The interval between the extensor carpi ulnaris and the anconeus is identified distally.
- The triceps in continuity with the anconeus is subperiosteally reflected. Sharp dissection frees the bony attachment of the triceps expansion to the anconeus from the lateral epicondyle.
- The triceps remains attached to the tip of the olecranon.
- The lateral collateral ligament complex is released from the humerus.
- The joint may be dislocated with varus stress. If additional exposure is necessary, the anterior and posterior capsule can be released.
- Routine closure of layers is performed, but the radial collateral ligament should be reattached to the bone through holes placed in the lateral epicondyle.

A
Mayo Modified Extensile Kocher Approach
- The extensile Kocher approach and the Mayo modification of the extensile Kocher approach provide sequentially greater exposure from the initial Kocher approach.

INDICATIONS
- Release of ankylosed joint
- Interposition arthroplasty
- Replacement arthroplasty

APPROACH
- A modification of the extensile Kocher approach consists of reflecting the anconeus and triceps expansion from the tip of the olecranon by sharp dissection.
- The extensor mechanism (triceps in continuity with the anconeus) may be reflected from lateral to medial.
- The ulnar nerve should be decompressed or transposed if an extensile lateral approach is used.
- The triceps is reattached in a fashion identical to that described for the Mayo approach.

Triceps-Preserving Approaches
Posterior Triceps-Sparing Approach
- Because the triceps is not elevated from the tip of the olecranon, rapid rehabilitation is possible.

**INDICATIONS**
- Tumor resection
- Joint reconstruction for resection of humeral nonunion
- Joint replacement

**APPROACH**
- A posterior incision is made medial to the tip of the olecranon.
- Medial and lateral subcutaneous skin flaps are elevated.
- The ulnar nerve is identified and transposed anteriorly.
- The medial and lateral aspects of the triceps are identified and developed distally to the triceps attachment on the ulna.
- For distal humerus fractures fixation:
  - The common flexors and common extensors are partially released from the distal humerus to expose the supracondylar column for plate fixation.
- For total elbow arthroplasty or tumor resection:
  - The common flexors and extensors are fully released from the medial and lateral epicondyle. The collateral ligaments and capsule are released and the distal humerus is excised.
  - The distal humerus is exposed by bringing it through the defect along the lateral margin of the triceps.
  - The ulna is exposed by supinating the forearm.
  - After the implant has been inserted, the joint is articulated.
There is no need to close or repair the extensor mechanism with this approach.

**Olecranon Osteotomy**

- Worldwide, the transosseous approach is probably the exposure most often used, especially for distal humeral fractures. The oblique osteotomy has almost been abandoned, and the transverse osteotomy has largely been replaced by the chevron.

**Chevron Transolecranon Osteotomy**

- Intra-articular osteotomy, first described by MacAusland, was originally recommended for ankylosed joints.
- It has been adapted by some for radial head excision and synovectomy and used or modified by others for T and Y condylar fractures.
- The chevron osteotomy enhances rotational stability compared to a transverse osteotomy.

**INDICATIONS**

- Ankylosed joints
- T or Y condylar fractures

**APPROACH**

- A posterior incision is made medial to the tip of the olecranon.
- Medial and lateral subcutaneous skin flaps are elevated.
- The ulnar nerve is identified and transposed anteriorly.
- The medial and lateral aspects of the triceps are identified and developed distally to the triceps attachment on the ulna.
- An apex-distal chevron or V osteotomy is performed with a thin oscillating saw but not completed through the subchondral bone. An osteotome completes the osteotomy, creating irregular surfaces that interdigitate increasing stability (**FIG 11A,B**).
- The triceps tendon, along with the osteotomized portion of the olecranon, may then be retracted proximally, and by flexing the elbow joint, the joint can be exposed (**FIG 11C**).

Occasionally the medial or lateral collateral ligaments are released for better exposure.
- These ligaments are then repaired at the end of the procedure.
- At the completion of the procedure, the tip of the olecranon is secured via tension-band or plate fixation.

**LATERAL APPROACH TO THE ELBOW**

- Lateral exposures to the elbow are widely used to treat a variety of elbow pathologies. The exposures differ according to the deep interval used.
- With any of the lateral exposures to the joint or to the proximal radius, the surgeon must be constantly aware of the possibility of injury to the posterior interosseous or recurrent branch of the radial nerve.

**Anterolateral Approach to the Elbow (Kaplan)**

**Indications**

- Anterior capsular release
- Posterior interosseous nerve exposure
- Capitellar/lateral column fractures

**Approach**

- Deep interval for the anterolateral approach lies between the extensor digitorum communis and the extensor carpi radialis longus muscles. (Intermuscular interval is best found by observing where vessels penetrate the fascia along the anterior margin of the extensor digitorum communis aponeurosis.)
- Fascia is split longitudinally between the extensor digitorum communis and the extensor carpi radialis longus. (As the dissection is carried deep through the extensor carpi radialis longus, the extensor carpi radialis brevis is encountered.)
- Deep to the extensor carpi radialis brevis, the transversely oriented fibers of the supinator are encountered, along with the posterior interosseous nerve. The posterior interosseous
nerve defines the distal extent of the exposure. Pronation moves the radial nerve away from the surgical field.

- If required, proximal dissection with elevation of the extensor carpi radialis longus, extensor carpi radialis brevis, and brachioradialis anteriorly from the lateral supracondylar ridge of the humerus provides exposure of the anterior joint capsule.

**Modified Distal Kocher Approach**

**Indications**

- Reconstruction of the lateral ulnar collateral ligament

**Approach**

- The skin incision begins just proximal to the lateral epicondyle of the humerus and extends obliquely for about 6 cm in line with the fascia of the anconeus and extensor carpi ulnaris muscles (FIG 12A).
- The Kocher interval between the anconeus and flexor carpi ulnaris is incised (FIG 12B).
- Development of the Kocher interval reveals the lateral joint capsule.

- The anconeus is then reflected posteriorly off the joint capsule distally to expose the crista supinatoris.
- The extensor carpi ulnaris and the common extensor tendon are released from the lateral epicondyle and reflected anteriorly, exposing the lateral capsule. The radial nerve is at a safe distance from the dissection, and it is protected by the extensor carpi ulnaris and extensor digitorum communis muscle mass (FIG 12C).
- A longitudinal incision is made through the capsules to expose the radiocapitellar joint.

**Boyd (Posterolateral) Approach**

**Indications**

- Monteggia fracture-dislocations
- Radial head fractures
- Radioulnar synostosis

**Approach**

- The incision begins just posterior to the lateral epicondyle lateral to the triceps tendon and continues distally to the lat-
eral tip of the olecranon and then down to the subcutaneous border of the ulna.
- The anconeus and supinator are subperiosteally elevated from the subcutaneous border of the ulna (anconeus and supinator) (FIG 13A,B).
- Retraction of the anconeus and supinator exposes the joint capsule overlying the radial head and neck.
- The supinatis muscle protects the posterior interosseous nerve.
- This lateral capsule contains the lateral ulnar collateral ligament, and its division can lead to posterolateral rotatory instability.
- To expose the radial shaft, the incision may be continued along the subcutaneous ulnar border, elevating the muscles off the lateral aspect of the ulna (extensor carpi ulnaris, abductor pollicis longus, and extensor pollicis longus).
- The posterior interosseous and recurrent interosseous arteries may need ligation.

**MEDIAL APPROACH TO THE ELBOW**
- There are relatively few indications for medial exposure of the elbow joint. This has been superseded by arthroscopic approaches.
- The most valuable contribution to medial joint exposure is that described by Hotchkiss. This extensile exposure provides greater flexibility, particularly for exposure of the coronoid and for contracture release.

**Extensile Medial Over-the-Top Approach**
- Excellent visualization of the anteromedial and posteromedial elbow
- Not a sufficient approach for excision of heterotopic bone on the lateral side of the joint
- Does not provide adequate access to the radial head

**Indications**
- Coronoid fractures
- Contracture release (when ulnar nerve exploration required)
- Anterior and posterior access to the joint
- May be converted to a triceps-reflecting exposure of Bryan-Morrey

**Approach**
- Superficial dissection
  - Skin incision can vary between the boundaries of a pure posterior skin incision and midline medial incision (FIG 14A).
  - Subcutaneous skin is elevated.
  - The medial supracondylar ridge of the humerus, the medial intramuscular septum, the origin of the flexor pronator mass, and the ulnar nerve are identified.
  - Anterior to the septum, running just on top of the fascia (not in the subdermal tissue), the medial antebrachial cutaneous nerve is identified and protected.
  - The ulnar nerve is identified. If the patient previously had surgery, the ulnar nerve should be identified proximally before the surgeon proceeds distally.
  - If anterior transposition was performed previously, the nerve should be mobilized carefully before the operation proceeds.
  - The surface of the flexor pronator muscle mass origin is found by sweeping the subcutaneous tissue laterally with the medial antebrachial cutaneous nerve in this flap of subcutaneous tissue.
  - The medial intramuscular septum divides the anterior and posterior compartments of the elbow. The medial intramuscular septum is ultimately excised from the medial epicondyle to 5 cm proximal to it (FIG 14B).
  - The ulnar nerve is protected and the veins at the base of the septum are cauterized.
- Deep anterior exposure
  - The flexor pronator mass origin is identified and totally or partially released from the medial epicondyle.
  - If extensile exposure is needed, the entire flexor pronator mass is elevated from the medial epicondyle (FIG 14C,D).
  - If less extensile exposure is needed, the flexor pronator mass is divided parallel to the fibers, leaving about 1.5 cm of flexor carpi ulnaris tendon attached to the epicondyle.
  - A small cuff of fibrous tissue of the origin can be left on the supracondylar ridge as the muscle is elevated; this facilitates reattachment when closing.
  - The flexor pronator origin should be dissected down to the level of bone but superficial to the joint capsule. As this

---

**FIG 13** • The Boyd approach. A, The incision begins along the lateral border of the triceps about 2 to 3 cm above the epicondyle and extends distally over the lateral subcutaneous border of the ulna about 6 to 8 cm past the tip of the olecranon. The ulnar insertion of the anconeus and the origin of the supinator muscle are elevated subperiosteally. More distally, the subperiosteal reflection includes the abductor pollicis longus, the extensor carpi ulnaris, and the extensor pollicis longus muscles. The origin of the supinator at the crista supinatorus of the ulna is released, and the entire muscle flap is retracted radially, exposing the radiohumeral joint. B. The posterior interosseous nerve is protected in the substance of the supinator.
plane is developed, the brachialis muscle is encountered from the underside.
- The brachialis muscle is identified along the supracondylar ridge and released in continuity with the flexor pronator mass.
- These muscles should be kept anterior and elevated from the capsule and anterior surface of the distal humerus.
- The median nerve and the brachial vein and artery are superficial to the brachialis muscle and protected with the subperiosteal release of the brachialis.
- Dissection of the capsule proceeds laterally and distally to separate it from the brachialis.
- In the case of contracture, the capsule, once separated from the overlying brachialis and brachioradialis, can be sharply excised (FIG 14E).

Deep posterior capsule exposure
- The ulnar nerve is mobilized to permit anterior transposition with a dissection carried distally to the first motor branch to allow the nerve to rest in the anterior position without being sharply angled as it enters the flexor carpi ulnaris.
- With the Cobb elevator, the triceps is elevated from the posterior distal surface of the humerus.
- The posterior capsule can be separated from the triceps as the elevator sweeps from the proximal to distal.

Closure
- The flexor pronator mass should be reattached to the supracondylar ridge.
- The ulnar nerve should be transposed and secured with a fascial sling to prevent posterior subluxation.

FIG 14 • A. Medial skin incision along the midline. 
B. The medial intermuscular septum (light blue) is excised from the medial epicondyle to 5 cm proximal to it. The ulnar nerve is shown tagged with a suture loop. 
C,D. If the extensile exposure is needed, the entire flexor pronator muscle mass is elevated from the medial epicondyle. 
E. The capsule can be sharply excised in cases of capsular contracture.
ANTERIOR APPROACH TO THE ELBOW

- Because of the vulnerability of the brachial artery and median nerve, the anterior medial approach to the elbow is not recommended.
- The extensile exposure described by Henry, and modified by Fiolle and Delmas, is best known and is the most useful for anterior exposure of the joint. Minor modifications of the Henry approach have been described, and a limited anterolateral exposure has been described by Darrach.

Modified Anterior Henry Approach

**Indications**
- Anteriorly displaced fracture fragments
- Excision of tumors in this region
- Reattachment of the biceps tendon to the radial tuberosity
- Exploration of nerve entrapment syndromes
- Anterior capsular release for contracture

**Approach**
- The skin incision begins about 5 cm proximal to the flexor crease of the elbow joint and extends distally along the anterior margin of the brachioradialis muscle to the flexion crease.
- At the elbow flexion crease, the incision turns medially to avoid crossing the flexor crease at a right angle. The incision continues transversely to the biceps tendon and then turns distally over the medial volar aspect of the forearm (FIG 15A).
- The fascia is released distally between the brachioradialis and pronator teres (FIG 15B).
- The interval between the brachioradialis laterally and the biceps and brachialis medially is identified. This interval is entered proximally, and gentle, blunt dissection demonstrates the radial nerve coursing on the inner surface of the brachioradialis muscle (FIG 15C).
- Care is taken to avoid injury to the superficial sensory branch of the radial nerve.
- Because the radial nerve gives off its branches laterally, it can safely be retracted with the brachioradialis muscle.
- At the level of the elbow joint, as the brachioradialis is retracted laterally and the pronator teres is gently retracted medially, the radial artery can be observed where it emerges from the medial aspect of the biceps tendon, giving off its muscular and recurrent branches in a mediolateral direction.
- The muscle branch is ligated, but the recurrent radial artery should be sacrificed only if the lesion warrants an extensive exposure.
- The posterior interosseous nerve enters the supinator and continues along the dorsum of the forearm distally.
- Dissection continues distally, exposing the supinator muscle, which covers the proximal aspect of the radius and the anterolateral aspect of the capsule (FIG 15C).
- Muscle attachments to the anterior aspect of the radius and those distal to the supinator include the discrete tendinous insertion of the pronator teres and the origins of the flexor digitorum sublimis and the flexor pollicis longus.
- The brachialis muscle is identified, elevated, and retracted medially to expose the proximal capsule.
- If more distal exposure is needed, the forearm is fully supinated, demonstrating the insertion of the supinator muscle along the proximal radius.
- This insertion is incised and the supinator is subperiosteally retracted laterally (FIG 15D).
- The supinator serves as a protection to the deep interosseous branch of the radial nerve, but excessive retraction of the muscle should be avoided.
- The proximal aspect of the radius and the capitellum are thus exposed.
- Additional visualization may be obtained both proximally and distally, because the radial nerve has been identified and can be avoided proximally.
- The posterior interosseous nerve is protected distally by the supinator muscle, and the radial artery is visualized and protected medially if a more extensile exposure is required.

Table 1: Indications and Recommended and Alternative Surgical Approaches
The anterior Henry approach. 

A. An incision is made about 5 cm proximal to the elbow crease on the lateral margin of the biceps tendon. It extends transversely across the joint line and curves distally over the medial aspect of the forearm. The interval between the brachioradialis and brachialis proximally and the biceps tendon and pronator teres in the distal portion of the wound is identified. The radial nerve is protected and retracted along with the brachialis.

B. The supinator muscle is released from the anterior aspect of the radius, which is fully supinated.

C. The radial recurrent branches of the radial artery and its muscular branches are identified and sacrificed if more extensive exposure is required. The biceps tendon is retracted medially along with the brachialis muscle.

D. This interval may now be developed to expose the anterior aspect of the elbow joint.
DEFINITION
- Shoulder instability is caused by a disruption of the normal stabilizing anatomic structures of the shoulder, leading to recurrent dislocation or subluxation of the glenohumeral joint.

ANATOMY
- Glenohumeral stability depends on the integrity of static and dynamic components.
- Dynamic stabilizers include the rotator cuff muscles, which provide a concavity compression effect, the scapular stabilizers, and the biceps tendon, which contributes to anterior stability when the arm is in an abducted and externally rotated position (FIG 1A,B).
- Static stabilizers consist of the bony and articular anatomy of the glenoid and humeral head, the negative intra-articular pressure supplied by the intact glenohumeral capsule, and the capsule-labral complex, which contains the glenoid labrum and anterior, middle, and superior glenohumeral ligaments (FIG 1C).
- The glenoid labrum plays an important role in deepening the glenoid socket and as an attachment site for the glenohumeral ligaments (FIG 1D).
- The primary restraint to anterior inferior translation of the humeral head in 90 degrees of abduction and external rotation is the inferior glenohumeral ligament (IGHL).
- The middle glenohumeral ligament (MGHL) has a variable attachment site into the glenoid labrum, glenoid neck, and biceps tendon origin. The MGHL is important in resisting anterior subluxation of the humeral head in the middle range of shoulder abduction (45 degrees).
- The superior glenohumeral ligament (SGHL) is located in the rotator interval capsule, and prevents inferior and posterior subluxation of the humeral head with the arm in an ad-
ducted and neutral or internally rotated position. The SGHL is important in inferior and posterior translation of the humeral head.

PATHOGENESIS
- Glenohumeral instability (subluxation or dislocation) occurs when the static or dynamic stabilizers of the gleno-humeral joint are disrupted, either from acute rupture or repetitive microtrauma.
- The “essential anatomical defect,” or Bankart lesion, was first described by a British pathologist, A. Blundell Bankart, in 1923, and the operative procedure was first described in 1938 (FIG 2A).³,²⁰
  - The Bankart lesion is present in at least 40% of shoulders undergoing anterior instability procedures.
  - The “essential” nature of the Bankart lesion has been challenged, since a simulated Bankart lesion without capsular stretching does not lead to significant increases in gleno-humeral translation.
- In addition to tearing of the glenoid labrum, the labrum may also be avulsed from the glenoid rim as a sleeve of tissue (anterior labral periosteal sleeve avulsion [ALPSA]) (FIG 2B).¹⁷
- Recurrent major trauma and repetitive microtrauma creates substantial deformation to the IGHL, producing subsequent episodes of symptomatic subluxation.
- Biomechanical studies of this ligament have demonstrated that failure typically occurs at the glenoid insertion (40%), followed by the ligament substance (35%) and the humeral attachment (25%). Significant capsular stretching can occur (23% to 34%) before failure.
- Osseous deficiency on the anterior rim (bony Bankart) may contribute to glenohumeral instability (FIG 2C).
- Significant defects accounting for instability occur when 30% of the glenoid is involved, and the glenoid acquires an “inverted pear” appearance (FIG 2D).

NATURAL HISTORY
- The incidence of glenohumeral instability has been estimated at 8.2 to 23.9 per 100,000 person-years.²³
- The incidence in at-risk populations is significantly higher (military population, 1.69 per 1000 person-years; NCAA athletes, 0.12 injuries/1000 athletic exposures).¹⁹
- Overhead athletes are prone to this repeat injury as their motions in the abducted, externally rotated position put stress on the capsulolabral structures. Contact athletes (football players and wrestlers) have the highest incidence of shoulder dislocations as compared to other sports.
- Depending on the patient’s age and activity level, redislocation rates in active patients may be as high as 92% with non-operative treatment.¹³,¹⁹,²⁴

PATIENT HISTORY AND PHYSICAL FINDINGS
- Evaluation of the patient with suspected instability begins with a thorough history.
- Arm dominance, sport, position, and level of competition should be noted, as well as associated factors, including other sporting activities, training modalities, and past history of injuries.
- Traumatic causes of instability should be determined, as these are more likely to be associated with Bankart lesions.
- The character of the problem should be elicited.
  - Does the athlete complain of pain or instability?
  - Does the shoulder subluxate or dislocate?
  - What arm positions reproduce symptoms?
- Any prior treatments (physical therapy, training modifications, medication, and surgery) should be noted.
- Physical examination should include assessment of both shoulders.
- Inspection should be performed to identify any skin incisions, evidence of wasting in the deltoid, rotator cuff, or periscapular...
musculature, and gross evidence of laxity, including sulcus signs or signs of generalized ligamentous laxity.

- Palpation is performed to identify point tenderness; anterior joint line tenderness may be present in acute anterior dislocations; subacromial tenderness may be present with impingement secondary to subtle instability.
- Active and passive motion tests are an important part of the instability examination. Significant variations in motion are encountered in throwing athletes, with increased external rotation and decreased internal rotation common in the affected shoulder.
- Provocative testing is perhaps the most important aspect in the clinical evaluation of shoulder instability.
  - The sulcus sign is often elicited in patients with inferior instability.
  - Anterior translation and posterior translation are similarly graded with the patient supine and with an anterior or posterior load and shift test, although this test is performed only in the anesthetized patient.
  - In the awake patient, signs of instability can be more subtle. The apprehension test is routinely performed with the arm abducted, extended, and externally rotated. A sensation of impending subluxation or dislocation in the patient is diagnostic of instability. Pain is less specific and may instead indicate internal impingement of the articular surface of the rotator cuff or functional impingement of the bursal side of the rotator cuff on a prominent coracoacromial ligament.
  - A posterior-directed force on the arm by the examiner that relieves the apprehension in this position (Jobe relocation test) suggests an unstable shoulder.
  - Subscapularis integrity and strength should be evaluated in patients with glenohumeral instability.
    - Inability to press the hand to the belly is a positive result of the belly press test and indicates subscapularis muscle weakness or tear.
    - Inability to lift the hand from the back is a positive result in the lift-off test and indicates subscapularis muscle weakness or tear.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs include anteroposterior (AP), lateral, and axillary views (**FIG 3A, B**).
  - The axillary view is particularly important for assessing anterior glenoid rim defects.

- The Hill-Sachs lesion of the posterosuperior humeral head is best seen on the AP internal rotation or Stryker notch views.
- CT scan is not necessary in all cases but may be helpful in patients with bony defects (see Fig 2C,D).
- MRI scan is not necessary in all cases but can be useful in identifying labral lesions as well as subscapularis tears (**FIG 3C**).
- MRI arthrogram is more sensitive in identifying labral pathology and may be necessary when superior or posterior labral pathology is suspected.

**DIFFERENTIAL DIAGNOSIS**

- External impingement, subacromial bursitis, rotator cuff tendinitis
- Internal impingement
- SLAP (superior labral tear)
- Voluntary instability
- Collagen disorder (Ehlers-Danlos syndrome, Marfan syndrome)
- Subscapularis insufficiency, tear

**NONOPERATIVE MANAGEMENT**

- After reduction of an acute dislocation, a sling is used for immobilization. The duration of immobilization has been controversial, but 3 to 6 weeks is recommended.21
  - Some surgeons recommend immobilization in a position of abduction and external rotation to improve healing. However, many patients will not tolerate this position, and a position of adduction and internal rotation therefore is more commonly used.
  - For treatment of acute injuries, rotational and scapular strengthening exercises of the affected shoulder are started after the initial immobilization period. The program is progressed toward normalization of strength and motion through increased resistance training.
  - Return to sports is allowed when the patient has a full and pain-free range of motion, normal strength, and little or no apprehension.21
  - For chronic and recurrent instability, strengthening is focused on the rotator cuff and scapular stabilizers, as well as core strengthening of the abdominal and trunk musculature. Resistive exercises of the rotator cuff are begun with the arm in neutral below 90 degrees and are progressed gradually. Strengthening of scapular stabilizers is particularly important.
The rate of redislocation after nonoperative treatment depends on the patient’s age and activity level. In young patients participating in high-risk activities (eg, military cadets), the rate of redislocation is as high as 92%.24

In a meta-analysis comparing operative to nonoperative treatment for first-time dislocators, 50% of the conservatively treated patients eventually opted for surgery.19

**SURGICAL MANAGEMENT**

- Surgical treatment options are generally categorized into anatomic and nonanatomic procedures.
- Nonanatomic procedures (Putti-Platt, Magnuson-Stack) are aimed at tightening the anterior structures and preventing at-risk arm positions (ie, abduction and external rotation). These procedures have largely been abandoned after it was discovered that overtightening the anterior structures could lead to posterior subluxation and glenohumeral arthritis.11,18
  - The Putti-Platt procedure consists of a vertical incision through both the subscapularis tendon and capsule followed by repair of the lateral flap to the soft tissue at the glenoid rim.18
  - The Magnuson-Stack procedure is a transfer of the subscapularis tendon lateral to the bicipital groove (FIG 4A).
- Coracoid transfer procedures are other nonanatomic procedures where the coracoid process, with its attached short head of the biceps and coracobrachialis tendons, is transferred to the anterior glenoid rim and secured with screws.1
  - The Bristow procedure uses the tip of the coracoid and typically a single bicortical cancellous screw.
  - The Laterjet procedure lays the coracoid on its side and is typically secured with two screws (FIG 4B).
- Although several authors have achieved excellent success with these procedures, the concern for hardware migration and late resorption of the bone block have made these procedures less popular than the anatomic procedures. They are used mainly for revision procedures and in cases where there is deficient glenoid bone stock.
- Anatomic reconstruction procedures have been aimed at reconstructing the anterior labrum using sutures, staples, or tacks.2,8,9,12,22 These anatomic procedures have had excellent success, with minimal (less than 5%) recurrence rates, and therefore are the procedure of choice in the surgical treatment of glenohumeral instability.
- The Bankart repair and inferior capsular shift procedures are the most commonly used anatomic reconstruction procedures.
- Although recurrence rates for arthroscopic Bankart repair and capsular shift were initially higher than open procedures, these rates have become comparable to open as the arthroscopic techniques have evolved.
- Open treatment, however, is recommended over arthroscopic treatment in the following situations:
  - Significant bony Bankart lesions (over 30%)
  - Significant Hill-Sachs defects where the defect “engages” the glenoid rim with external rotation as visualized during diagnostic arthroscopy
  - Revision procedures
  - Some contact athletes (football) and extreme sports, where a slightly lower recurrence rate can be expected in comparison to the arthroscopic procedure

**Preoperative Planning**

A careful assessment of the patient’s expectations of the surgery and postoperative care, including thorough discussions with the patient and family, are required as part of the preoperative plan.

- Noncompliance with the postoperative restrictions will increase the risk of redislocation after surgical repair.
- It is important to assess mental status and any secondary gain issues in patients with multidirectional instability. Patients with voluntary dislocations and malingering (Munchausen syndrome) patients have a high rate of failure and should be identified before surgery.
- It is important to identify before surgery any glenoid bony deficiency that may require bony augmentation via coracoid transfer or allograft reconstruction. Special equipment (allograft bone and instrumentation to perform ORIF) may be required and should be arranged before surgery.

**Positioning**

- Interscalene block anesthesia is preferred because of the excellent muscle relaxation and postoperative pain relief it offers. If an adequate block cannot be performed, however, general anesthesia can also be used.
- The patient is positioned in the beach-chair position with the back elevated. The patient should be moved to the edge of the table or the shoulder cut-out removed to allow access to the anterior and posterior shoulder as required.
- A hydraulic arm positioner (Tenet Spider) is particularly helpful and can obviate the need for an additional assistant to hold the arm (FIG 5).
Approach

- The bony landmarks of the shoulder are identified, including the acromion, clavicle, and coracoid process.
- Approaches to the shoulder that may be used include the deltopectoral, the concealed axillary incision, and the mini-incision approach. All of these are variations of the standard deltopectoral approach.
  - Standard deltopectoral approach
    - This is the utility approach to the shoulder.
    - A 7- to 15-cm incision is made lateral to the coracoid process beginning below the clavicle and extending toward the anterior humeral shaft at the deltoid insertion. Skin flaps are elevated and the deltopectoral interval is identified.
    - The remainder of this approach is described in detail below.
  - Concealed axillary incision
    - Whereas the traditional deltopectoral approach is about 15 cm in length, the concealed axillary incision begins 3 cm inferior to the coracoid and extends only 7 cm into the axillary crease (Fig. 6A). Skin flaps are widely elevated and the deltopectoral interval is identified.
    - This incision is cosmetically appealing and is useful in patients where cosmesis is important.
  - Mini-incision approach
    - A 5-cm incision just lateral to the coracoid process can be used in shoulder stabilization procedures (Fig. 6B). Wide subcutaneous flaps are created and the deltopectoral interval is identified. The remainder of the exposure is similar to the standard deltopectoral approach.
    - The location of this incision is important to achieve direct access to the glenoid without extending the incision: one third of the incision should be above and two thirds below the coracoid process.

BANKART PROCEDURE

- The skin incision is based on surgeon preference as described above. The concealed axillary incision is the most commonly used.
- Skin flaps are elevated and the deltopectoral interval is identified (Tech Fig 1A).
- The cephalic vein is taken laterally with the deltoid muscle, and the clavipectoral fascia overlying the subscapularis tendon and strap muscles is exposed.
- When additional exposure is needed, it is helpful to incise and tag with a suture the upper third of the pectoralis major insertion into the humerus. Great care should be taken not to injure the biceps tendon, which lies just underneath the pectoralis major insertion.
- The clavipectoral fascia is incised lateral to the strap muscles, and a retractor is placed between them to expose the subscapularis muscle and tendon.
- A small wedge of the coracohumeral ligament can be removed to increase superior exposure (Tech Fig 1B). The branches of the anterior circumflex humeral vessels at the inferior margin of the subscapularis muscle should be cauterized at this time to control bleeding.
- The subscapularis tendon is exposed and incised vertically just medial to its insertion. The tendon can be peeled off the underlying capsule with a combination of the periosteal elevator for blunt dissection and the needle-tip Bovie cautery for sharp dissection (Tech Fig 1C,D).
The anterior capsule is then incised vertically at the level of the glenoid rim (TECH FIG 1E,F).

With a curette or osteotome, the anterior glenoid rim is roughened and any soft tissue removed to allow for healing of the repair (TECH FIG 1G).

Transosseous sutures are passed through holes made with pointed forceps or a drill.

Alternatively, suture anchors may be placed at the margin of remaining articular cartilage. Often, two and sometimes three anchors are used between the 2:30 and 6:00 positions (TECH FIG 1H).

The capsule is shifted or repaired anatomically as required. Typically, an inferior capsular shift procedure is performed in combination with the Bankart procedure as described below.

The subscapularis tendon is repaired anatomically at its insertion.
T-PLASTY MODIFICATION OF THE BANKART PROCEDURE

- To address capsular laxity in addition to the Bankart lesion, Altchek and Warren described a modification of the Bankart procedure by performing a T incision in the capsule.
- The approach is the same as in the Bankart procedure described and involves dissection of the subscapularis from the anterior glenohumeral capsule.
- Unlike the inferior capsular shift procedure, the T-plasty involves a medially based capsular incision at the glenoid margin.
  - The T capsulotomy is made two thirds from the top of the capsule, with the vertical component adjacent to the glenoid rim (TECH FIG 2).
- The Bankart lesion is repaired using suture anchors or transosseous sutures.
- The laterally based inferior flap of capsule is advanced superiorly and medially and secured to the glenoid rim.
- The superior flap is then advanced medially and oversewn to the inferior flap.
- The subscapularis tendon is repaired anatomically at its insertion.

ANTERIOR CAPSULOLABRAL RECONSTRUCTION

- Because of the loss of strength and velocity in throwing athletes undergoing anterior stabilization procedures, Jobe in 1991 proposed a subscapularis-sparing procedure in which the tendon is split in line with its fibers and its humeral attachment left intact.
- A deltopectoral approach to the shoulder is used and the strap muscles are retracted medially to expose the subscapularis tendon.
- The subscapularis is then divided horizontally in line with its fibers at the junction of the upper two thirds and lower one third (TECH FIG 3A,B).
- A horizontal capsulotomy is now made in the middle of the capsule extending medial to the glenoid rim. The capsule is elevated off the glenoid subperiosteally to allow for superior and inferior capsular advancement (TECH FIG 3C).
The capsule is elevated off the glenoid subperiosteally to allow for superior and inferior capsular advancement. The laterally based inferior flap is shifted superiorly and secured to the intra-articular portion of the glenoid rim using transosseous sutures to attempt to recreate the labral "bumper" (TECH FIG 3D,E). The superior flap is then shifted medially and oversewn to the inferior flap.

Because the subscapularis tendon is not detached, active assistive rehabilitation exercises are begun immediately on postoperative day 1, and rehabilitation is progressed more rapidly.

**ANTEROIOR INFERIOR CAPSULAR SHIFT**

- The anterior inferior capsular shift operation was first described by Charles Neer in 1980.
- The procedure was designed to treat involuntary inferior and multidirectional instability of the shoulder that could not be addressed by repair of the anterior glenoid labrum alone (the Bankart procedure).
- The skin incision may be chosen based on the desired approach.

The subscapularis tendon is incised about 1 to 2 cm medial to its insertion at the lesser tuberosity, leaving an adequate cuff of tissue for repair.

The subscapularis consists of both a superior tendinous portion (two thirds) and inferior muscular (one third) portion.

To expose the inferior portion of the glenohumeral joint capsule, it is important to carefully separate the
muscle fibers’ insertion from the underlying anterior capsule using a combination of sharp and blunt dissection. The arm should be in a position of adduction and external rotation during this inferior dissection, and great care is taken to protect the axillary nerve.

- A laterally based capsular shift is then performed by incising the capsule vertically about 5 to 10 mm medial to its insertion on the humeral neck (see Tech Fig 1E,F).
- The medial leaf of the capsule is tagged sequentially with nonabsorbable sutures as the capsular incision is continued inferiorly to at least the 6 o’clock position (TECH FIG 4A).
- By placing traction on the capsular tag sutures in a superior and lateral direction, the axillary pouch should be obliterated when an adequate amount of capsular dissection has been performed.
- It is important to release the inferior capsular attachments to the humerus, which have a broad insertion inferior to the articular surface. This is typically done with blunt subperiosteal dissection with the periosteal elevator and needle-tip Bovie cautery (TECH FIG 4B, C).
- The medial insertion of the glenohumeral ligaments and glenoid labrum should then be assessed for avulsion or tear. Bankart lesion and ALPSA both describe a disruption of the medial capsulolabral complex that must be repaired.
- This technique is described in the Bankart repair technique section.
- Once secure fixation to bone is achieved, the capsule is shifted superiorly and laterally and the nonabsorbable sutures are passed through the capsule from an intra-articular to extra-articular location.
- It is important to place the sutures as close to the glenoid rim as possible so that the capsule is not shortened by medial plication.
- A bimanual technique can be used in which one needle driver is used to pass the suture and a second to “catch” the needle on the extra-articular side. The sutures are then tied on the extra-articular side to secure the capsule to the glenoid rim.
- If excess anteromedial capsular redundancy (AMCR) exists after the Bankart repair, a “barrel stitch” technique has been described in which a nonabsorbable pursestring suture is placed to imbricate the anterior capsule.7 The barrel stitch is placed vertically at the level of the glenoid rim and tied on the extra-articular side. Its size is titrated to the amount of AMCR encountered (TECH FIG 4D, E).

**TECH FIG 4** • **A.** In the inferior capsule shift procedure, the laterally based capsular incision is continued inferiorly using tag stitches on the released anterior capsule to apply traction. **B.** There is a dual attachment of the inferior capsule on the humeral neck. **C.** Release of the dual inferior capsular attachment, allowing a complete shift of the capsule. **D.** An anterior crimping (barrel) stitch is used to decrease the redundancy of the anteroinferior capsule. This is a mattress stitch started on the superficial side of the capsule. **E.** Once tied, the barrel stitch reduces anterior medial capsular redundancy and an anterior inferior bolster is created. *(continued)*
PEARLS AND PITFALLS

Voluntary instability

- Patients with voluntary instability should be carefully screened before surgery. If there are significant issues of secondary gain, surgical treatment will not be successful and should be discouraged. Preoperative psychiatric evaluation has been suggested but is seldom helpful in screening these patients.

Humeral bone defects (Hill-Sachs lesions)

- It is important to recognize and quantitate humeral bone defects, which are best seen on the radiograph (AP in internal rotation or Stryker notch view), CT scan, or MRI, or by diagnostic arthroscopy. With “engaging” defects, open treatment is favored over arthroscopic, and filling of the defect (autograft, allograft) may be considered.

Glenoid bone defects (bone Bankart)

- Glenoid defects can be assessed with preoperative imaging (radiographs, CT scan, MRI) and diagnostic arthroscopy. Significant defects (more than 30% of the glenoid) require a coracoid transfer (Bristow or Laterjet) procedure.
POSTOPERATIVE CARE

- The rehabilitation protocol must be planned individually.
- The patient remains in a sling for 4 weeks postoperatively.
- Passive forward elevation to 110 degrees and external rotation to 15 degrees is begun at 10 days to 2 weeks, and is gradually increased to 140 degrees forward elevation and 30 degrees external rotation by 4 weeks. During this period, isometric strengthening exercises are begun.
- From 4 to 6 weeks, elevation is increased to about 160 degrees and external rotation to 40 degrees.
- After 6 weeks, motion is increased to achieve a normal range.
- Exercises should be progressed slowly to avoid apprehension and resubluxation.
- Resistive exercises are begun with the arm in neutral below 90 degrees and progressed gradually.
- Strengthening of scapular stabilizers is particularly important.
- Full motion and strength should be regained before contact sports are resumed, usually between 6 and 9 months, depending on the sport and the patient.

OUTCOMES

- The first long-term follow-up study of the Bankart procedure was reported by Carter Rowe in 1978, with only a 3.5% rate of redislocation.
- Neer reported on 40 unstable shoulders that were repaired with the anterior inferior capsular shift between 1974 and 1979, 11 of which had undergone prior procedures for glenohumeral instability. Satisfactory results were achieved in all except one patient, who had postoperative subluxation of the shoulder.
- Since Neer’s initial report, multiple series have been published that have used the anterior inferior capsular shift procedure for anteroinferior instability. Although the surgical technique and the extent of capsular shift may vary with different surgeons, recurrence rates have ranged from 1.5% to 9%.5,6,9,16,25
- T-plasty results: In 42 shoulders with an average of 3 years of follow-up in this initial series, 95% of the patients were satisfied and there were four recurrences (10%).
- A report on the results of anterior capsulolabral reconstruction at an average of 39 months of follow-up in 25 throwing athletes found excellent or good results in 92% of patients, and 17 (68%) returned to their prior level of competition.
- A subsequent series of 22 subluxators and 9 dislocators found 97% good to excellent results and 94% return to sport.
- Return-to-sport rates of 32% to 94% have been reported for open surgical treatment of anteroinferior instability in various series.2,5,12

COMPLICATIONS

- Injury to the axillary nerve can occur as it travels an average of only 2.5 mm deep to the IGHL and lies only 12 mm from the glenoid at the 6 o’clock position.
- Nerve injury typically involves sensory function only, and function usually recovers spontaneously.
- Recurrent dislocations may occur in up to 5% of patients. However, this rate may be higher when appropriate indications for surgery are not strictly followed.
- Hardware-related complications may occur owing to loosening, bending or breakage of screws, anchors, or tacks (FIG 7).
- Synovitis in response to PLLA absorbable implants has also been described.
- Misplacement of labral tacks or suture anchors, both metallic and absorbable, may lead to early arthritis or arthritis.
- Complications due to positioning have been described including deep venous thrombosis and compression neurapraxia. Bony prominences should be well padded and constrictive bandaging avoided during and after surgery.
- Infection in shoulder surgery is uncommon. When it occurs, however, *Propionibacterium acnes* is a common organism, and specific cultures should be requested.

REFERENCES

DEFINITION
- Symptomatic recurrent posterior instability represents up to 12% of all cases of shoulder instability and is subdivided into two discrete entities.\textsuperscript{28,35}
- The first, true posterior dislocation is acute in nature and often related to trauma. It is readily managed with shoulder re-reduction and carries a low recurrence rate if not associated with a large engaging humeral head defect or a primary uncontrolled seizure disorder.
- If the primary dislocation is overlooked, this condition can manifest itself as a chronic locked posterior dislocation with its pathognomonic internally rotated position and loss of external rotation on physical examination.
- The second entity is recurrent unidirectional posterior subluxation, which often represents the more challenging dilemma confronting the orthopaedic surgeon and will be the principal topic of this chapter.
  - Whether due to an increase in awareness by physicians or a more active athletic population, recurrent posterior instability is being recognized, diagnosed, and treated more frequently.
  - Patients with recurrent posterior subluxation complain primarily of pain and weakness. As time progresses, symptoms of posterior subluxation become a secondary complaint. Eventually patients often learn the selected muscular contractions, scapular winging, and arm position (forward elevation, adduction, and internal rotation) needed to demonstrate their instability.
  - See Table 1 for the classification of posterior instability.

ANATOMY
- Posterior instability may be secondary to a tear of the posteroinferior labrum or a patulous posterior capsule.
- Rarely it can involve a posterior labrocapsular periosteal sleeve avulsion or an avulsion of the posterior glenohumeral ligaments as they insert on the humerus (posterior HAGL lesion).
- Recently Kim described a concealed and incomplete avulsion of the posteroinferior labrum (type II marginal crack or Kim lesion).\textsuperscript{20}
- Pathology may also be bony in nature and secondary to posterior glenoid avulsions, erosions, increased glenoid retroversion or large engaging reverse Hill-Sachs impression defects.

PATHOGENESIS
- A significant percentage of patients (40% to 50%) with recurrent posterior subluxation relate a history of trauma. Usually athletes, these individuals are 18 to 30 years of age and are involved in competitive contact sports.
- Traumatic cases are often associated with the arm in a straight and locked position such as in weight lifting or during football while line blocking. A fall or collision with the individual’s arm in at-risk position (forward elevation, adduction, internal rotation) can also be the cause.
- Frequently, instead of a traumatic event, subluxation episodes with a poorly defined onset are clearly documented.
- In many cases, especially with repetitive overhead endeavors such as swimming, gymnastics, baseball, and volleyball, the athlete recalls first the gradual onset of discomfort, with subluxation episodes occurring later. Such an onset is thought to be atraumatic and involves repetitive “microtrauma” with resultant stretching of the capsular restraints.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Whether the patient presents with a clear traumatic episode or a longer atraumatic course, he or she often has a feeling of the shoulder “coming out.” Such instability episodes occur when the arm is in the at-risk position of forward elevation, adduction, and internal rotation.
- Patients often describe a vague discomfort, pain, or weakness as their principal complaint. This actually may lead to misdiagnosis at first.
- True apprehension or a feeling of “impending doom” when the extremity is placed in the provocative position is less common but can be present.
- Overhead throwers may complain of a loss of velocity, fatigue, or aching over the posterior shoulder.
- Usually there is no obvious asymmetry of the muscles on inspection.
- Palpation may elicit some tenderness along the posterior glenohumeral joint line.
- Crepitation or a click along the posterior joint line due to labral pathology may be noted.
- The range of motion is full, often with a decrease in internal rotation and an excess of external rotation.
 Often patients, if voluntary subluxators, can reproduce the subluxation episode on command with arm position and selective muscular contraction (FIG 1).

Physical examination should include the following:
- Modified load shift test: documents direction and degree of instability
- Supine load shift test (Gerber and Ganz)\(^1\): documents direction and degree of instability
- Seated load shift test: documents direction and degree of instability
- Posterior stress test: documents direction and degree of instability
- Sulcus sign: evaluates for an inferior component of the posterior instability (bidirectional) or a more global instability (ie, multidirectional instability)
- Scapular compression test: verifies the importance of scapular winging in the patient’s ability to reproduce the instability and proves to the patient the need to strengthen the periscapular musculature to control instability
- Jerk test: to document instability. A painful jerk test suggests a posteroinferior labral lesion and is a predictor of the success of nonoperative treatment.
- Kim test: evaluates for the presence of a labral tear posteriorly
- Pivot shift of the shoulder: documents direction of the instability

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographic evaluation includes a three-view trauma series of the shoulder, including a true anteroposterior (AP) view of the shoulder, a scapular lateral, and, more importantly, an axillary view.
- A Velpeau axillary view can be substituted if the attempted axillary view is impossible because of painful abduction of the shoulder.
- Axillary radiographs of patients with a voluntary component to their instability can be taken while the patient reproduces and maintains the subluxation episode to document the direction (FIG 2A).
- A computed tomography (CT) scan is rarely needed but can be helpful to evaluate humeral head defects and associated fractures of the tuberosities, humeral shaft, and posterior glenoid rim. Significant posterior glenoid retroversion can also be demonstrated on CT scanning (FIG 2B).

MRI is the imaging modality of choice after plain radiographs to evaluate the posterior capsule and labrum for tears and associated pathology.
- In certain situations a MRI arthrogram can help diagnose a posteroinferior labral tear.

DIFFERENTIAL DIAGNOSIS
- Superior labrum anterior from posterior tear (SLAP)
- Anterior instability
- Multidirectional instability
- Internal impingement
- Posterior Bennett lesion

NONOPERATIVE MANAGEMENT
- Nonsurgical treatment of posterior unidirectional instability is reportedly successful in up to 80% of the patients.\(^9,18\)
- The physical therapy program consists of concentric and eccentric resistive band exercises that strengthen the external rotators, the deltoid, and the important periscapular musculature.
- Resistive upright and seated rows, with an emphasis on trying to pinch the medial scapular borders together during the exercise, are key, especially in patients whose scapular winging contributes to their instability.
- A strengthening program as well as a sport-specific attempt to decrease those activities that place the arm at risk is key.
- The length of nonoperative treatment must be individualized.
- Patients who have lower physical demands, are younger, and have an atraumatic history are treated 6 months or more.
- Higher-level athletes or those who have a traumatic cause with an associated labral tear are more likely to respond to surgical treatment. Despite their associated labral tears, such
elite athletes are often treated with an exercise strengthening program for at least 3 months.

**SURGICAL MANAGEMENT**
- Although open procedures have been the mainstay and gold standard in the treatment of patients with recurrent unidirectional posterior subluxation, when nonoperative care has failed, arthroscopic treatment has become common.
  - As with anterior instability 20 years ago, arthroscopic evaluation in posterior instability patients has led to the diagnosis and treatment of an increasing number of associated soft tissue and articular injuries. Obviously, arthroscopic treatment of posterior capsular avulsions or redundancy in the absence of soft tissue deficiencies or bony abnormalities can have similar success rates without the morbidity of more extensive open surgery.2,6,20,33
  - Surgical treatment is considered only after an adequate trial of strengthening has failed and the patient remains significantly symptomatic.
  - The ideal surgical candidates are those with recurrent posterior unidirectional subluxation secondary to a traumatic episode. These patients often have an associated traumatic posterior labral tear, which is optimal for arthroscopic repair.

**Site Preparation**
- The anterior portal is established in the rotator interval under direct visualization using needle localization.
- A 6.5-mm cannula is established to allow insertion of the arthroscope and an 8-mm cannula is placed in the posterior portal to allow the passage of the Spectrum crescent suture-passing devices (ConMed Linvatec, Largo, FL).

**Portal Placement**
- Most posterior reconstructions are performed using only two portals.
- The first is a posterior portal established just lateral to the posterior lateral corner of the acromion.
  - This differs from the traditional posterior viewing portal, which is 1 cm medial and 2 cm inferior from the posterior lateral corner of the acromion.
  - Lateralization of this portal and moving it somewhat superiorly provides an optimal angle of attack to the posterior and inferior portion of the posterior glenoid.
- Patients with atraumatic subluxation due to capsular redundancy can be managed either through an open procedure or an arthroscopic capsular shift or plication procedure.
- Patients who have multifactorial causes for their instability or are revision situations are better treated with an open approach.

**Preoperative Planning**
- An extensive history and physical examination are key to establishing the direction and degree of the patient’s instability.
- All imaging studies are reviewed. Plain films and MRI studies are reviewed for the presence of old fractures, loose bodies, and hardware from previous procedures. More importantly, the MRI establishes whether the instability is due to an associated traumatic posterior labral tear or capsular redundancy.
- Associated bony pathology (traumatic glenoid avulsions, glenoid retroversion) and soft tissue deficiencies (from previous procedures) should be addressed concurrently.
- Examination, this time under anesthesia, should be accomplished before positioning to confirm the direction and degree of the instability.
Suturing

- A Spectrum 45-degree-offset suture passer, preloaded with a number 0 polydioxanone (PDS) monofilament suture (Ethicon, Somerville NJ), is passed through the posterior cannula, capturing the inferior capsule in the area of the posterior band of the IGHL (TECH FIG 2A).
  - This tissue is brought superiorly and the second pass comes deep, exiting at the posterior labral defect.
  - The PDS suture is reeled into the joint through the passer and retrieved in the posterior cannula using a ring grasper (TECH FIG 2B,C).
  - The deep limb of the PDS is tied to one limb of the anchor suture, and using a pulling technique, the PDS is drawn in a retrograde fashion, with the anchor suture attached, through the capsule and labral tissue, thereby creating a simple stitch (TECH FIG 2D).
- This allows the inferior capsule to be drawn superiorly and medially while at the same time closing the posterior Bankart lesion.
A second suture is placed after tying the first suture in a similar fashion, again incorporating the capsule as well as labrum (TECH FIG 2E,F).

This process is repeated as many times as is necessary, moving superiorly at 6-mm to 8-mm increments, thereby obliterating any labral defect and capsular redundancy (TECH FIG 2G,H).

Capsular Plication

Alternatively, if no labral detachment is identified and only excessive capsular redundancy exists, a posterior superior capsular shift without anchors is performed.

The posterior capsule is lightly abraded with a synovial shaver or rasp to promote healing.

A Spectrum suture passer is used again to pierce the capsule 1 cm lateral to the labrum at the 6:30 position on the glenoid.

The capsule is then advanced superiorly and medially, with the suture passer re-entering the joint at the junction between the intact labrum and the glenoid rim articular cartilage.

This is repeated at least two or three times, depending on amount of laxity.

With each suture the capsule is advanced about one hour’s position on the glenoid face (ie, 6:30 capsular stitch to the 7:30 labral position, 7:30 to 8:30, and so on).

Rotator Interval Plication

In individuals with a significant component of ligamentous laxity, additional closure of the rotator interval is accomplished by moving the arthroscope back to the posterior portal.

Through the anterior portal, a number 0 PDS suture is passed through the upper border of the middle glenohumeral ligament, capturing the superior glenohumeral ligament and rotator interval capsule.

This suture is used as a pulling stitch for a number 2 braided polyester fiber (Ti•CRON) suture (Tyco, United States Surgical, Norwalk, CT).

This is repeated again and sutures are tied just outside the capsule.
OPEN POSTERIOR HUMERAL-BASED CAPSULAR SHIFT (AUTHORS’ PREFERRED TECHNIQUE)

Positioning
- Under general anesthesia the patient is positioned in the lateral decubitus position using a full-length beanbag.
- A large axillary roll is placed under the down nonsurgical axilla.
- The operative arm and shoulder are draped free.

Incision and Dissection
- A longitudinal incision in the posterior axillary fold is made beginning at a point 2 cm medial to the posterolateral corner of the acromion and extending distally, following the posterior axillary line (TECH FIG 3).
- The underlying deltoid muscle is split along its fibers bluntly, and a self-retaining retractor is placed.34
  - Caution should be exercised as to not split the deltoid distally greater than 4 to 5 cm to avoid injuring the axillary nerve.8,34
  - If the individual is larger and more exposure is needed, the deltoid can be detached from its scapular origin for a short distance, leaving a small tendinous attachment to repair later.
  - Repair of the deltoid origin can also be accomplished by placing drill holes along the scapular spine for suture passage.
- The underlying infraspinatus is identified by its bipennate nature, a central fatty raphe dividing the muscle, and the fiber direction change compared with the teres minor inferiorly.
- The infraspinatus can be handled in three ways:
  - It can be split horizontally to expose the underlying capsule.32 Care is taken with this technique not to extend the split farther than 1.5 to 2 cm medial to the glenoid rim, as the infraspinatus branches of the suprascapular nerve are coursing along the inferior fascia of the infraspinatus directly on the scapular surface. Extension of the split into the branches or elevation of the fascia off the scapula will injure a number of, if not all, the branches to the infraspinatus.
  - The second method is to identify the interval between the infraspinatus and teres minor. This interval is developed with the muscle being worked superiorly, thereby exposing underlying capsule.
  - Third, the infraspinatus may be completely detached, leaving a 2-cm remnant of the tendon still attached for later repair (TECH FIG 4). It is tagged and carefully released from the underlying thin capsule.

Capsulotomy
- A vertical capsulotomy is made on the humeral side with the arm in neutral rotation (TECH FIG 5A).

TECH FIG 3 • The posterior longitudinal incision begins about 2 cm medial to the posterolateral corner of the acromion and extends into the axillary crease.

TECH FIG 4 • With the deltoid fibers bluntly split, a vertical incision is made directly through the infraspinatus while keeping a small stump of infraspinatus tendon attached laterally for reattachment later.
Chapter 4 TREATMENT OF RECURRENT POSTERIOR SHOULDER INSTABILITY

**Techniques**

- A small amount of capsule, 3 to 4 mm, can be left on its humeral attachment to aid in repair of the capsular flaps laterally during the shift.
- Care is taken to protect the axillary nerve inferiorly from retractors as it is traversing from anterior to posterior to exit in the quadrangular space inferiorly.
- With the vertical capsulotomy completed, two traction stitches are placed at the midposition and the capsule is horizontally divided, between the stitches, toward the middle of the glenoid rim, stopping 1 to 2 mm from the posterior glenoid labrum (*TECH FIG 5B*).

**Capsulorrhaphy**

- Although both medial and lateral capsular shifts have been described, we prefer a humeral-based T capsulorrhaphy because we believe tensioning of the capsular flaps is easier to control and a larger volume reduction can be achieved, if desired.
- Those who prefer a glenoid-based T-capsular shift cite advantages of a muscle-splitting approach and ease of repair if an associated reverse Bankart lesion is encountered.
- If a glenoid-based shift is selected, most authors position the arm in 20 degrees of abduction and neutral to 20 degrees of external rotation while doing the capsular repair.

**Posterior Inferior Capsular Shift**

- The posterior glenoid labrum is inspected and if there is a small detachment, it is repaired before completing the capsular shift procedure.
- The inferior flap of the capsule is carefully mobilized past the 6-o’clock position, inferiorly on the humerus.
- This step is critical as an inadequate release of the inferior capsule will prevent correction of the posteriorinferior capsular redundancy and volume.
- The nonarticular sulcus, medial to the capsular remnant left behind, is then decorticated with a high-speed burr to facilitate healing (*TECH FIG 6A*).
- The inferior capsular flap is brought superiorly and slightly laterally with the arm held in 40 to 45 degrees of abduction and 15 to 20 degrees of external rotation.
- This inferior flap is sutured in place with multiple figure eight nonabsorbable sutures.
- If the capsular remnant to suture to is of poor quality, suture anchors are used for repair. In a similar fashion, the superior capsular flap is shifted inferiorly down over the inferior flap and sutured (*TECH FIG 6B,C*).
- The horizontal portion of the T capsulorrhaphy is then closed and reinforced with nonabsorbable sutures.
- The degree of closure of this horizontal portion can further tighten the posterior capsule if desired.
- If the infraspinatus was released with a small remnant left attached to the humeral side, the infraspinatus is sutured back to its tendinous stump anatomically with nonabsorbable suture.
- If the infraspinatus was split, it is allowed to fall back in position and the fascia is closed with absorbable suture.
- Routine closure is performed, and the arm is placed into a shoulder orthosis or spica cast depending on patient compliance, incorporating 20 degrees of abduction and 20 degrees of external rotation.
The patient positioning and surgical exposure are similar down to the infraspinatus musculature.

The infraspinatus can be split, as is our preference, or a horizontal incision can be made 2 cm lateral to the glenoid rim through both the infraspinatus and capsule as one layer.

The posterior capsulolabral tissue is freely mobilized from the glenoid neck.

The scapular neck is then decorticated with a motorized burr to promote healing and the labrum is reattached using the surgeon’s preferred commercially available absorbable suture anchors or through transosseous tunnels.

Again, the goal is to roll the labrum up onto the posterior glenoid rim, restoring the capsulolabral bumper effect.

Although this procedure is usually done as a primary procedure, it may be combined with a humeral or glenoid based posterior-inferior T-capsular shift in patients with excessive laxity or instability on clinical examination.

Care must be taken not to overtighten the repair when both procedures are used, since postoperative stiffness and loss of motion, especially internal rotation, can occur.

TECH FIG 6 • A. With the capsular flaps fully developed, the metaphyseal area between the capsular insertion and the articular surface is decorticated using a motorized burr. B,C. The arm is then brought into slight extension and the inferior capsular flap is first shifted superiorly with the arm positioned in about 45 degrees of abduction. The superior capsular flap is subsequently shifted inferiorly.
OPEN POSTERIOR INFRASPINATUS CAPSULAR TENODESIS

- The posterior infraspinatus and capsular tenodesis, as described by Hawkins, is reproducible and takes advantage of the thick quality of the infraspinatus tendon and underlying capsule layer.\(^4,16\)
- It is extremely useful, in our opinion, in situations of poor-quality capsular tissue, since often the posterior capsule is only 1 to 2 mm thick, and in revision cases in which multiple posterior procedures have failed (TECH FIG 7).

Positioning

- This technique is performed using the same positioning and exposure as described earlier down to the infraspinatus musculature.
- Preoperatively the patient can be placed into an outrigger shoulder spica cast with a fiberglass long-arm component and a detachable spica bar or a shoulder orthosis.
- Preparation and draping are done with the involved arm free.

Incision and Approach

- The same posterior axillary incision and split of the underlying deltoid muscle described earlier are used.
- With the arm in neutral position, the glenoid rim is located under the infraspinatus using a spinal needle, starting medially and walking the needle laterally over the glenoid rim until the exact location of the joint is identified.
- This position is then marked to confirm the lateral extent of the glenoid rim.
  - This is a crucial step because if the vertical incision to be made through both the infraspinatus and capsule is made too far laterally, severe overtightening will result.

Vertical Arthrotomy

- A single vertical incision is made through the infraspinatus tendon and underlying capsule parallel to and 1.0 to 1.5 cm lateral to the joint line with the arm in neutral rotation (TECH FIG 8).
  - Most of the infraspinatus tendon runs on its inferior surface, with visible overlying muscle. This anatomic situation leads to a feeling of uneasiness as the surgeon begins to incise through the fleshy infraspinatus musculature portion posteriorly.
  - However, one should not worry, since the thicker tendinous portion of the infraspinatus will be encountered deeper during the vertical incision.
- With the capsulotomy complete, a Fukuda retractor is placed in the joint and the posterior labrum is inspected.

Posterior Repair

- The retractor is then removed and the arm is externally rotated 20 degrees (TECH FIG 9A).
- The lateral stump of the infraspinatus and capsule (one layer) is sutured to the intact posterior labrum using nonabsorbable sutures (TECH FIG 9B).
- The remaining medial portion of the infraspinatus and capsule is then reflected laterally overlapping the primary repair and sutured, again with nonabsorbable sutures (TECH FIG 9C).
- The deltoid is allowed to fall back together and the fascia is closed. Routine wound closure is performed.
TECH FIG 9 • A. After completing the posterior capsulotomy, the arm is positioned in about 20 degrees of external rotation and the lateral tendon portion of the infraspinatus and capsule are sutured to the intact posterior labrum. B. The arm is then externally rotated 20 degrees and the lateral flap of infraspinatus and capsule is sutured to the posterior glenoid labrum. C. The medial flap of the infraspinatus is then overlapped and sutured to its lateral tendon.

OPEN POSTERIOR GLENOID OSTEOTOMY

- Preoperative evaluation will rarely identify a patient who demonstrates excessive glenoid retroversion in excess of 20 degrees.30,31
- In these situations, the surgeon may need to consider a posterior glenoid osteotomy as the primary procedure or in combination with a posterior capsulorrhaphy or shift.17
- This procedure is rarely needed, however, and is reserved for those special circumstances. This procedure is technically demanding and should be performed by a surgeon with previous exposure to the procedure.
Positioning and Approach

- The initial steps, including preoperative spica application and positioning, are repeated.
- The standard approach down to the infraspinatus is used, with the infraspinatus released from its lateral insertion.

Vertical Capsulotomy

- A vertical capsulotomy is made 1 cm lateral to the glenoid rim.
- The medial capsule is detached sharply from the posterior aspect of the glenoid, with the labrum left attached to the posterior glenoid rim.
  - Caution is again exercised because the suprascapular nerve is running superiorly around the spine of the scapula about 2 to 3 cm from the glenoid rim.
- The Fukuda retractor is placed into the joint to permit visualization of the glenoid retroversion and orientation of the plane of the glenoid.

Glenoid Osteotomy

- With the orientation determined and the line of the osteotomy marked, drill holes are made through both anterior and posterior cortices.
  - These holes should be no closer than 1 cm from the glenoid articular surface.
  - The concavity of the glenohumeral joint as well as its superior to inferior and anterior to posterior orientation is kept in mind to avoid accidental intra-articular penetration and fracture.
  - A depth gauge is used to measure each hole to get an idea of the depth of the glenoid neck.
  - The oscillating saw blade is marked just short of this glenoid depth, thus decreasing the potential for traversing both the anterior and posterior cortices with the saw blade, which would result in creation of a free-floating glenoid (TECH FIG 10A).
  - With the osteotomy complete, a 1-inch osteotome is gently tapped into place and the osteotomy is opened by moving the osteotome and glenoid laterally.
  - The partially intact anterior periosteum and cortex maintain the appropriate position of the glenoid fragment.
- The osteotomy is then opened with a 1-inch osteotome and a quarter-inch osteotome is placed perpendicular to the osteotomy at either the superior or inferior margin to hold the osteotomy in the open position (TECH FIG 10B).
- A tricortical graft harvested from the posterior acromion or iliac crest is placed into the osteotomy and its position and stability are checked.
  - Usually the humeral head against the graft will provide an adequate compressive force to close down the osteotomy and stabilize its position without hardware or internal fixation (TECH FIG 10C). If fixation is required, small fascial or hand set plates are ideal.
  - This procedure can be combined, depending on how the infraspinatus is handled, with a humeral-based posteroinferior capsular shift or infraspinatus capsular tenodesis.
  - The arm is placed in a shoulder spica postoperatively and held for 4 to 6 weeks to allow consolidation of the posterior bone graft.

TECH FIG 10 • A. Bicortical drill holes are created about 1 cm medial and parallel to the posterior glenoid rim. An oscillating saw then completes the osteotomy posteriorly. B. A small osteotome is used to gently hinge open the osteotomy site laterally, thus preserving somewhat the integrity of the anterior cortex and its periosteal and soft tissue attachments. (continued)
TECH FIG 10 • (continued) C. A tricortical graft is harvested from the posterior acromion or iliac spine and inserted into the osteotomy site. This procedure can be also combined with a posteroinferior capsular shift or also infraspinatus tenodesis.

OPEN POSTERIOR BONE BLOCK GRAFT AUGMENTATION

- A posterior-placed bone block may be selected as the primary procedure but is usually needed as an additional augmentation procedure to back up a soft tissue procedure in revision situations with inadequate capsular tissue.
  - This technique has been used only twice in 10 years as an augmentation procedure by the authors.
  - We prefer a bone block placed extra-articularly in those often-difficult patients with soft tissue deficiencies, such as seen in Ehlers-Danlos syndrome.
  - Using the bone block extra-articularly allows the capsular repair anterior to the graft to act as a soft tissue interposition.
  - The positioning and exposure down to the capsule are as earlier described.

- After the posterior capsule has been shifted, a 3 × 2-cm, 8- to 10-mm-thick bone graft is obtained either from the posterior acromial spine or iliac crest.
- After the glenoid neck is exposed and the glenoid neck decorticated, the cancellous side of the graft is placed posterior and inferior and fixated with two cancellous screws.
- The graft is tailored to its final desired shape using a motorized burr.
- Care must be used such that the graft is not placed excessively lateral to the glenoid rim with secondary impingement on the humeral head or too medial to the glenoid rim, rendering it ineffective. The goal is to increase the width and depth of the glenoid without contacting the humeral head.

PEARLS AND PITFALLS

| Indications | • Failure to make an accurate diagnosis of the direction or degree of instability
|            | • A complete history and physical examination is crucial and must be performed. If needed, an examination under anesthesia to rule out a more global instability is useful.
|            | • Patient selection is key for each planned procedure.
|            | • Failure to identify the habitual “pathologic” voluntary dislocator
| Soft tissue management | • Failure to address associated ligamentous laxity
| | • It is imperative to rule out a more global instability (multidirectional instability).
| | • Beware of patients with previous failure from an extensive thermal capsulorrhaphy procedure. |
**POSTOPERATIVE CARE**

- Using these techniques, the procedure can be tailored to meet the patient’s clinical instability; however, the rehabilitation is similar in all patients regardless of technique.
- After completion of the repair, the arm can be removed from traction and posterior translation reassessed.
- The patient is then placed in a 30-degree external rotation brace and held in this position for 3 to 4 weeks postoperatively (Ultra-Sling, DonJoy, Carlsbad, CA).
- At that point, gentle active-assisted range-of-motion exercises are begun, avoiding all internal rotation posterior to the coronal plane for the first 6 weeks.
- At the 6-week mark postoperatively, a gentle isometric strengthening program is started.
- Throwing activities are not started until the fourth month, with resumption of athletic endeavors anticipated at 6 months.
- While the surgical approach may vary, all posterior reconstructions are treated similarly in their postoperative regimen.

**COMPLICATIONS**

- Recurrent or residual instability
- Postoperative loss of motion or stiffness
- Neurovascular injury, especially posterior cord or axillary or suprascapular nerve
- Anchor pullout or hardware failure
- Infection
- Post–instability repair arthritis (capsulorrhaphy arthropathy)
- Chondral injury
- Chondrolysis secondary to thermal capsular shrinkage
- Hematoma
- Postoperative rotator cuff atrophy or weakness

- Subcoracoid impingement (obligate anterior humeral head shift due to posterior capsular tightness or glenoid osteotomy)

**OUTCOMES**

- Posterior instability encompasses a continuum from acute and chronic posterior dislocation to the more frequently encountered recurrent posterior subluxation. Earlier reports in the literature have often involved small patient populations and isolated case reports with minimal follow-up.
- Past surgical treatment options included a number of nonanatomic reconstruction procedures to indirectly control posterior subluxation or dislocation.
- Eventually, a more anatomic approach developed, with procedures designed to openly repair the detached labrum (reverse Bankart repair) or address the patient’s excessive capsular redundancy (posterosuperior capsular shift).
- Preliminary results, published in 1980 by Neer and Foster, described a humeral-based posterior and inferior capsular shift with early good results. Since then, multiple authors have advocated the use of Neer’s posterosuperior capsular shift with excellent results. Other authors have modified this concept by using a glenoid-based posterior T-capsular shift to similarly tighten the posterior capsule.
- More recently, Misamore and Facibene reported promising results in unidirectional posterior instability patients using such an open posterior glenoid-based capsular shift. Excellent results were achieved, with 12 of 14 returning to competitive sports.
- Fronek and colleagues, using a similar capsular shift, reported on 10 of 11 patients without further episodes of instability and overall good results. However, only 3 patients were able to return to their preinjury ability level during...
sports. If the capsular laxity was not eliminated by this medi- 
dialized shift, then an additional lateral incision in the capsule and an H-type repair was used.

- Osseous reconstructions, including a posterior opening wedge gelenoid osteotomy,\textsuperscript{4,7,14,23,32} and posterior bone block procedures,\textsuperscript{1,10,11,19,26} to augment or address bony deficiencies have been described and although rarely used still have a place under certain circumstances. Hernandez and Drez\textsuperscript{17} combined geleno-plasty with a capsularorrhaphy and infraspinatus advancement.

- The posterior infraspinatus tenodesis, as illustrated, remains a valuable procedure, especially in cases of poor posterior capsular tissue or in revision cases. Hawkins and colleagues\textsuperscript{16} reported an 85% success rate using such a tenodesis as a primary procedure. Even when including revision cases, Pollock and Bigliani\textsuperscript{29} reported an 80% success rate using the same technique.

- Papendick and Savoie,\textsuperscript{28} followed by McIntyre and associates,\textsuperscript{24} were among the first of many to describe their arthroscopic techniques in the treatment of unidirectional posterior subluxation with encouraging results.

- Further improvements in arthroscopic suture repair techniques and instruments have led to the effective and reproducible arthroscopic treatment of recurrent posterior subluxation. The most promising arthroscopic repair techniques include posterior labral repair using suture anchor fixation, posterior capsulolabral plication, and the increasing role of rotator cuff interval plication as an augmentation to the primary repair.

- Kim and colleagues\textsuperscript{21} prospectively reported on 27 athletes with unidirectional recurrent posterior subluxation due to a distinct traumatic event. All were treated with an arthroscopic posterior Bankart repair and capsular shifting superiorly. Suture anchors were used in all cases and, if an incomplete labral lesion was encountered, it was converted to a complete detachment before repair. At a mean of 39 months postoperatively, patients had improved functional scores and only 1 patient out of 27 (4%) had a recurrence.

- Recently, Bradley and colleagues,\textsuperscript{6} in the largest prospective study to date, reviewed 91 athletes (100 shoulders) with unidirectional, recurrent posterior instability. Three types of capsulolabral repairs were performed based on preoperative clinical examination and arthroscopic findings: capsulolabral plication without suture anchors, capsulolabral plication with suture anchors and additional plication sutures, and capsulolabral plication with suture anchors.

- The capsulolabral repair without suture anchors was used in cases of significant posterior capsular laxity even though the labrum was not detached. The labrum was advanced superiorly and medially. Patients with acute traumatic injuries with minimal capsular stretching underwent minimal capsular advancement during the repair. Patients with chronic capsular redundancy required more advancement.\textsuperscript{6}

- The mean follow-up in the study was 27 months. All were involved in athletics, and 51% were involved in contact sports. Of these, 66% had an isolated posterior labral tear. Of the eight failures due to recurrent instability, pain, or decreased function, only one had a traumatic reinjuring event. All failures had a patulous capsule and 25% had a recurrent labral tear. Twenty-five percent of the failures had a previous thermal capsulorrhaphy before being referred for treatment. Only 11% of the patients in the study group did not return to their sport, and 33% returned but were unable to perform at the same level of competition.\textsuperscript{6}

REFERENCES

DEFINITION
- Glenoid bone loss after anterior dislocation is the loss of bone due to fracture, abrasion, or compression at the anteroinferior glenoid.
- This bone loss is frequently seen after anterior dislocation and varies greatly in its extent and significance.\(^4,6\)
- The use of a coracoid bone block to prevent anterior dislocation was first proposed by Latarjet\(^7\) in 1954.
- In 1958 Helfet\(^5\) described the Bristow technique, in which the tip of the coracoid is sutured to the capsuloperiosteal elements of the anterior glenoid. This was later modified to screw fixation.
- Patte\(^9\) described the effectiveness of the Latarjet procedure as being due to the “triple blocking effect”:
  - The effect of the conjoint tendon when the arm is in the abducted and externally rotated position, where it acts as a sling on the inferior subscapularis and the inferior capsule (FIG 1).
  - The effect of the anterior bone block
  - The effect of repairing the capsule to the stump of the conjoint tendon
  - The original technique described by Latarjet involved cutting the subscapularis tendon, but this has been modified to a subscapularis split, thus preserving the integrity of its fibers.

ANATOMY
- The glenoid has a pear shape, with an average height of 35 mm and an average width of 25 mm.
- The fibrous glenoid labrum provides attachment for the glenohumeral ligaments to the bony glenoid and increases the depth of the glenoid by 50%.
- The inferior glenohumeral ligament (IGHL) attaches to the glenoid between the 2 o’clock and 4 o’clock positions in a right shoulder.

FIG 1 • A. In normal circumstances the subscapularis provides no inferior support. B. Completed Latarjet procedure with the arm in neutral. C. The inferior displacement of the subscapularis creates a sling beneath the inferior capsule, especially in the abducted, externally rotated at-risk position.
The coracoid is directed anteriorly and then hooks laterally and inferiorly from its origin on the anterior scapular neck. The distal and lateral coracoid is the portion osteotomized for the Latarjet procedure. It is the origin for the short head of biceps and the coracobrachialis tendons (conjoint tendon) at its tip. Medially the pectoralis minor is attached, and laterally there is the insertion of the coracoacromial and the coraco-humeral ligaments.

- Proximal to the “knee” of the coracoid and untouched by the osteotomy are the conoid and trapezoid ligaments.
- The musculocutaneous nerve enters the conjoint tendon from the medial aspect on its deep surface at an average of 5 cm from the tip of the coracoid (range 1.5 to 9 cm).
- The axillary nerve runs on the anterior surface of the subscapularis muscle lateral to the axillary artery before it enters the quadrilateral space at the inferior portion of the subscapularis.
- The anterior inferior glenohumeral ligament lies deep to the middle and lower portions of the subscapularis muscle.

**PATHOGENESIS**

- Anterior glenoid bone loss occurs because of either impaction of the humeral head on the anterior glenoid at the moment of dislocation or recurrent subluxation or dislocation.
- Acute impaction may result in anteroinferior glenoid fractures, the so-called bony Bankart lesions.
- Recurrent subluxation or dislocation may also result in erosion or impaction of the glenoid rim.
- Recurrent dislocation occurs owing to multiple factors, one of which is the presence of a bony lesion.
- Following Bankart repair, loss of external rotation is 25 degrees per centimeter of anterior glenoid defect. This is due to anterior capsular tightness. An osseous defect with a width that is at least 21% of the glenoid length may cause instability.
- The normally pear-shaped glenoid assumes the shape of an inverted pear.
- Redislocation in contact athletes after arthroscopic anterior stabilization occurs more frequently in those with anterior bone loss.

**NATURAL HISTORY**

- Bone loss of varying degrees is seen in 90% to 95% of individuals with anterior shoulder instability.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The history should include the mechanism of dislocation (although this is often not clear), the site of the pain, maneuvers required for reduction, recurrence, and associated injuries.
- Recurrent anterior subluxation may be difficult to diagnose. A history of pain in the abducted externally rotated arm, pain resulting in a temporarily useless arm (dead arm syndrome), and more subtle variations can occur. Diagnosis is aided by a good clinical examination and imaging showing lesions of passage.
- The clinician should always assess for axillary nerve injury by checking sensation in the regimental badge area and motor power in the deltoid.

**IMAGING AND DIAGNOSTIC STUDIES**

- Plain radiographs should include anteroposterior (AP) views in neutral, internal and external rotation, and a profile view of the glenoid (ie, as per Bernageau) of the normal and abnormal sides.
- Radiographic accuracy and quality are improved when images are taken with fluoroscopic assistance.
- CT scanning may supplement radiographs.
DIFFERENTIAL DIAGNOSIS
- Posterior dislocation
- Posterosuperior cuff pathology in throwers
- Voluntary subluxation or dislocation
- Recurrent subluxation or dislocation

SURGICAL MANAGEMENT

Preoperative Planning
- Preoperative radiographs are analyzed to establish the presence and size of any bony glenoid defect.
- We use the Latarjet procedure for all individuals with anterior instability requiring surgery. The size of the glenoid defect does not change our operative technique.
- MRI or CT scans are not part of the standard preoperative planning but may assist in the diagnosis in cases of subtle instability.
- The presence of large Hill-Sachs lesions, SLAP lesions (superior labrum, from anterior to posterior), or other intra-articular pathology has no influence on outcome after the Latarjet procedure and hence does not influence the operative technique.

Positioning
- Under general anesthesia in association with an interscalene block for postoperative pain control, the patient is placed in the beach-chair position.
- A folded sheet is placed under the scapula to reduce scapula protraction and enable better access to the coracoid and glenoid (FIG 3).
- The arm is draped free to allow intraoperative abduction and external rotation.

CORACOID OSTEOTOMY AND PREPARATION
- Maintain the arm in abduction and external rotation to tension the coracoacromial ligament, which is incised 1 cm from its coracoid attachment.
- Partially incise at the same time the coracohumeral ligament lying deep to the coracoacromial ligament and free the upper lateral aspect of the superior conjoint tendon (TECH FIG 1A).
- Now adduct and internally rotate the arm to allow exposure of the medial side of the coracoid process. The pectoralis minor is released from this attachment with electrocautery, taking care not to go past the tip of the coracoid and damage its blood supply.
- A periosteal elevator is then used to remove any soft tissue from the undersurface of the coracoid. This elevator also aids visualization of the “knee” of the coracoid, which is the site of the osteotomy.
- Using a 90-degree oscillating saw, the osteotomy is made from medial to lateral.
- The arm is then placed in abduction and external rotation for the second time. The coracoid is grasped with a toothed forceps and any remnants of the coracohumeral ligament are released.

FIG 3 • Placement of the folded sheet on the medial border of the scapula reduces scapula protraction, making it easier to place your drill holes in the glenoid parallel to the articular surface.

Approach
- A deltopectoral approach is used.
- The skin incision is from the tip of the coracoid extending 4 to 5 cm toward the axillary crease.
- The cephalic vein is taken laterally and its large medial branch is ligated.
- A self-retaining retractor is used to maintain exposure between the deltoid and pectoralis major.
- The arm is placed in abduction and external rotation and a Hohmann retractor is placed over the top of the coracoid process.
The arm is then returned to a neutral position and the coracoid is delivered onto a swab at the inferior aspect of the wound (TECH FIG 1B).

Preparation of the bed of the coracoid is important to avoid a pseudarthrosis. Soft tissue is removed with a scalpel and then the oscillating saw is used to remove the cortical bone, exposing a cancellous bed for graft healing (TECH FIG 1C).

An osteotome is placed beneath the coracoid to protect the skin and two drill holes are made using a 3.2-mm drill (TECH FIG 1D). The holes are in the central axis of the coracoid and about 1 cm apart.

The swab protecting the skin is removed, the arm is externally rotated, keeping the elbow by the side, and the lateral border of the conjoint tendon is released for about 5 cm using a Mayo scissors.

The coracoid is then pushed beneath the pectoralis major, exposing the underlying subscapularis muscle.

GLENOID EXPOSURE

- Identify the superior and inferior margins of the subscapularis; the location for the subscapularis split is at the junction of its superior two thirds and inferior one third (TECH FIG 2A).

- A Mayo scissors is used to create the split. It is pushed between the fibers as far as the capsule, then opened perpendicular to the plane of the muscle fibers. Keeping the scissors open, push a small swab into the subscapular fossa in a superomedial direction and then place a Hohmann retractor on the swab in the subscapularis fossa (TECH FIG 2B).

- Using a curved retractor such as a Bennett retractor on the inferior part of the subscapularis, extend the lateral part of the split with a scalpel to the lesser...
tuberosity. The joint line is then more easily visualized and incised for about 1.5 to 2 cm, allowing a retractor to be placed in the joint (Trillat or Fukuda retractor; TECH FIG 2C).

- Superior exposure is created when a Steinmann pin is hammered into the superior scapular neck as high as possible.
- The medial Hohmann retractor is now exchanged for a link retractor and placed as medial as possible on the scapula neck.
- A small Hohmann retractor is placed inferiorly between the capsule on the inferior neck and the inferior part of the subscapularis.
- The anteroinferior part of the glenoid should now be easily visualized.

**PREPARATION OF THE GLENOID AND CORACOID FIXATION**

- The anteroinferior labrum and periosteum are incised with the electrocautery, exposing the glenoid 2 cm medially and from about 5 o’clock to 2 o’clock in a right shoulder (a vertical distance of 2 to 3 cm).
- An osteotome is then used to elevate this labral–periosteal flap from lateral to medial (TECH FIG 3A). The frequent presence of a Bankart lesion makes this quite simple.
- The osteotome is then used to decorticate this anteroinferior surface of the glenoid. We aim to create a flat surface on which to place our graft.
- The use of bone graft (excepting the coracoid process) is not required.
- Using the 3.2-mm drill, drill the inferior hole in the glenoid (TECH FIG 3B). This is at the 5 o’clock position, parallel to the plane of the glenoid and sufficiently medial that the coracoid will not overhang the glenoid (generally 7 mm, but depends on coracoid morphology). Both anterior and posterior cortices are drilled.
- The coracoid is now retrieved from its position under the pectoralis major and grasped at the cut end in a medial–lateral fashion.
- A 4.5-mm partially threaded malleolar screw is fully inserted into the inferior hole (tendinous end). The length of this screw is typically 35 mm but can be verified by adding together the depth of the coracoid and the depth of the glenoid hole (TECH FIG 3C).
- The screw is then placed into the already drilled inferior hole and tightened into position, ensuring that the coracoid comes to lie parallel to the anterior border of the glenoid with no overhang. A slightly medial position (2 to 3 mm) is acceptable. Rotation of the coracoid is adjusted using a heavy forceps.
- When the position of the coracoid is parallel to the glenoid, the second drill hole is made through the superior hole already drilled in the coracoid (TECH FIG 3D). It is important to avoid rotation of the coracoid at this stage.
The hole is measured and the correct-sized malleolar screw is inserted into position.

Repair of the capsule is then carried out by suturing the capsule to the stump of the coracoacromial ligament using a number 1 Dexon suture with the arm in external rotation, after removing the intra-articular retractor.

The retractors are removed, as is the sponge that was on the medial scapula neck.

There is no need to close the split in the subscapularis muscle.

**PEARLS AND PITFALLS**

- Dissection on the medial side of the coracoid is not necessary and risks nerve injury.
- The surgeon should not cut the subscapularis to gain access to the glenoid; the subscapularis split is used instead.
- The surgeon should decorticate the undersurface of the coracoid and the anterior glenoid to bleeding bone to avoid coracoid pseudarthrosis.
- Coracoid fracture can be avoided by using the two-fingers technique when tightening screws.
- Screws must be bicortical.
- Placing the coracoid in the “lying” position increases the coracoid–glenoid contact and decreases the risk of pseudarthrosis.
- If the coracoid fractures longitudinally, it should be turned 90 degrees. If it fractures transversely, the tip should be placed in a standing position.
- The coracoid must never overhang the glenoid, as this leads to arthritis (FIG 4).

**FIG 4** Postoperative AP and lateral views showing correct placement of screws and no overhanging of the coracoid.
**POSTOPERATIVE CARE**

- A simple sling is used for 2 weeks.
- Rehabilitation begins on the first postoperative day with gentle active range-of-motion exercises.
- Full activities of daily living are allowed at 6 weeks and a return to all sports is permitted at 3 months.

**OUTCOMES**

- In a study of 160 Latarjet procedures, we had a recurrence rate of 1%. Of those who played sports, 83% returned to their preinjury level or better. Overall, 98% rated their result as excellent or good and 76% had excellent or good results using the modified Rowe score.11
- The occurrence of postoperative shoulder arthritis is related to preventable factors (ie, lateral overhang of the coracoid) and pre-existing factors (eg, increased age at the time of first dislocation, increased age at the time of surgery and the presence of arthritis before to surgery).

**COMPLICATIONS**

- Intraoperative fracture of the coracoid
- Infection
- Hematoma formation
- Pseudarthrosis (not associated with poor outcome)
- Pain related to screws (2% incidence of screw removal)
- Recurrence
- Arthritis (if graft overhangs the anterior glenoid)

**REFERENCES**

DEFINITION
- Anterior shoulder instability typically results from an injury to the capsule, ligaments, and labrum that stabilize the glenohumeral joint.
- In cases of higher-energy trauma or recurrent dislocation, however, there can be significant bone loss or erosion of the anterior glenoid rim.
- The key to correctly treating anterior shoulder instability is recognizing whether the lesion involves injury to only capsulolabroligamentous structures or if it also involves the anterior glenoid bone.

ANATOMY
- Shoulder stability is provided by both dynamic and static stabilizers (Fig 1).
- Dynamic stabilizers include:
  - Rotator cuff
  - Biceps
  - Coordinated scapulothoracic motion
  - Proprioception
- Static stabilizers include:
  - Bony anatomy of the glenoid and humeral head
  - Labrum
  - Glenohumeral capsule and ligaments
  - Negative intra-articular pressure
- The inferior glenohumeral ligament (IGHL) complex limits anterior translation of the humeral head on the glenoid in abduction. It takes origin from the labrum on the glenoid inferiorly. The complex consists of an anterior band, posterior band, and intervening pouch. The anterior band is responsible for anterior restraint with the arm in high degrees of abduction with external rotation.
- Normal glenoid morphology is the shape of a pear. There is normally a surface area mismatch of the glenohumeral joint whereby only 20% to 30% of the humeral head contacts the glenoid surface at any point in time (Fig 1).
- The synchronized contraction of the rotator cuff and biceps provides a compressive force directing the convex humeral head into the concave glenoid and labrum unit. This is known as concavity compression.

PATHOGENESIS
- Anterior shoulder instability typically follows a dislocation event that results from a fall or collision with the arm in external rotation and abduction.
- First-time dislocators typically require a closed reduction of their shoulder after muscle relaxation and sedation, while recurrent dislocators can often reduce their shoulders with minimal effort.
- An injury to the labrum in the anteroinferior quadrant of the glenoid destabilizing the IGHL complex as well as stretching or a tear of the anteroinferior capsule can result in anterior shoulder instability.
- A rotator cuff tear should be suspected in patients greater than 40 years old who suffer from a dislocation episode.
- Recurrent anterior glenohumeral instability can also occur in the setting of anterior glenoid bone loss due to glenoid fracture after a single dislocation event or erosion as a result of recurrent subluxations or dislocations.
PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete examination of the shoulder should also include the evaluation of other concomitant injuries and ruling out differential diagnoses. A thorough examination includes but is not limited to the following:
  - Apprehension test: Apprehension, not simply pain, is required for a positive apprehension test.
  - Relocation test: Relief of apprehension with posterior pressure is necessary for a positive relocation maneuver.
  - Load and shift test: The examiner should note the degree of displacement of the humeral head on the glenoid rim.
  - Belly press: A positive belly press test is when the patient must flex the wrist and extend the arm to maintain the palm of the hand on the abdomen.
  - Assessment for generalized ligamentous laxity: Specifically, hyperextension of the elbows and knees as well as the ability to oppose the thumb to the forearm should be noted.
  - Rotator cuff: Manual strength testing of the subscapularis, supraspinatus, infraspinatus, and teres minor muscles must be done. Rotator cuff tears can contribute to instability.
  - Subscapularis insufficiency: Weakness of internal rotation with the shoulder adducted to the side suggests a subscapularis injury but is not specific. Increased external rotation of the injured side with the shoulder adducted compared to the contralateral shoulder, pain with external rotation of the shoulder, a positive belly press sign, or positive lift-off sign should raise suspicion for subscapularis insufficiency.
  - Axillary nerve injury: Both the deltoid motor strength and sensation in the distribution of the axillary nerve should be assessed. Atrophy of the deltoid muscle should be noted.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs are useful to detect Hill-Sachs lesion, glenoid dysplasia, and anterior glenoid fractures or erosion. Standard images should include a true anteroposterior (AP) view of the glenoid, an axillary view, and a Stryker notch view. Fractures and erosions of the glenoid as well as the position of the humerus on the glenoid should be noted.
- If a significant anterior bony glenoid lesion is suspected owing to plain film findings or a history of recurrent dislocations, a CT arthrogram should be obtained. This allows an evaluation of the subscapularis tendon, bony architecture of the glenoid, humeral head, and tuberosities as well the degree of capsulolabral injury and redundancy.
- Both Itoi\textsuperscript{5,6} and Gerber\textsuperscript{3} have described techniques to assess anterior glenoid bone quantitatively that serve as a guide for when bony augmentation is indicated for recurrent anterior shoulder instability. Gerber’s method\textsuperscript{3} is easily performed on oblique sagittal or 3D reconstructions of the glenoid surface (FIG 3). Cadaveric studies have shown that the force required for anterior dislocation is reduced by 70% from an intact glenoid if the length of the glenoid defect exceeds the maximum radius of the glenoid.

DIFFERENTIAL DIAGNOSIS

- Bankart lesion
- Multidirectional instability
- Hill-Sachs lesion
- Tuberosity fracture
Rotator cuff tear (especially subscapularis)
Scapular winging (especially serratus anterior dysfunction)
Axillary nerve injury

NONOPERATIVE MANAGEMENT
Conservative therapy for recurrent anterior shoulder dislocation includes strengthening of the rotator cuff musculature as well as the periscapular stabilizers. Deltoid muscle strengthening should be incorporated into a rotator cuff strengthening protocol. Periscapular strengthening should focus on the rhomboids, trapezius, serratus, and latissimus dorsi muscles.
Conservative treatment of recurrent shoulder dislocation in the setting of a bony glenoid defect, however, is rarely successful.

SURGICAL MANAGEMENT
Preoperative Planning
All imaging studies, including plain radiographs (true AP glenoid view, axillary view, Stryker notch view) and CT scan with intra-articular gadolinium, are reviewed. Additional radiographic views can be helpful. The apical oblique can demonstrate anterior glenoid lip defects as well as posterolateral impression fractures of the humeral head. Both the West Point and Bernageau views are useful to note defects of the anteroinferior glenoid rim.
The CT arthrogram is examined for evidence of anterior glenoid bone loss:
The degree of bone loss is assessed on oblique sagittal reconstruction or a 3D reconstruction of the glenoid face (FIG 4).
The length of the anterior glenoid defect is measured.
If the length of the glenoid defect exceeds half of the maximum diameter of the glenoid, an anatomic glenoid reconstruction of the anterior glenoid with autologous iliac crest bone graft is considered.
Often, the anterior erosion is extensive, making it difficult to accurately measure the glenoid diameter. In these instances, the superoinferior axis of the glenoid should be drawn on the glenoid face image and the maximum radius determined from this line to the posterior aspect of the glenoid (Fig 4).
Associated superior labral tears, biceps pathology, rotator cuff tears, and the presence of articular erosion and osteoarthritis should be noted preoperatively and treated appropriately at the index operation.
An examination under anesthesia should assess passive range of motion, noting any restrictions as well as excessive motion, which may indicate subscapularis insufficiency. In addition, the glenohumeral joint should be assessed for laxity to ensure there is not a bidirectional or multidirectional component.

Positioning
Although some surgeons choose to use a bean bag, we prefer to use a beach chair with an attachable hydraulic articulated arm holder (Spider Limb Positioner, Tenet Medical Engineering, Calgary, Canada) (FIG 5).
The head of the beach chair is elevated 30 to 45 degrees to allow access to the ipsilateral iliac crest.

FIG 3 • A 3D CT reconstruction effectively demonstrates the degree of anterior glenoid bone loss.

FIG 4 • Gerber’s method for evaluating the degree of glenoid erosion. \( x \) is the length of the glenoid defect. Half of the maximum diameter of the glenoid, \( r \), can be measured from a vertical line (blue) connecting the superior glenoid rim to the inferior glenoid rim in cases of significant erosion. If \( x > r \), then the force for dislocation is decreased by 70%.

FIG 5 • The patient is secured into a beach chair with an attachable hydraulic articulated arm holder (Spider Limb Positioner, Tenet Medical Engineering, Calgary, Canada). The upper body is positioned at 30 to 45 degrees to allow access to the ipsilateral iliac crest.
EXPOSURE OF GLENOID

- A well-padded bump is placed behind the ipsilateral buttock and hip to ensure that the iliac crest is prominent for ease of dissection.
- The shoulder and iliac crest are prepared and draped in the standard sterile fashion.

Approach

- Anterior glenoid reconstruction with iliac crest bone graft requires two approaches:
  - Deltopectoral approach for glenoid preparation
  - Tricortical anterior iliac crest bone graft harvesting

- The clavipectoral fascia is sharply incised lateral to the conjoint tendon, making sure to stay lateral to any muscle of the short head of the biceps.
- The musculocutaneous nerve can then be palpated on the deep surface of the conjoint tendon. The conjoint tendon is retracted medially, exposing the subscapularis tendon and muscle.
- The coracoacromial ligament can be released if additional exposure is needed superiorly.
- The circumflex vessels are then identified and ligated or coagulated (TECH FIG 1B).
- The axillary nerve can be palpated as it passes over the inferior portion of the subscapularis and loops under the inferior capsule. A blunt retractor can be placed lateral and deep to the axillary nerve, thus retracting it gently medially away from the subscapularis musculotendinous junction.
- The subscapularis tendon is then incised from bone off the lesser tuberosity to avoid disrupting the long head of the biceps tendon in the bicipital groove (TECH FIG 1C).
- Through sharp dissection, an interval between the subscapularis tendon and capsule is developed, leaving the capsule intact. It is often easier to start inferiorly and use a blunt elevator to dissect the interval.
- The subscapularis tendon and muscle are retracted medially using an anterior glenoid neck retractor.
- A blunt retractor is repositioned deep to the axillary nerve to retract away from the capsule, which should be widely exposed at this point.
- An inverted L-shaped capsulotomy is then created based on the humeral neck and extending horizontally across the rotator interval region (TECH FIG 1D).

TECH FIG 1 - A. The pectoralis major and deltoid muscles are retracted to reveal a broad exposure of the conjoint tendon (CT) and muscle belly passing over the subscapularis muscle (SS). The coracoacromial ligament (CA) can be released if needed for additional exposure. B. A blunt curved retractor can be placed inferiorly along the subscapularis to protect the axillary nerve. (continued)
The anterior glenoid and scapular neck are then exposed (TECH FIG 2).

After the L-shaped capsulotomy, a periosteal elevator is used to strip the periosteal sleeve from the anterior scapular neck.

An anterior glenoid neck retractor is positioned to retract the capsule medially.

The iliac crest is harvested as a tricortical bone graft (TECH FIG 3).

A 2- to 3-cm curved incision is made overlying the iliac crest and posterior to the anterosuperior iliac spine.

A Fukuda retractor or similar blunt retractor is used to retract the humeral head posteriorly, thus exposing the face of the glenoid.

The length of the osseous defect is measured and compared to the width of the maximum AP radius of the glenoid. The measured defect length will be the basis for the size of the iliac crest bone graft harvested.

Soft tissue and scar tissue are removed from the anterior glenoid, and this bone and the adjacent scapular neck are roughened with a high-speed burr to create punctate bleeding and a smooth surface for bone grafting.

The incision is carried sharply through subcutaneous tissue down to the periosteum, which is incised sharply and superiosteally elevated to expose the inner and outer tables. Self-retaining retractors are placed be-
Part 7 SHOULDER AND ELBOW • Section II GLENOHUMERAL INSTABILITY

TECHNIQUES

**TECH FIG 3** • Tricortical iliac crest bone graft. **A.** Bone graft is harvested from the iliac crest using an oscillating saw and preserving both the inner and outer tables. A high-speed burr is used to contour the graft. **B.** The size of the graft is typically 3 cm in length and 2 cm in width but should be based on the measured size of the defect. A fixator for the graft is used to secure the graft to the glenoid.

**TECH FIG 4** • Fixation of graft to the glenoid. **A.** The graft is positioned to establish concavity to the glenoid as well as a smooth transition between the graft and native glenoid to avoid an articular step-off. **B.** A number 2 braided polyethylene suture is placed around each 4.0-mm screw before it is fully tightened to assist in later capsular repair. (continued)

**TECH FIG 59** • Glenoid defect. **A.** The graft is secured with screws and sutures. **B.** The graft is secured with screws and sutures.
The capsulotomy and subscapularis are then repaired (TECH FIG 5).

- The sutures from the graft fixation screws are passed through the capsule–periosteal sleeve as horizontal mattress stitches and tied.

- Avoid too vertical of an angle, as this may result in humeral impingement.
- Avoid too horizontal of an angle, as this may fail to re-establish glenoid concavity.
- With the graft correctly positioned, it can be temporarily secured to the anterior glenoid using two or three terminally threaded Kirschner wires from the stainless steel AO 4.0-mm cannulated screw set (AO/Synthes, Paoli, PA).
- Two or three partially threaded 4.0-mm cannulated screws are then placed over the Kirschner wires to secure the graft.
- A number 2 braided polyethylene suture is placed around the shaft of each screw before the screw is fully seated and compressing the graft. These sutures may be used for later capsular repair.
- The Fukuda retractor is gently removed and the position of the humeral head is noted. The glenohumeral joint is ranged and any incongruity or instability noted should prompt a change in graft position.

- The capsulotomy can be further repaired in one of two ways:
  - If the L-shaped capsulotomy can be repaired primarily, it is reapproximated using number 2 braided polyethylene suture. Often, though, the graft occupies enough space and the capsule is contracted so that a primary repair of the capsulotomy is not possible.
  - If the L-shaped capsulotomy cannot be repaired primarily to the neck of the humerus with the arm in at least 30 degrees of external rotation, then the capsule is repaired to the lateral portion of the subscapularis tendon. This will tension the anterior capsule as the subscapularis becomes more taut with external rotation.
  - The lesser tuberosity is gently abraded with a high-speed burr to cause punctate bleeding.
  - The subscapularis is then meticulously repaired to the lesser tuberosity with two or three suture anchors using a modified Mason-Allen stitch.
  - The shoulder incision is closed in layers.

REPAIR OF CAPSULE AND SUBSCAPULARIS

- The capsulotomy and subscapularis are then repaired (TECH FIG 5).

- The sutures from the graft fixation screws are passed through the capsule–periosteal sleeve as horizontal mattress stitches and tied.
**PEARLS AND PITFALLS**

**Indications**
- A complete history and physical should be performed.
- Associated pathology must be recognized and addressed:
  - The glenohumeral joint must be assessed for osteoarthrosis.
  - The humeral head must be assessed for a significant engaging Hill-Sachs lesion. It is rare for the lesion to be engaging after reconstruction of the width of the glenoid.

**Tricortical graft harvest**
- Care should be exercised to avoid disrupting the anterosuperior iliac spine.
- The lateral femoral cutaneous and ilioinguinal nerves are at risk during dissection of the anterior ilium.

**Tricortical graft placement**
- Placement of the graft in too vertical of a position may result in impingement of the humeral head and articular erosion.
- Placement of the graft in too horizontal of a position does not recreate concavity of the glenoid.
- There must be a smooth transition between the native glenoid and bone graft. This is ensured by proper positioning. A burr can be used to remove any prominences from the graft that remain after fixation.

**Stiffness**
- Patients should be counseled to expect some limitation of external rotation postoperatively.
- The goal is to achieve a stable joint with no more than 20 degrees loss of external rotation to limit the risk of capsulorrhaphy arthropathy. This should be considered during capsular repair.

**POSTOPERATIVE CARE**
- Radiographs are obtained to judge graft placement and screw position. A CT scan is helpful to estimate graft incorporation (FIG 6).
- The shoulder is maintained in a sling immobilizer for 4 weeks.
- Pendulum exercises are allowed after the first week.
  - At 4 weeks, the sling is removed to allow:
    - Activities of daily living
    - Passive range of motion, active assisted range of motion, water therapy
  - At 3 months, strengthening is initiated.
  - Participation in overhead recreational sport (golf, tennis, swimming) is allowed at 4 months.
  - Participation in contact or collision sports is allowed at 6 months.

**OUTCOMES**
- With appropriate preoperative workup, diagnosis, and surgical technique, anatomic reconstruction of the glenoid with tricortical iliac crest bone graft is very effective at treating recurrent dislocations in the setting of a bony glenoid defect.
- Hutchinson and colleagues demonstrated no recurrent dislocations after tricortical iliac crest bone grafting in a population of epileptics who continued to have seizures postoperatively.
- Warner and associates reported no recurrent dislocations or subluxations after anterior glenoid bone grafting in a population of athletes with traumatic recurrent anterior instability. There was a mean loss of external rotation in abduction of 14 degrees.

**COMPLICATIONS**
- Subscapularis insufficiency
- Hardware failure and migration
- Stiffness
- Brachial plexus injury

REFERENCES

DEFINITION
- The glenohumeral joint is one of the most commonly dislocated joints in the body.
- With anterior dislocations, bony defects of the anterior glenoid and posterosuperior aspect of the humeral head occur with relative frequency.
- One of the first descriptions of the lesions found on the humeral head was by Flower in 1861, with many subsequent investigators reporting on these bony defects. In 1940, two radiologists, Hill and Sachs, reported that these defects were actually compression fractures produced when the posterosilateral humeral head impinged against the anterior rim of the glenoid.
- Since then, Hill-Sachs lesions have been found to occur with an incidence between 32% and 51% at the time of initial anterior glenohumeral dislocation.
- In shoulders sustaining a Hill-Sachs lesion at the initial dislocation, there exists a statistically significant association with recurrent dislocation. Although Hill-Sachs lesions are common after anterior glenohumeral dislocations, there are relatively few publications describing specific treatments for these humeral head defects.
- In general, specific surgical procedures to address Hill-Sachs lesions have not been recommended in the initial surgical management of recurrent anterior dislocations because the majority of these lesions are small to moderate in size and do not routinely cause significant symptoms of instability.
- Certain subsets of patients exist with more significant bony defects and ongoing symptoms of “instability” or painful clicking, catching, or popping. This occurs even after surgical procedures directed at treating their anterior instability.

ANATOMY
- With an anterior shoulder dislocation, the humeral head is positioned anterior to the glenoid rim.
- The posterosuperior aspect of the humeral head then impacts upon the anterior aspect of the glenoid rim and creates the Hill-Sachs lesion (FIG 1A).
- Only after the shoulder joint is relocated can the influence of the size and shape of the Hill-Sachs lesion on overall shoulder stability be determined (FIG 1B, C).
- Although there is not scientific proof, our clinical experience suggests that lesions representing 25% to 30% of the articular surface area of the humeral head often lead to symptoms.

PATHOGENESIS
- The concept of “articular arc length mismatch” has been recently put forth by Burkhart to “explain the ongoing sensation of catching or popping” arising in the shoulder with a large Hill-Sachs lesion alone or in combination with glenoid defects. Patients with these symptoms have often undergone previous anterior stabilization procedures and reconstruction of damaged glenohumeral ligaments at that time.
- This phenomenon, debatably referred to as “instability,” occurs mainly in a position of abduction and external rotation of the shoulder.
- In this position, a large “engaging” Hill-Sachs lesion encounters the anterior glenoid rim, resulting in the rim “dropping into” the Hill-Sachs lesion.
- The sudden loss of smooth articular surface on the humeral side of the joint presents an irregularly contoured area to the glenoid, causing an uneasy sensation in the patient that feels much like subluxation.
- As Burkhart and DeBeer pointed out, for every “Hill-Sachs lesion, there is a position of the shoulder at which the humeral bone defect will engage the anterior glenoid.”
- Clinically, it is important to differentiate between “engaging” and “nonengaging” Hill-Sachs lesions.
- An engaging Hill-Sachs lesion is one that presents the long axis of its defect parallel to the anterior glenoid with the shoulder in a functional position of abduction and external rotation, such that the Hill-Sachs lesion encounters the rim of the glenoid.
- Lesions can be considered engaging even in positions that are considered “nonfunctional,” such as in some degree of extension, or in lesser degrees of abduction.
- Apprehension and instability in lesser degrees of shoulder abduction often indicate a significant bony defect that is leading to the perceived instability.
- A nonengaging Hill-Sachs lesion is one that either fails to engage the glenoid or engages the glenoid only in a nonfunctional arm position. For example, the Hill-Sachs defect can pass diagonally across the anterior glenoid with external rotation; therefore, there is continual contact of the articulating surfaces and no engagement of the Hill-Sachs lesion by the anterior glenoid.
- Hence, when a patient has symptomatic anterior instability associated with an engaging Hill-Sachs lesion with an articular arc deficit, treatment must be directed at both repairing the Bankart lesion, if present, and preventing the Hill-Sachs lesion from engaging the anterior glenoid.
- We believe that the treatment of symptomatic anterior glenohumeral instability, involving an engaging Hill-Sachs lesion with an articular arc deficit, can be accomplished satisfactorily with a technique of anatomic allograft reconstruction of the humeral head using a side- and size-matched humeral head osteoarticular allograft.
- This technique involves an anatomic reconstruction that eliminates the structural pathology while maintaining the range of motion of the glenohumeral joint.

NATURAL HISTORY
- One of the most clearly documented series of nonoperatively treated shoulder dislocations placed into immobilization is that of Hovelius and associates.
Chapter 7  MANAGEMENT OF GLENOHUMERAL INSTABILITY WITH HUMERAL BONE LOSS

- They determined that the “type and duration of the initial treatment had no effect on the rate of recurrence; with a higher rate of recurrence the younger the patient.”
- Overall, 52% of 247 primary anterior dislocations had no further dislocations.
- Patients who were 12 to 22 years old had a 34% redislocation rate, while those who were 30 to 40 years had a rate of 9%.
- Ninety-nine of 185 shoulders that were evaluated with radiographs had evidence of a Hill-Sachs lesion; and of these 99 shoulders, 60 redislocated at least once and 51 redislocated at least twice during the 10-year follow-up.
- This compares with 38 (44%) of the 86 shoulders that did not have such a lesion documented ($P < 0.04$).
- Acute first-time shoulder dislocations have traditionally been treated nonoperatively with reduction followed by a form of immobilization.
- Currently recommended types of immobilization after shoulder dislocations are as follows:
  - Simple sling immobilization with the arm in internal rotation$^{11}$
  - Immobilization in external rotation$^{9,10}$
- No clear evidence has quieted this discussion.

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- All patients are initially evaluated with complete history and physical examination.
- Specifics of the history include questioning for the mode of onset and timing of initial symptoms, and for the details of present symptoms, including pain, frequency, instability, and level of function.
- All previous surgical procedures performed on the shoulder should be noted.
- Most patients will give a history of recurrent dislocations or multiple surgical attempts to correct the instability.
- Although thought to be a procedure for failed attempts at shoulder stabilization after dislocation, there are other situations that might lead the surgeon to consider this procedure initially.
- Significant traumatic mechanism with an extensive Hill-Sachs lesion (more than 25% to 30% of the articulating surface of the humeral head)

---

**FIG 1** • Posterior views of an anterior glenohumeral dislocation (A), an “engaging” Hill-Sachs lesion after relocation of the gleno-humeral joint (B), and a humeral head with a large Hill-Sachs lesion (C).
• Patients with a history of grand mal seizures often have fairly large Hill-Sachs defects and significant apprehension about the use of their arm. Also, as a result of the violence of the dislocations, the amount of bone pathology present, and the inability to predict the onset of epileptic events, it is worth considering treating this group of patients with an allograft reconstruction of the humeral head defect at the index procedure, as soft tissue repairs alone may not be enough to prevent recurrent injury.

• Physical examination should focus on inspection for previous scars, a thorough determination of active and passive range of motion, and evaluation of the integrity and strength of the rotator cuff.

• The clinician should perform a detailed examination for glenohumeral laxity in the anterior, posterior, and inferior directions.

• Examination for apprehension should be performed in multiple positions, as patients with large Hill-Sachs lesions usually exhibit apprehension that often occurs with the arm in significantly less than 90 degrees abduction and 90 degrees external rotation.13,14

• A comprehensive examination should include but is not limited to:
  - Anterior apprehension test: Positive apprehension can be associated with anterior labral injuries.
  - Bony apprehension test: Apprehension with fewer degrees of abduction may indicate a significant and symptomatic bony contribution to the instability.

IMAGING AND OTHER DIAGNOSTIC STUDIES

• Preoperative imaging includes a comprehensive plain film evaluation with anteroposterior (AP), true AP, axillary, and Stryker notch views of the involved shoulder (FIG 2A).

• All patients require a preoperative axial imaging study (CT or MRI) to more fully define the bony architecture of the glenoid and humeral head and specifically the details of the Hill-Sachs lesion (FIG 2B).

• One must be careful when interpreting these studies, since the plane of the Hill-Sachs defect is oblique to the plane of the axial image. Therefore, the size of these defects is often underestimated in standard axial imaging.

• Three-dimensional reconstruction can be a useful tool to more clearly define the size and location of the defect and to estimate the amount of the articular surface involved.

• While the volume and depth of the lesion certainly affect the stability of the shoulder, even more important may be the size of the defect in the articular arc.

DIFFERENTIAL DIAGNOSIS

• Anterior shoulder dislocation with or without:
  - Bankart lesion
  - “Bony Bankart” or an anterior glenoid lesion
  - Hill-Sachs lesion
  - Combination of the above

• Posterior shoulder dislocation with or without associated soft tissue and bony lesions

• Inferior shoulder dislocation with or without associated soft tissue and bony lesions

NONOPERATIVE MANAGEMENT

• Given a mechanism of shoulder dislocation, the presence of significant bony defects to the glenoid or the humeral head, and associated functional instability, there are not anticipated gains through nonoperative management.

SURGICAL MANAGEMENT

• Several techniques have been described in the literature to address symptomatic engaging Hill-Sachs lesions.

  - Open anterior procedures, such as an East–West plication to limit external rotation, designed to limit external rotation such that the humeral head defect is kept from engaging1,2
  - Rotational proximal humeral osteotomy as described by Weber and colleagues17
  - Transfer of the infraspinatus into the defect to render the lesion essentially extra-articular3,18
  - Filling in of the Hill-Sachs defect so that it can no longer engage, using either a corticocancellous iliac graft or a femoral head osteoarticular allograft

  - If the defect is severe, prosthetic replacement using a hemiarthroplasty may become necessary.16

  - In the case of posterior glenohumeral dislocation, Gerber and coworkers5 have reported on the successful reconstruction of the humeral head by elevation of the depressed cartilage and subchondral buttressing with cancellous bone graft, as well as femoral head osteoarticular allograft reconstruction of the humeral head defect.

  - The indications for anatomic allograft reconstruction of the humeral head are as follows:
    - Ongoing symptomatic anterior glenohumeral instability or painful clicking, catching, or popping in a patient with a large engaging Hill-Sachs lesion in patients who have failed to respond to previous soft-tissue stabilization procedures
    - A large engaging Hill-Sachs lesion is identified before undergoing initial surgical treatment.

  - Clinical experience suggests that lesions involving more than 25% to 30% of the articular surface may be significant.14
The entire tendon is transected vertically about 0.5 cm medial to its insertion onto the lesser tuberosity.
- Tag sutures of number 2 Control Release Ethibond Excel (#DC494, Ethicon, Somerville, NJ) are placed in the lateral aspect of the subscapularis tendon as it is released from the lesser tuberosity.
- The interval between the subscapularis and the anterior capsule is then carefully developed using sharp dissection, continuing medially to the neck of the glenoid.
- The inferior capsule is then further isolated using careful blunt dissection.
- A laterally based capsulotomy is made with the vertical limb in line with the subscapularis incision and continuing superiorly.
- The anteroinferior capsule is then released off the surgical neck of the humerus with intra-articular dissection using a periosteal elevator.
EXPOSURE OF THE HILL-SACHS LESION

- The humeral head retractor is withdrawn and the humerus is brought into maximal external rotation to expose the Hill-Sachs lesion.
- Unroof the synovial expansion of the supraspinatus to allow the humerus to be more fully externally rotated, allowing better visualization and access to the Hill-Sachs lesion.
- A flat narrow retractor (e.g., Darach) is then placed over the reflected undersurface of the subscapularis tendon and behind the neck of the humerus on the posterior rotator cuff in order to lever out the humeral head (TECH FIG 1).

TECH FIG 1 • Intraoperative exposure of large Hill-Sachs lesion to be reconstructed.

HUMERAL HEAD OSTEOTOMY

- With the Hill-Sachs lesion adequately exposed, a micro-sagittal saw is used to smooth and reshape the defect into a chevron-type configuration.
- The piece of matching allograft humeral head to be inserted should resemble a deep-dish slice of pie (TECH FIG 2A,B).
- The base and side of the defect can then be further smoothed using a hand rasp to achieve precise, flat surfaces.
- The base (X), height (Y), length (Z), and rough outside partial circumference (C) of the defect are then measured to the nearest millimeter (TECH FIG 2C).

OSTEOTOMY OF THE HUMERAL HEAD ALLOGRAFT

- A corresponding piece is cut from the matched humeral head allograft that is 2 to 3 mm larger in all dimensions than the measured defect.
- The allograft segment is then provisionally placed into the Hill-Sachs defect and resized in all three planes.
- Excess graft is then carefully trimmed with the micro-sagittal saw and is reshaped in the other two planes as well.
- Fine-tuning of graft size is then continued in one plane at a time until a perfect size match is achieved in all planes, including base (X), height (Y), length (Z), and outside partial circumference (C).
The allograft segment is placed into the defect and aligned so as to achieve a congruent articular surface. It is provisionally secured in place with two or three smooth 0.045-inch Kirschner wires (TECH FIG 3A,B). The wires are then sequentially replaced with 3.5-mm fully threaded cortical or 4.0-mm cancellous screws placed in a lag fashion (TECH FIG 3C,D).

Ensure that the screw heads are countersunk so that they are below the level of the articular surface. The joint is irrigated and taken through a range of motion to ensure that the reconstructed humeral head provides a smooth congruent articulating surface.

The capsulotomy is closed with absorbable suture, tying any previously placed sutures used to repair the capsulolabral pathology if present. The subscapularis tendon is then reapproximated to its stump anatomically, without shortening, using suture anchors or a soft tissue repair with nonabsorbable suture. Allow the conjoined tendon, deltoid, and pectoralis major muscles to return to their normal anatomic positions. A routine subcutaneous and skin closure is then performed. Sterile dressing is applied. The arm is placed into a shoulder immobilizer.
This area of the humeral head can be accessed through external rotation and forward flexion of the joint. Anchors or sutures are placed in the anterior glenoid for later labral repair after reconstruction of the Hill-Sachs lesion. Exposure of the posterior superior humeral head This area of the humeral head can be accessed through external rotation and forward flexion of the upper extremity. Appropriately placed retractors assist in this exposure. Allograft sizing The surgeon should ensure the allograft obtained is larger in dimension by 2 to 3 mm than the actual defect. This allows for in situ sizing. Screw placement It is easier to initially place two 0.045-inch Kirschner wires for fixation and then replace them with two 3.5-mm stainless steel AO screws lagged into position. Screw heads are countersunk beneath the surface of the allograft articular surface to prevent hardware penetration.

**POSTOPERATIVE CARE**

- After surgery, patients are given a sling for comfort and allowed full passive range of motion immediately as tolerated.
- Because of the subscapularis detachment, we protect against active and resisted internal rotation for 6 weeks.
- After the initial 6-week period, patients are allowed terminal stretching and strengthening exercises.
- The shoulders are imaged with repeat radiographs at 6 weeks and 6 months, and with CT scans at 6 months to assess for consolidation and incorporation of the graft.

**OUTCOMES**

- Between 1995 and 2001, we performed and reviewed this procedure in 18 patients who had failed previous attempts at surgical stabilization.13,14
- Fifteen patients had a history of traumatic anterior glenohumeral instability related to sports, and three patients had instability related to seizures or other trauma.
- All had posterolateral humeral head defects (Hill-Sachs lesions) that represented greater than about 25% to 30% of the humeral head.
- One patient had both anterior and posterior humeral head defects from bidirectional shoulder instability sustained as a result of a seizure disorder.
- No patients had true multidirectional instability.
- Patients in the formal review were assessed preoperatively and postoperatively with:
  - Detailed history
  - Physical examination
  - Radiographic evaluation (plain films and axial imaging [CT, MRI, or both])
  - Validated clinical evaluation measures (Constant-Murley shoulder scale, Western Ontario Shoulder Instability Index [WOSII], and SF-36)
- Findings at the time of surgery included:
  - Nine patients with recurrent Bankart lesions
  - Nine patients with capsular redundancy only
  - No patients with subscapularis tears
  - One patient with posterior glenoid erosion
  - Three patients with anterior glenoid deficiency (less than 20%), which was not reconstructed
  - Mean length of follow-up was 50 months (range 24 to 96 months).
  - There were no episodes of recurrent instability. Sixteen of 18 (89%) patients returned to work.
- The average Constant-Murley score postoperatively was 78.5. The WOSII, which is a validated quality-of-life scale specific to shoulder instability using a visual analog scale response format, decreased and patients were significantly improved.
- Overall, this represents the first reported series of anatomic allograft reconstruction of Hill-Sachs defects for recurrent traumatic anterior instability after failed repairs.
- This technique has been shown to be effective for a difficult problem with few available treatment options.
- The patients demonstrated improvement in stability, loss of apprehension, and high subjective approval, allowing return to near-normal function with no further episodes of instability.
- Although infrequently a cause for clinical concern, Hill-Sachs defects can be the source of significant disability and recurrent instability in a subset of patients.
- One should consider anatomic allograft reconstruction of these defects as a viable treatment alternative.

**COMPLICATIONS**

- Complications that occurred in our series of humeral osteoarticular allograft reconstruction of the Hill-Sachs lesions included radiographic follow-up evidence of partial graft collapse in 2 of 18 patients, early evidence of osteoarthritis in 3 patients (marginal osteophytes), and 1 mild subluxation (posterior).12–14
- Hardware complications developed in two patients, who complained of pain with extreme external rotation.
- The screws were removed at about 2 years postoperatively in both patients, thereby relieving their symptoms.
- One must weigh the risks of continued shoulder dysfunction versus the risk associated with the use of fresh osteoarticular allografts.

**REFERENCES**

4. Flower WH. On the pathological changes produced in the shoulder-joint by traumatic dislocations, as derived from an examination of all specimens illustrating this injury in the museums of London. Trans Pathol Soc London 1861;12:179.
DEFINITION

- Posterosuperior tears of the rotator cuff involve the supraspinatus, infraspinatus, and occasionally the teres minor.
- Some of the surgical techniques to be described here are not commonly used currently, as most tears can be repaired by arthroscopic approaches, either with mini-open or all-arthroscopic techniques.
- These approaches, however, are still useful for treating those massive tears that may need special procedures to accomplish the repair.

ANATOMY

- The rotator cuff is a group of four musculotendinous structures arising from the scapula: the supraspinatus, the infraspinatus, the teres minor, and the subscapularis. The first three insert on the greater tuberosity of the humerus, while the subscapularis inserts on the lesser tuberosity. The cuff muscles not only rotate the humerus at the glenohumeral joint but also act to keep the humeral head centered in the glenoid fossa, providing a fixed fulcrum for the arm to be elevated, primarily by the deltoid. The subacromial bursa overlies the tendons.
- These structures, in turn, sit under the coracoacromial arch, which consists of the acromion, the coracoacromial ligament, and the outer end of the clavicle at the acromioclavicular joint.
- The three parts of the deltoid arise from the acromion and lateral clavicle, and this muscle lies over the cuff and bursa. It acts to elevate, abduct, and extend the humerus at the shoulder joint.

PATHOGENESIS

- Rotator cuff tears have a multifactorial pathogenesis.
- Among the factors are tendon insertion degeneration (enthesopathy), shear (the inferior third of the cuff tendons being more susceptible to shear failure than the superior two thirds), hypovascularity, impingement, and microtrauma.
- Although impingement was felt to be the sole underlying cause of cuff disease for some time, it is now felt to be a secondary factor, in that it likely comes into play once the cuff is weakened and is unable to balance the upward pull of the deltoid. This then brings the cuff into contact with the undersurface of the anteroinferior acromion and the rest of the coracoacromial arch.
- Major injury is uncommonly a factor and usually involves an already degenerative tendon. A common major injury, which can result in a rotator cuff tear, is a primary, or a first-time, anterior dislocation of the shoulder in a patient over age 40. The older the patient, the more likely there is a cuff tear.

NATURAL HISTORY

- The natural history of rotator cuff tears is unknown. There have been several studies in cadavers and by MRI that have confirmed that the incidence of asymptomatic cuff tears over the age of 60 is around 33%. These subjects have been pain-free and fully functional.
- Any study that has tried to follow asymptomatic tears prospectively over time has suffered from an unacceptably high loss of patients being followed, thereby negating any conclusions.
- Even the condition of cuff tear arthropathy does not occur regularly with known cuff tears, even massive ones.
- It has been shown that after a traumatic tear, the outcome is influenced by the time interval to repair—in other words, those repaired within the first 3 weeks do better than those repaired between 3 and 6 weeks, and those older than 6 weeks do even worse. These outcomes apply only to the uncommon traumatic tear, not to the far more common degenerative type.
- Therefore, treatment should be based purely on the presenting symptoms of pain and functional limitation, not on the possibility that a tear may progress in size or develop into cuff tear arthropathy, since the latter possibilities cannot be predicted.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Barring the unusual history of a significant injury, such as a primary anterior glenohumeral dislocation over the age of 40 resulting in a traumatic tear, most patients will present with a complaint of pain of indeterminate onset.
- The pain is often worse at night and with use, especially overhead.
- Use of nonsteroidal anti-inflammatories (NSAIDs) may provide some temporary relief, as might stretching.
- The pain can radiate, but not to below the elbow or into the neck and occiput.
- There rarely will be significant motion loss (ie, motion will be unaffected) nor will the patient often notice weakness.
- The first step in the physical examination is to examine the neck to eliminate that as a source of the pain.
- One should inspect the shoulder for atrophy of the supraspinatus and infraspinatus or rupture of the tendon of the long head of the biceps, which usually occurs with a large or massive tear. One should also palpate the region of the greater tuberosity and the bicipital groove for tenderness. In thin patients, it is possible to feel the cuff defect through the skin and deltoid.
- Motion is assessed by having the patient elevate the arms actively and comparing this to passive motion and by placing the arms in 90 degrees of abduction and maximal external rotation, as well as maximal external rotation with the arm at the side.
- The inability to hold the arm in maximum active external rotation in abduction or at the side, causing the arm to drift toward internal rotation, is a positive lag sign, indicating a major defect in the musculotendinous unit.
Internal rotation is evaluated by having the patient reach up the back to the highest point possible. Further testing for this (subscapularis function) is discussed in another chapter.

Strength of the external rotators is tested with the arm at the side and in maximal external rotation, having the patient resist a force directed toward the body. Strength in elevation is assessed by resisting the patient’s attempt to raise the arm.

Provocative signs for cuff and biceps disease include the following:

- Impingement sign: Forcing the fully forward elevated arm against the fixed scapula helps to localize the finding to the rotator cuff when the patient experiences pain.
- Palm-down abduction test: By internally rotating the arm, the supraspinatus and anterior infraspinatus tendons are placed directly under the coracoacromial arch. Elevating the arm in the scapular plane when it is in internal rotation compresses these tendons against the undersurface of the acromion.
- Biceps resistance test (Speed’s test): Pain during this maneuver indicates involvement of the long head of the biceps tendon.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard radiographs, including anteroposterior (AP) views in internal and external rotation, an axillary view, and an outlet view at minimum, should always be taken to look for the type of acromion (FIG 1A), acromioclavicular joint changes, and narrowing of the acromial–humeral interval (FIG 1B) and to rule out other conditions.
- Additional preoperative studies include MRI, ultrasound, and arthrography.
- Ultrasound is institutional-specific and operator-dependent, so it is not widely used.
- Arthrography once was the gold standard but now is used only under rare circumstances (ie, when an MRI cannot be done). It can show a full-thickness cuff tear (FIG 1C) but requires an intra-articular injection with fluoroscopy and radiography.
- The most commonly used study is an MRI. It not only shows the integrity of the tendons but also provides a three-dimensional view of it (FIG 1D–G). This capacity makes the MRI a versatile preoperative planning tool.

FIG 1 • A,B. Type III acromion, the so-called hooked acromion, on the outlet and AP views. C. Arthrogram confirming the presence of a rotator cuff tear with dye in the glenohumeral joint and the subacromial bursa simultaneously. D. T2-weighted coronal MRI showing cuff tear and its lateral-to-medial extent. E. T2-weighted sagittal oblique MRI showing the AP extent of the cuff defect. F. Another T2 sagittal oblique MRI showing the tear involving the teres minor but not the subscapularis. G. Axial T2 MRI of the same tear showing rupture of the teres minor with an intact subscapularis.
DIFFERENTIAL DIAGNOSIS

- Cuff tendinitis without tear
- Incomplete rotator cuff tear
- Bicipital tendinitis
- Calcific tendinitis
- Suprascapular neuropathy

NONOPERATIVE MANAGEMENT

- If there is a history of an acute injury with immediate inability to raise the arm, the patient can be treated symptomatically and followed every 5 to 7 days for the first 2 weeks. If the ability to raise the arm does not recover, then nonoperative treatment should be abandoned and surgery undertaken.
- The objective of treating rotator cuff disorders, in the absence of an acute injury with immediate loss of elevation, is primarily to relieve pain and secondarily to restore function or strength. Pain relief is a more predictable outcome of treatment than is restoration of function or strength. Therefore, nonoperative treatment should be directed at relieving pain.
- Although NSAIDs can help with pain, a subacromial steroid injection is often more effective and immediate in its relief.
- Once the pain is improved, physical therapy should be instituted. This involves two aspects: stretching and strengthening of the rotators and elevators.

SURGICAL MANAGEMENT

- As noted earlier, in the unusual case in which there is an acute injury resulting in an immediate loss of elevation of the arm, if symptomatic treatment fails to restore the ability to raise the arm, surgical repair should be undertaken before the 3-week mark.
- For the more common chronic attritional tear, surgery is considered if the injection, NSAIDs, and physical therapy fail to produce a level of pain relief and function that is acceptable to the patient.
- Patients make the decision to have surgery based on whether they can live with the pain and functional limitation that they have. They need to understand that the operation can help them but can also leave them unchanged or worse.

Preoperative Planning

- The radiographs and MRI should be reviewed preoperatively.
- The radiographs will help in planning the need for and extent of acromioplasty.
- The MRI will show which tendons are torn and the degree to which they are torn. It will also show the presence or absence of fatty infiltration of the muscles.

Positioning

- The patient is positioned in a sitting position, even more upright than the so-called beach chair position (FIG 2A). The arm is draped free to allow uninhibited mobility of the extremity (FIG 2B).
- This allows the surgeon to look down on the cuff from above, therefore, being able to see posterosuperiorly as well as superiorly and anteriorly. It also permits better access to the posterior part of the infraspinatus and the teres minor.

Approach

- There are basically three approaches to cuff repair:
  - The all-arthroscopic approach (discussed in another chapter)
  - Arthroscopic decompression and mini-open repair of the cuff
  - Open repair of the cuff: includes direct repair, grafting, and tendon transfers

FIG 2 • A. Sitting position for surgery allows the surgeon to look down on the cuff and see posterior superior. B. The arm is draped free, giving extensive access to the entire shoulder.
ARThROSOCopIC SUBACROMIAL DECOMPRESSION AND MINI-OPEN CUFF REPAIR

- The standard posterior viewing portal is established, and the glenohumeral joint is evaluated. The defect in the cuff is viewed from the articular side, and the long head of the biceps is assessed.
  - Any débridement or other intra-articular procedures deemed necessary can be carried out at this time.
- The arthroscope is then redirected into the subacromial space and enough bursa resected to allow adequate visualization of the cuff tear, the anterior inferior surface of the acromion, and the coracoacromial ligament. If deemed appropriate (as discussed later), the ligament is released and the anterior and anterolateral margins of the acromion are defined.
  - A burr is used to perform an acromioplasty to the same degree that is done in the open technique. This is an important point. Although the means of accomplishing the decompression differ, the ultimate result is the same: an adequate decompression.
- Through a small lateral portal, a suture punch is used to pass several traction sutures through the leading edge of the torn tendons. Using these sutures as handles to control and apply traction to the cuff, a small elevator is introduced through the same lateral portal and used to free the surrounding adhesions on both surfaces of the cuff. The degree of mobility achieved can be assessed by applying traction through the previously placed sutures.
  - Once enough mobility of the cuff has been restored, an incision is made at the anterolateral corner of the acromion for about 1.5 to 2 cm (TECH FIG 1). The deltoid is split in the same line as the skin, and additional subdeltoid freeing is done. Narrow retractors are placed under the acromion and anteriorly to expose the tear.
  - The procedure at this point is the same as described in the next section.

OPEN REPAIR OF THE CUFF

Incision and Dissection

- With the patient in the position described above and the arm draped free, an incision is made beginning superiorly at the posterior aspect of the acromioclavicular joint, continuing over the top of the joint, and ending at a point at the lateral tip of the coracoid (TECH FIG 2A).
  - After mobilization of the skin flaps, the deltotrapezial aponeurosis and the superior acromioclavicular ligament are incised into the acromioclavicular joint.
  - The deltoid muscle is split in line with its fibers only as far distally as the tip of the coracoid.

TECH FIG 1 • Skin incision for the mini-open repair technique.

TECH FIG 2 • A. Skin incision for the standard anterosuperior approach. B. Subperiosteal dissection of deltoid origin from superior aspect of the lateral clavicle, acromioclavicular joint, and anterior acromion, without cutting across the deltoid origin. (continued)
Using a sharp knife blade, the deltoid origin is dissected subperiosteally from the lateral clavicle for about 1 cm. It is also dissected from the anterior, superior, and undersurface of the acromion out to the anterolateral corner of the acromion (TECH FIG 2B–D).

No incision is made across the tendon of origin of the deltoid on the acromion; that is, the deltoid is not detached from the acromion.

**Clavicular Resection and Acromioplasty**

The coracoacromial ligament is identified and isolated. If, in the judgment of the surgeon, the cuff can be securely repaired, the ligament is released from its attachment on the acromion. If the repair is tenuous, the ligament is not released, or if it is, it is dissected from the undersurface of the acromion to achieve maximal length and repaired back to the acromion through drill holes in the acromion at the end of the procedure.

This is necessary to prevent anterosuperior escape of the humerus, which occurs when the cuff is deficient and there is no coracoacromial arch to contain the humeral head, which is being pulled upward by the unopposed deltoid.

Using a reciprocating saw, the lateral 7 to 8 mm of the lateral end of the clavicle are removed without damaging the periosteum or posterior capsule. The portion removed is trapezoidal in shape, with the larger base being posterior, to prevent contact of the clavicle with the acromion posteriorly.

The clavicular resection allows the acromion and scapula to be rotated posteriorly more easily and gives greater access to the posterior cuff.

Using the same instrument, an acromioplasty is performed by removing the anteroinferior surface of the acromion from the medial articular margin out to the anterolateral corner. The anterior edge is not recessed beyond its normal anatomy, and it is not the removal of the full thickness of the acromion, creating a type I acromion (TECH FIG 3). The portion removed is a triangular piece, with its base being the anterior edge.
The entire subacromial space is freed bluntly of adhesions between the bursa and the undersurface of the deltoid. retractors are placed into the subacromial space under the acromion to avoid tension on the deltoid.

**Tear Repair**

- The bursa is incised, undermined, and reflected. The tear in the cuff can now be seen. The friable, avascular edges are trimmed with a sharp knife. This resection is minimal—only until healthy tendon is seen (TECH FIG 4A), not to bleeding tendon. This usually requires the removal of only a few millimeters.
- Number 1 nonabsorbable traction sutures are placed in the edges of the freshened cuff. Applying traction through these sutures, blunt mobilization is done using an elevator, dissecting scissors, or the surgeon’s finger. This step of mobilization is critical, and as the musculotendinous unit becomes free, additional sutures are placed successively medially until the apex of the tear is identified (TECH FIG 4B).
- If the cuff edge cannot be brought sufficiently far to reach its original insertion, interval releases are done by incising between the supraspinatus and the subscapularis and between the infraspinatus and the teres minor. This restores the differential gliding between these adjacent tendons.
- When the leading edge of the cuff can be brought to its insertion on the greater tuberosity, a shallow trough is made in the anatomic neck at the greater tuberosity (TECH FIG 4A).
- Drill holes are made in the trough and the lateral side of the tuberosity and connected with a punch. Locking horizontal mattress sutures or modified Mason-Allen sutures are placed in the cuff and passed through the bone tunnels created by connecting the drill holes (TECH FIG 4C). Suture anchors can also be used in the trough and the tuberosity in a double-row fashion instead of the bone tunnels.
- With the arm in some internal rotation and slight abduction, the sutures are tied securely to bring the free edge of the cuff into the trough.
- This leaves a longitudinal split, which is sutured side to side, not only closing the split but also helping to relieve tension on the cuff advanced into the trough (TECH FIG 4D).

**BICEPS GRAFT**

- If the cuff cannot be brought to the greater tuberosity and there is a residual defect of modest size, an interpositional graft of the tendon of the long head of the biceps can be used. The critical requirement to use this or any graft is that the musculotendinous motor must be functional, not fixed and immobile. If there is no springy give when traction is applied to the tendon, no graft should be done.
- First, the tendon of the long head is tenodesed to the transverse humeral ligament in the bicipital groove using three figure 8 nonabsorbable number 1 sutures. The tendon is transected just above the most proximal suture and then released from its origin at the supraglenoid tubercle.
- This segment of tendon is filleted (TECH FIG 5A) and placed into the cuff defect. It is trimmed to fit the defect and contoured to accommodate it.
- It is sutured side to side to the cuff and to a trough in the anatomic neck at the greater tuberosity, as described above (TECH FIG 5B).

**FREEZE-DRIED CADAVER ROTATOR CUFF GRAFT**

- If the residual defect is too large for a biceps graft to cover, a larger graft is needed. The best choice is a freeze-dried graft of human rotator cuff. As with every graft, the musculotendinous motor (ie, the native rotator cuff) must be a functional unit, as noted above.
- After the described mobilization techniques have reduced the size of the defect as much as possible, the graft is reconstituted in sterile saline for 30 minutes so that it becomes soft and pliable (TECH FIG 6A).
- It is then trimmed and contoured to accommodate the free edge of the native cuff and then sutured to it with nonabsorbable number 1 sutures.
- It is also trimmed to reach a trough in the anatomic neck adjacent to the greater tuberosity and secured in the same fashion as the direct repair through drill holes in the bone or by anchors, as previously described (TECH FIG 6B).
LOCAL TENDON TRANSFERS

- When the cuff cannot be closed by direct repair and the proximal native cuff is not mobile, the subscapularis and teres minor can be used as local tendon transfers.
- The interval between the subscapularis and the anterior capsule is identified near the musculotendinous junction and traced laterally toward the insertion on the lesser tuberosity.
- The tendon is separated from the capsule and released from the insertion. A traction suture is placed in the tendon, and the subscapularis is mobilized so that it can be shifted superiorly.
- The subscapularis is then transferred superiorly (TECH FIG 7A) to close the residual defect. Its superior border is sutured to the intact portion of the cuff, its distal end to the greater tuberosity, and its inferior border to the superior edge of the undisturbed anterior capsule (TECH FIG 7B,C).
- If the subscapularis alone does not provide adequate closure of the tear, the teres minor can also be transferred from posterior to superior. The interval between the tendon of the teres minor and the posterior capsule is developed (TECH FIG 7D), starting medially at the musculotendinous junction, and freed laterally to its insertion on the greater tuberosity. It is detached from the tuberosity.
- The muscle–tendon unit is mobilized bluntly and transferred superiorly to meet the transposed subscapularis (TECH FIG 7E).
- The two tendons are sutured together to form a new broad tendon, which is inserted into a trough at the greater tuberosity, as described earlier.
- The inferior borders of the respective tendons are sutured to the superior edges of the undisturbed capsules (teres minor to the posterior capsule and the subscapularis to the anterior capsule) (TECH FIG 7F,G).
- If none of these techniques allows the cuff to be reconstructed satisfactorily, a latissimus dorsi transfer is undertaken; this is described elsewhere.

**TECH FIG 7** • A. Detached subscapularis mobilized and moved superiorly. B. Subscapularis transferred and sutured to residual cuff, the greater tuberosity, and the superior border of the undisturbed anterior capsule. C. Subscapularis transferred and sutured. D. Interval between the teres minor and posterior capsule developed. (continued)
### CLOSURE

- The closure is the same for all procedures.
- Since the deltoid has not been detached from its origin, it is allowed to fall back to its normal anatomic position or brought back by the surgeon. Simple sutures with the knots buried under the deltoid are placed to repair the side-to-side split, being sure to pass the suture through the external muscle fascia, the muscle itself, and the internal muscle fascia.
- If the deltopectoral aponeurosis and superior acromioclavicular ligament have been incised, they are repaired side to side with figure 8 sutures.
- The skin is closed with a subcuticular 3-0 nylon suture and Steri-Strips. A sterile dressing is applied, and the extremity is immobilized in an immobilizer with the elbow forward of the midline of the body and the shoulder in internal rotation.

### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Condition</th>
<th>Advice</th>
</tr>
</thead>
<tbody>
<tr>
<td>Postoperative deltoid detachment</td>
<td>This can be avoided by subperiosteally elevating the origin and not incising across it.</td>
</tr>
<tr>
<td>Axillary nerve injury with deltoid split</td>
<td>This can be avoided by not splitting the deltoid beyond the tip of the coracoid. Exposure is achieved by superior access, not distally.</td>
</tr>
<tr>
<td>Excessive tendon resection</td>
<td>Friable, poor-quality tendon should be trimmed only to healthy fibers, not to bleeding tendon.</td>
</tr>
<tr>
<td>Postoperative repair failure</td>
<td>Tendons should be repaired to bone under only normal resting tension. If this is not possible, the described grafts or tendon transfers should be used. The early postoperative rehabilitation program is used to regain motion; strengthening is avoided until at least 3 weeks.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

■ Within 24 to 72 hours of the surgery, the dressing is changed. The patient is instructed in passive-only forward elevation and external rotation at the side while lying supine. The operative arm must be completely relaxed with no muscle activity at all, and the arm is elevated to at least 90 degrees forward and external rotation to neutral only.

■ Over the next 4 to 6 weeks the amount of passive forward elevation is slowly increased, as is the external rotation at the side, but the latter should not go beyond 10 to 15 degrees of external rotation at most.

■ The extremity is kept in the immobilizer at all other times during this period. At 4 to 6 weeks postoperatively, depending on the security of the repair and the technique used, formal active and assisted exercises are permitted, along with continued passive stretching. Strengthening, weights, or resistive exercises are avoided until at least 3 months.

OUTCOMES

■ Repairs of small and medium-sized tears have a high rate of success in relieving pain and recovering motion and function while remaining structurally intact, regardless of whether repaired by arthroscopic, mini-open, or open techniques.

■ Repairs of large and massive tears also have resulted in good pain relief and functional recovery but have a much lower incidence of remaining intact structurally.

COMPLICATIONS

■ Deltoid origin detachment
■ Cuff repair dehiscence
■ Anterosuperior instability or escape
■ Infection
■ Loss of motion
■ Cuff tear arthropathy

REFERENCES

Subscapularis tears are less common than supraspinatus or infraspinatus tears. They occur in 2% to 8% of rotator cuff tears and are often missed.\textsuperscript{5,12}

Subscapularis tears can be:
- Isolated tears (partial or complete)
- Partial-thickness tears
- Anterosuperior (involving the supraspinatus)
- Rotator interval lesions (with associated biceps tendon injury)

There is a high association of concomitant biceps tendon pathology.\textsuperscript{12,18}

ANATOMY

- The subscapularis is innervated by the upper and lower subscapular nerves (C5–C8). Its origin is at the subscapularis fossa, and the upper two thirds inserts onto the lesser tuberosity, while the inferior third inserts onto the humeral metaphysis.
- The subscapularis is the strongest of the rotator cuff muscles. It acts to internally rotate the humerus along with the teres major, latissimus dorsi, and pectoralis major muscles. It resists anterior and inferior translation of the humeral head.\textsuperscript{10,17}
- The upper fibers of the subscapularis and the anterior fibers of the supraspinatus contribute to the rotator interval as well as the transverse humeral ligament.
- The coracohumeral ligament is the roof of the rotator interval and blends with the supraspinatus and subscapularis. The coracohumeral ligament and the superior glenohumeral liga-
- The biceps muscle is innervated by the musculocutaneous nerve (C5–C6). It is composed of a long head, which originates from the supraglenoid tubercle, and a short head, which originates from the coracoid process. Both heads insert onto the bicipital tuberosity of the radius and the ulnar fascia of the forearm.
- The long head of the biceps tendon provides superior shoulder stability when the arm is abducted. It also provides posterior shoulder stability when the arm is in midranges of elevation.
- The coracoid is located just anterior to the superior border of the subscapularis. It projects laterally, anteriorly, and inferiorly toward the glenoid.
- The subcoracoid bursa does not communicate with the glenohumeral joint but can communicate with the subacromial bursa.

PATHOGENESIS

- In the young patient, subscapularis tears occur as a result of trauma. The typical mechanisms include hyperextension of an externally rotated arm or forced external rotation of an abducted arm.\textsuperscript{5,8}
- In older patients a tear is typically degenerative in nature, although it may be the result of a glenohumeral dislocation or other trauma.\textsuperscript{13,15,16}

Frequently, there is associated long head of the biceps pathology. This may include tenosynovitis, subluxation, dislocation, degeneration, or complete rupture.\textsuperscript{12,19}

Subcoracoid impingement may also be a cause of subscapularis tendon tears.

NATURAL HISTORY

- Isolated subscapularis tendon ruptures are relatively rare. Subscapularis tears are often associated with tears of the supraspinatus and infraspinatus.
- One study found that subscapularis tears occur in 8% of rotator cuff tears.\textsuperscript{7}
- An MRI study was performed on 2167 patients with rotator cuff tears.\textsuperscript{12}
  - 2% of the patients had subscapularis tendon tears.
  - 27% of those tears were partial-thickness tears and 73% were full-thickness tears.
- One study found a high correlation between subscapularis tendon tears and medial biceps subluxation, biceps tendinopathy, superior labral pathology, and fluid within the subscapular recess or the subcoracoid space.\textsuperscript{12,18}
- The above-listed MRI study found that 25 of the 45 patients with subscapularis tendon tears had associated biceps pathology.

PHYSICAL FINDINGS

- Patients with complete tears of the subscapularis have increased passive external rotation compared with the unaffected shoulder.
- Several muscles contribute to internal rotation of the shoulder, including the pectoralis major, latissimus dorsi, and teres major, and can compensate for loss of the subscapularis.
- Passive external rotation: Increased passive external rotation may indicate a complete rupture of the subscapularis.
- Passive forward flexion, external rotation, and internal rotation: Limited passive range of motion is indicative of adhesive capsulitis.
- Active forward flexion: Limited active forward flexion is indicative of a possible large rotator cuff tear.
- The lift-off test isolates the subscapularis muscle. Inability to lift the hand off the back is a positive test.
- Internal rotation lag sign: The examiner measures the lag between maximal internal rotation and the amount the patient can maintain. A positive sign shows increased sensitivity over the classic lift-off test.
- Belly press (Napoleon test): A positive test is the inability to bring the elbow forward. An intermediate test is the ability to bring the elbow forward partially. A positive test indicates a complete rupture, while an intermediate test indicates a partial tear of the subscapularis.
- The bear hug test: If the examiner is able to lift the hand off the shoulder, then the patient likely has a partial or complete.
tear of the upper subscapularis tendon. This is perhaps the most sensitive test for a subscapularis tear.

- Coracoid impingement: Reproduction of pain or a painful click indicates a positive test. A positive test indicates impingement of the coracoid onto the subscapularis.
- Speed’s test: If the maneuver produces pain or tenderness, the test is positive, which may indicate bicipital pathology, although the test is not specific.
- Yergeson test: The patient will experience pain as the biceps tendon subluxes out of the groove with a positive test; this indicates biceps instability.

Pain may inhibit a patient from maneuvering the arm behind the body into the lift-off position, thereby preventing assessment.

- A complete rupture of the long head of the biceps tendon will result in an obvious cosmetic deformity in the anterior arm as the muscle retracts distally.
- Tests used to diagnose superior labral lesions will be discussed in a separate section.

**IMAGING AND DIAGNOSTIC STUDIES**

- Anteroposterior (AP), outlet, and axillary view radiographs should be obtained to rule out any fractures or associated injuries.
- In chronic cases of subscapularis tears, anterior subluxation of the humeral head may be noted on the axillary view.
- MRI is the modality of choice for diagnosing subscapularis tears. MR arthrography improves the study accuracy to detect partial-thickness tears.
- Fatty degeneration of the subscapularis correlates with poor tendon quality.
- Although not sensitive, these signs are highly specific for subscapularis tears:
  - Leakage of contrast material onto the lesser tuberosity
  - Fatty degeneration of the subscapularis muscle
  - Abnormalities in the course of the long biceps tendon
  - Biceps dislocation deep to the subscapularis tendon is pathognomonic for a subscapularis tear.

Ultrasound is a noninvasive method for assessing the subscapularis and can be performed in the office. It is less expensive than MRI, but results are operator-dependent.

**DIFFERENTIAL DIAGNOSIS**

- Impingement syndrome
- Subscapularis tendinitis
- Bicipital tendinitis
- Posterosuperior rotator cuff tear (supraspinatus, infraspinatus, teres minor)
- Biceps pathology
- Coracoid impingement
- Labral tear
- Glenoid fracture
- Glenohumeral instability
- Glenohumeral arthritis
- Pectoralis major injury
- Contusion
- Cervical radiculopathy

**NONOPERATIVE MANAGEMENT**

- For subscapularis tears, nonoperative management is reserved for some chronic and atraumatic, degenerative, and asymptomatic tears.
- Treatment includes activity modification, anti-inflammatory medications, and physical therapy.
- Corticosteroid injections may be performed in the bicipital groove or subcoracoid bursa to treat biceps tendinitis and coracoid impingement.

It is likely that some degenerative subscapularis tendon tears are successfully treated nonsurgically without ever being diagnosed.

- In most cases, an acute symptomatic subscapularis tear should be managed operatively and whenever possible within the first 6 to 8 weeks, when retraction and scarring are minimal, to reduce the risks of dissection in the axillary recess.
- In young, active patients, attempts are made to repair acute biceps ruptures.
- In older, less active patients and in cases of chronic biceps ruptures more than 8 weeks old, biceps repair is discouraged.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- Physical therapy or a home exercise program emphasizing range of motion may be used to prevent stiffness and improve range of motion before surgery.
- All imaging studies are reviewed.
- An examination under anesthesia is performed before beginning surgery to evaluate for instability, increased external rotation, or decreased range of motion.

**Positioning**

- The patient is placed in a low beach chair position with the arm draped free.
- A McConnell arm holder (McConnell Orthopedic Manufacturing Co., Greenville, TX) is useful for maintaining arm positions throughout the case.

**FIG 1 • Axial T2-weighted MR images of right shoulders with an intact subscapularis tendon (A; arrow) and a complete rupture of the subscapularis tendon.**
Approach
- Both the deltopectoral and anterolateral deltid-splitting approaches have been described.\(^{20}\)
- The anterolateral deltid-splitting approach is useful for partial tears of the upper subscapularis and tears associated with supraspinatus tears. It is not recommended for large, retracted full-thickness subscapularis tears.
- The deltopectoral approach provides greater visualization and access to the inferior portion of the subscapularis. It also allows for concomitant biceps tenodesis and coracoplasty.

INCISION AND DISSECTION

- The deltopectoral approach is started just proximal to the coracoid process and extended distally 8 to 10 cm.
- Adducting the arm identifies the major axillary crease.
- The cephalic vein and deltoid muscle are carefully retracted laterally and the pectoralis muscle is retracted medially to facilitate exposure (TECH FIG 1A).
- Once the deltopectoral interval is developed, the clavpectoral fascia is identified.
- The clavpectoral fascia is divided at the lateral aspect of the conjoined tendon.
- Avoid excessive retraction on the conjoined tendon to avoid injuring the musculocutaneous nerve.
- The tendon of the subscapularis is often retracted inferiorly and medially and requires mobilization.
- A layer of scar tissue may be seen overlying the lesser tuberosity, which can mimic the subscapularis tendon.

- If the subscapularis tendon cannot be brought back to the lesser tuberosity easily, then the subscapularis requires systematic release from the glenohumeral ligaments.
- Begin by releasing the superior aspect of the tendon from the coracohumeral ligament. The rotator interval is opened from the glenoid to the bicipital groove to facilitate the release.
- Next release the inferior portion of the tendon from the capsular attachments. Care must be taken to identify and protect the axillary nerve and vascular supply inferiorly.
- Finally, release the remaining capsular attachments on the undersurface of the subscapularis (TECH FIG 1B).
BICEPS TENODESIS

- If a biceps tenotomy is performed, it is important to warn the patient of the resultant cosmetic deformity when the biceps retracts distally.
- Indications for biceps tenodesis include the following:
  - Tears involving more than 50% of the biceps tendon
  - Medial subluxation of the biceps tendon
- Open the bicipital groove from the medial side to expose the biceps tendon.

- The biceps tendon is released from the superior glenoid with curved scissors.
- The tendon is retracted distally from the bicipital groove.
- To ensure proper tensioning of the biceps tendon, the proximal portion of the tendon is resected to leave about 20 to 25 mm of tendon proximal to the musculotendinous junction.
- Running locking Krakow or whipstitches are placed up and down the proximal 15 mm of the biceps tendon.
- Abrade the bicipital groove to develop a bleeding surface.
- A burr hole the size of the biceps tendon is made in the bicipital groove about 15 mm from the articular surface. Two smaller 3.2-mm holes are made 15 mm distal to the burr hole in a triangular configuration.
- The tendon end is passed into the proximal hole by pulling the sutures out the distal holes. The sutures are then passed through and tied over the overlying biceps tendon (TECH FIG 2A,B).
- Another fixation option is to use a biotenodesis screw for the biceps tendon.
  - The tendon is prepared as above.
  - An 8-mm reamer is used to make a 25-mm-deep bone tunnel about 15 mm from the articular surface.
  - An 8 × 23-mm Arthrex Bio-Tenodesis screw is used for fixation.
  - One end of the suture is passed through the biotenodesis screw while the other suture passes outside of the screw. This ensures that the tendon will be pulled into the hole as the screw is advanced.
  - When the screw is flush with the bone tunnel, the sutures are tied over the screw (TECH FIG 2C). This provides both an interference fit and suture anchor stability.

TECH FIG 2 • A,B. The tunnel technique uses bone tunnels to fix the biceps tendon upon itself. C. A biceps tenodesis with interference screw fixation.
CORACOPLASTY

- The conjoined tendons are identified.
- Care is taken not to retract vigorously on the conjoined tendons to avoid injury to the musculocutaneous nerve.
- The coracoacromial ligament is released from the coracoid.
- The posterior aspect of the coracoid is exposed by removing the overlying soft tissue. The posterolateral portion is then resected in line with the subscapularis muscle with an osteotome (TECH FIG 3). Alternatively, a burr may be used to accomplish the same resection. Protect the neurovascular structures by placing a retractor on the posterior aspect of the coracoid.
- A rasp is then used to smooth out the bony surface.
- The goal is a 7- to 10-mm clearance between the coracoid and subscapularis.

- Confirmation of adequate decompression can be determined by manipulating the arm into the impingement position and confirming that there is adequate clearance for the subscapularis.

SUBSCAPULARIS REPAIR

- The residual soft tissue is cleaned from the lesser tuberosity. A burr is then used to expose bleeding bone for the tendon to heal to.
- To recreate the anatomic footprint of the subscapularis insertion, four suture anchors are used for the repair.
- Two anchors are placed at 1-cm intervals along the medial aspect of the lesser tuberosity and two are placed at the lateral aspect of the lesser tuberosity (TECH FIG 4A).
- The sutures from the medial anchors are passed in a mattress fashion near the musculotendinous junction of the subscapularis (TECH FIG 4B).

- The sutures from the lateral anchor are passed through the lateral edge of the tendon in a simple fashion and tied down to the lesser tuberosity.
- After repair of the subscapularis tendon, the shoulder is taken through a gentle range of motion to determine the safe arcs for postoperative rehabilitation.
- The lateral aspect of the rotator interval is closed while maintaining about 30 degrees of external rotation of the arm to prevent overtightening of the subscapularis repair.
PEARLS AND PITFALLS

**Indications**
- A complete history and physical examination should be performed.
- The surgeon should identify and address all associated pathology.
- Any limitations of motion should be addressed before surgery.

**Coracoplasty**
- The surgeon should take care to protect the musculocutaneous nerve.
- A 7- to 10-mm clearance should be achieved for the subscapularis.

**Biceps tenodesis**
- Tears in the biceps tendon of over 50% and subluxing tendons should be tenodesed.
- The surgeon should maintain proper tension of the biceps muscle; typically, 20 to 25 mm of tendon should be maintained proximal to the musculotendinous junction.
- A “hidden lesion” describes the presence of a partial undersurface subscapularis tear with a medially dislocated or subluxed biceps. This injury can be missed at the time of open surgery because the bursal surface of the subscapularis remains intact. Diagnostic arthroscopy or proper imaging will prevent missing this lesion.

**Subscapularis repair**
- In chronic cases, a scar layer covers the lesser tuberosity and is usually attached at its medial extent to the retracted and scarred subscapularis tendon. The presence of this scar layer may lead to the misdiagnosis of an intact subscapularis.
- The surgeon should prepare a bleeding bony surface for the tendon to heal to.
- The rotator interval is closed in external rotation to avoid loss of motion.
- External rotation is limited for 6 weeks postoperatively to protect the repair.
POSTOPERATIVE CARE

- The most important postoperative management for subscapularis tears is limitation of external rotation for 6 weeks to avoid stressing the repair.
  - Complete tears are not allowed to externally rotate past 0 degrees.
  - Partial tears are allowed to externally rotate 20 to 30 degrees.
  - At 6 weeks the patient may begin active and active-assisted external rotation exercises, as well as overhead stretching.
  - At 12 weeks strengthening exercises are initiated for partial tears. At 16 weeks strengthening exercises are initiated for complete tears.

OUTCOMES

- Isolated subscapularis tears have favorable surgical outcomes.
  - At 2 years of follow-up, good or excellent results were reported in 13 of 14 isolated subscapularis tears.4
  - Another study demonstrated good or excellent results in 13 of 16 patients with acute traumatic subscapularis tears at 43 months of follow-up. The Constant scores were 82% of age-matched controls.8
  - Poor prognostic factors include chronic tears (symptoms for more than 6 months), fatty degeneration of the subscapularis muscle, and anterosuperior tears (combination of subscapularis and supraspinatus tears).19
  - Comparative outcomes between open and arthroscopic techniques remain to be determined.

COMPLICATIONS

- Repair failure
- Infection
- Loss of motion
- Axillary nerve injury
- Vascular injury

REFERENCES

DEFINITION

- Irreparable posterosuperior rotator cuff tears are tears that involve the supraspinatus and infraspinatus tendons, where there is an inability to repair the tendons back to the anatomic footprint of the greater tuberosity with the arm at the side.
- Some tears can be determined to be irreparable preoperatively, if the MRI or CT scans demonstrate severe muscle atrophy of the supraspinatus or infraspinatus muscles.
- This may help indicate that a patient has an irreparable tear and may be a candidate for muscle transfer, but the final determination of whether a tear is reparable is made at the time of surgery.

ANATOMY

- The latissimus dorsi is normally an adductor and internal rotator of the humerus however, after transfer it is expected to act as an abductor and external rotator of the humerus.
- The ability of the patient to retrain his or her neural pathways to achieve this active in-phase function varies dramatically.
- In some cases, the latissimus dorsi transfer has only a tenodesis effect.
- Originating from the supraspinatus and infraspinatus fossa respectively, the supraspinatus and infraspinatus muscle-tendon units become confluent and insert as a common tendon on the greater tuberosity of the humerus immediately lateral to the humeral head articular margin.
- Their combined footprint area averages 4.02 cm².
- The insertion of the supraspinatus averages 1.27 cm from medial to lateral and 1.63 cm from anterior to posterior.
- The infraspinatus insertion averages 1.34 cm medial to lateral and 1.64 cm anterior to posterior.
- Over the superior aspect of the glenohumeral joint, the deepest fibers of the supraspinatus and infraspinatus tendons are intimately interwoven with the joint capsule such that the rotator cuff tendons and joint capsule function as a single unit. As a result, rotator cuff tears involving the supraspinatus or infraspinatus tendons result in direct communication between the glenohumeral and subacromial spaces.
- The latissimus dorsi muscle has a broad origin from the aponeurosis of spinous processes T7 through L5, the sacrum, the iliac wing, ribs 9 through 12, and the inferior border of the scapula.
- The latissimus dorsi tendon averages 3.1 cm wide and 8.4 cm long at its insertion between the pectoralis major and teres major tendons on the proximal, medial humerus.
- The fibers of the latissimus dorsi twist 180 degrees from origin to insertion, allowing the latissimus dorsi muscle to originate posterior to the teres major muscle on the posterior chest wall but insert immediately anterior to the teres major tendon on the proximal humerus.
- The latissimus dorsi humeral insertion never extends more distal along the shaft than that of the teres major.
- In most patients, the latissimus dorsi and teres major tendons insert separately onto the proximal humerus; however, 30% of patients have conjoined latissimus dorsi and teres major tendons that cannot be separated without sharp dissection.
- The neurovascular pedicle to the latissimus dorsi is the thoracodorsal artery and nerve (posterior cord, C6 and C7). The thoracodorsal artery and nerve enter the anterior, inferior surface of the latissimus dorsi, about 13 cm from the humeral insertion site.
- Anatomic studies have shown that this neurovascular pedicle is of adequate length to allow transfer and excursion of the latissimus dorsi without risk of undue tension, once any adhesions and fibrous bands have been released from the anterior surface of the muscle belly.
- Several important neurovascular structures lie close to the latissimus dorsi insertion, and careful attention to these structures must be given at the time of its release from the humerus to avoid injury.
- Anterior to the latissimus, the radial nerve passes an average of 2.4 cm medial to the humeral shaft at the superior border of the tendon.
- This distance increases with external rotation and abduction and decreases with internal rotation and adduction² (FIG 1A,B).
The axillary nerve runs superior to the latissimus dorsi tendon before exiting the quadrangular space (FIG 1C). In neural rotation and adduction, the average distance between the nerve and the superior border of the tendon is 1.9 cm.

This distance increases with external rotation and abduction and decreases with internal rotation.²

The anterior humeral circumflex artery runs along the superior border of the latissimus dorsi tendon.

**PATHOGENESIS**

| The axillary nerve runs superior to the latissimus dorsi tendon before exiting the quadrangular space (FIG 1C). In neural rotation and adduction, the average distance between the nerve and the superior border of the tendon is 1.9 cm. |
| This distance increases with external rotation and abduction and decreases with internal rotation.² |
| The anterior humeral circumflex artery runs along the superior border of the latissimus dorsi tendon. |

Multiple causes have been proposed for the development of rotator cuff tears, including decreased vascular supply, mechanical compression between the humeral head and the coracoacromial ligament or the undersurface of the acromion, and traumatic causes such as humeral head dislocation, or rapid or repetitive eccentric loading of the rotator cuff muscle–tendon units.

Isolated, acute traumatic events may cause massive rotator cuff tears, the majority of which can be repaired open or arthroscopically if diagnosis and surgical intervention are timely.

Alternatively, most degenerative tendon tears start small and progressively get larger until the muscle retraction, muscle atrophy, and tendon loss prevent primary repair.

Tear size may not predict reparability at the time of surgery, but it does influence healing postoperatively, with larger tears having a lower incidence of healing.

Tissue quality and tendon retraction are the major determinants intraoperatively of whether a repair is possible. These factors also influence healing of a primary repair.

Increased size and duration of a tear lead to retraction of the rotator cuff and fatty infiltration of the muscle belly within weeks to months of developing a tear. These changes result in decreased tendon excursion and tissue compliance that is often irreversible (FIG 2).

**FIG 1 • (continued)** B. Cadaveric dissection demonstrating the insertion of the latissimus dorsi (L) and teres major (TMa) tendons viewed from an anterior exposure. The pectoralis major (PMa) tendon has been reflected laterally and the long head of the biceps (B) tendon remains in the bicipital groove. Note the more distal insertion of the teres major relative to the latissimus dorsi. Ax, axillary nerve; P, posterior humeral circumflex vessel; R, radial nerve. C. Cadaveric dissection of the superficial muscular anatomy of the posterior shoulder. The axillary nerve (Ax) and posterior humeral circumflex artery are seen exiting the quadrilateral space before entering the posterior deltoid (D). L, latissimus dorsi; TMa, teres major; TMi, teres minor; I, infraspinatus; T, triceps.

**FIG 2 • A.** Coronal MRI of a massive cuff tear showing tendon retraction to the midhumeral head. B. Sagittal MRI through lateral supraspinatus and infraspinatus fossae showing fatty degeneration and muscle wasting consistent with decreased muscle compliance and increased risk of repair failure at the time of surgery. The suprascapular nerve (SN) can be seen crossing through the spinoglenoid notch. SS, supraspinatus; IS, infraspinatus; Sub scap, subscapularis.
As a result, the longer these massive tears go untreated, the higher the likelihood that the tear will be irreparable at the time of surgery.

Presentation of the patient with a massive irreparable cuff tear is often precipitated by a minor traumatic event such as a fall onto an outstretched hand, resulting in an acute-on-chronic tear and functional decompensation of the shoulder. Others present with a history of longstanding, worsening symptoms that finally reach a point that is no longer tolerable to the patient.

**NATURAL HISTORY**

- Massive posterosuperior rotator cuff tears are uncommon, representing less than one third of all rotator cuff tears even in practices limited to the treatment of shoulder pathology.\(^1\)\(^5\)
  - Not all patients with large posterosuperior cuff tears experience enough loss of function or pain to require surgery or even seek treatment.
  - It can be difficult to predict who will have significant shoulder dysfunction based on radiographic or MRI findings or direct inspection of a torn rotator cuff.
  - Some patients with large tears can still use their arm for many activities, and some even retain the ability to perform overhead activities.
  - Others with smaller tears may have significant difficulty or an inability to use their arm for anything above chest level.

Regardless of tear size, it is loss of the rotator cuff muscles’ ability to perform their role as humeral head stabilizers that eventually leads to functional decompensation.

As the tear progresses in size, behavioral and biomechanical compensation will allow maintenance of function to a point. However, once the rotator cuff can no longer stabilize the humeral head to create a fulcrum around which the deltoid can act to forward flex and abduct the arm, rapid decompensation, loss of function, and increased pain ensue.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The patient history should elicit the mechanism and duration of the current symptoms with the intent of determining if there was a specific traumatic event leading to the rotator cuff tear and whether symptoms of rotator cuff pathology were present before any such event.
- Determining if the tear is a result of an acute injury as opposed to an acute-on-chronic process will help in estimating the quality of the tissues and whether they will be amenable to repair at the time of surgery.
- The duration of dysfunction is also important in determining the likelihood of being able to repair any rotator cuff tear, since fatty degeneration of the supraspinatus and infraspinatus muscle bellies may start within weeks of the injury and will greatly decrease tissue compliance and increase tension placed on a potential repair.\(^9\)\(^,16\)
- A careful neurologic examination, starting with the neck, must be performed to rule out neurologic causes of shoulder symptoms.
- An understanding of the patient’s current functional limitations as well as expectations for postoperative function is necessary to elicit whether the patient’s disability is significant enough to benefit from the procedure.
- A focused examination for the rotator cuff-deficient shoulder includes but is not limited to:
  - Active forward flexion examination: Patients with function at or above shoulder level are more likely to have improved active forward flexion postoperatively.
  - Active external rotation examination: Decreased external rotation on the affected side indicates partial or complete loss of infraspinatus function due to tear involvement or muscle dysfunction.
  - External rotation lag sign: Inability to maintain maximal external rotation (greater than or equal to a 20-degree lag sign) suggests tear extension well into the infraspinatus.
  - Passive range of motion should be compared to the contralateral limb. Decreased range of motion suggests joint contracture, which requires treatment before consideration for muscle transfer.
  - Modified belly press test: Inability to perform this action demonstrates a dysfunctional or torn subscapularis tendon, and these patients will have a higher rate of clinical failure with muscle transfer.
  - Abduction strength testing: This tests deltoid muscle strength. A weak deltoid suggests less postoperative active range of motion secondary to inadequate strength.
  - External rotation strength testing: Full strength suggests no infraspinatus tear involvement, whereas weakness suggests progressive infraspinatus involvement or dysfunction.
  - Evaluation for superior escape: Superior escape suggests an incompetent coracoacromial arch and a high likelihood of failure to improve with muscle transfer.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A true anteroposterior (AP) radiographic view of the shoulder in the plane of the scapula and axillary view is obtained (FIG 3A,B).
  - This allows evaluation of glenohumeral arthritis, superior migration of the humeral head, and identification of any abnormal bony anatomy (FIG 3C,D).
MRI allows evaluation of the rotator cuff, biceps tendon, and labral and capsular pathology (see Fig 2):
- The size of the rotator cuff tear, especially the extent of subscapularis and infraspinatus involvement
- Distance of tendon retraction from the greater tuberosity
- Extent of fatty degeneration seen in involved muscle bellies
- Electromyography is used to evaluate nerve function around the shoulder girdle.
- It is necessary when nerve pathology is suspected as a cause of shoulder dysfunction.

DIFFERENTIAL DIAGNOSIS
- Frozen shoulder
- Adhesive capsulitis
- Massive rotator cuff tear that can be repaired
- Cervical nerve root compression
- Suprascapular nerve palsy
- Deltoid dysfunction

NONOPERATIVE MANAGEMENT
- Nonoperative management is directed toward optimizing the patient’s current function, managing pain, and modifying activities and expectations.
- Treatment of irreparable cuff tears begins with physical therapy focused on maintaining motion and strengthening the deltoid and scapular stabilizers.
- Physical therapy includes strengthening of the periscapular muscles and internal and external rotators, and stretching to prevent stiffness and further loss of motion.
- Cortisone injection: Forty to 80 mg triamcinolone with 5 to 10 mL 1% Xylocaine is placed in the subacromial–glenohumeral space to decrease synovitis and bursitis, improve pain, and facilitate physical therapy.
- Activity and expectation modification: The physician should explain avoidance of inciting activities that increase pain and discuss realistic functional goals for patients with irreparable cuff tears.
- Most patients with irreparable cuff tears who fail to gain adequate improvement from physical therapy and activity modification are still not good candidates for latissimus dorsi muscle transfers. For these patients, alternative surgical interventions such as limited-goals arthroscopic débridement or reverse total shoulder arthroplasty in low-demand patients, versus shoulder fusion in young, high-demand manual laborers, may be options.
- Limited-goals arthroscopy: If nonoperative management has failed but the patient is not a good candidate for latissimus transfer, an arthroscopic glenohumeral and subacromial débridement may be an option.
- The ideal patient is over the age of 65 and retired, has low functional demands, and has an irreparable tear, and the primary indication for surgery is pain (not weakness).
- These patients should have at least shoulder-level active elevation with an improvement in active elevation after having a positive injection test (10 cc lidocaine into the glenohumeral joint) and without shoulder arthritis.
- This débridement can include synovial débridement, bursectomy, abrasion chondroplasty, acromioplasty–greater tuberosity-plasty, and biceps tenotomy or tenodesis to decrease mechanical symptoms and remove inflamed and painful tissues.
- Successful results are characterized by a decrease in pain followed by a fairly aggressive postoperative strengthening program.

SURGICAL MANAGEMENT
- The treatment decisions regarding management of massive irreparable rotator cuff tears must be made in the context of the patient’s current functional deficits, level of pain and its suspected cause, and physical examination findings.
- What the patient should expect in terms of postoperative pain relief and functional improvement must be clearly delineated before surgery, since return of full (normal) strength, active range of motion, and complete resolution of pain are not realistic goals for even the best latissimus transfer candidates.
- Only a carefully selected subset of patients with irreparable rotator cuff tears are good candidates for latissimus dorsi transfers.
- Ideal patients are younger and have good deltoid and subscapularis muscle strength, limited glenohumeral arthritis, and the ability to get shoulder-level active forward flexion preoperatively.
- Table 1 lists specific prognostic factors.
Preoperative Planning

- Before surgery, plain radiographs and MRI must be reviewed to rule out other sources of pathology.
- Glenohumeral osteoarthritis should be ruled out as a predominant cause of the patient’s current pain.
- An estimate should be made of the likelihood of successful primary repair based on the degree of cuff retraction and tissue quality.
- The equipment needed for both an attempted cuff repair and for muscle transfer should be available at the time of surgery.

Positioning

- The patient is placed in the lateral decubitus position and secured with a bean-bag or hip positioner posts (FIG 4A).
- The patient is draped to keep the affected arm free during the case and allow access to the back, the superior aspect of the shoulder, and the arm down to the elbow (FIG 4B,C).
- An arm holder attached to the opposite side of the table will allow abduction, flexion, and rotation for positioning of the arm during the case.

Approach

- The surgical approach must allow wide access to the rotator cuff and to the muscle belly of the latissimus dorsi and its insertion.
- Although a single-incision technique has been described, most authors prefer a two-incision technique—one incision for exposure and preparation of the rotator cuff and a second for dissection and release of the latissimus dorsi.

- The possibility of needing to use autograft or allograft tendon to augment the length of the latissimus dorsi transfer should be discussed with the patient and the site for autograft harvest must be draped appropriately at the time of surgery, or allograft tissue must be available.

**Superior Approach to the Rotator Cuff**

- An incision is made at the lateral edge of the acromion parallel to the acromion’s lateral border (TECH FIG 1A).
- Subcutaneous flaps are raised just superficial to the deltoit fascia.
- The anterior deltoit is taken off the acromion from the acromioclavicular joint to the midpoint between the anterior and posterior borders of the acromion.
  - This dissection is done in the subperiosteal plane to ensure strong fascial and periosteal tissue for later closure.
- The deltoid is split distally in line with its muscle fibers at the mid-lateral or posterolateral corner of the acromion (depending on the amount of deltoit released), and a stay suture is placed in the deltoit about 5 cm distal to the lateral edge of the acromion to prevent propagation of the split distally, which may result in injury to the axillary nerve (TECH FIG 1B).
- This exposure removes at least half and in some cases all of the middle deltoit origin. This extensive exposure helps in repair of the cuff as well as for transfer and repair of the latissimus dorsi tendon.
- A complete bursectomy is performed, the size and pattern of the rotator cuff tear are delineated, and the leading edge of the cuff tear is debrided (TECH FIG 1C).
- Inspection of the subscapularis tendon should be performed at this stage and partial detachments should be repaired.
- Irreparable subscapularis tears should be considered for concomitant pectoralis major transfers.
- Double muscle transfers are rarely performed and have a worse prognosis than single muscle transfers.

**Index of Commonly Used Abbreviations**

- Acromion: The anterior projection of the scapula.
- Acromioclavicular joint: The joint between the acromion and clavicle.
- Deltoit: The large muscle of the shoulder that moves the arm.
TECH FIG 1 • A. Location of the skin incision for exposure of the subacromial space, at the lateral border of the acromion. B. View of the superior approach to the shoulder with the patient in a lateral decubitus position. A subperiosteal release of the anterior deltoid (AD) from the acromioclavicular joint to the midpoint of the lateral border of the acromion (A) ensures strong tissue for later deltoid reattachment. A stay suture is placed in the deltoid split 5 cm distal to the lateral acromial edge to prevent traction injury to the axillary nerve. PD, posterior deltoid. C. The subacromial space after complete bursectomy and débridement of the irreparable rotator cuff tear. A, acromion; B, biceps tendon; H, humeral head; TMi, teres minor. D. A Cobb or periosteal elevator is used to perform a capsulotomy and release of adhesions around the superior glenoid rim. Articular and subacromial-sided release of adhesions from the retracted rotator cuff allows full mobilization of the torn tendons for an attempted primary repair. E. The prepared greater tuberosity, lightly decorticated, with sutures in place to allow tendon fixation.

- An acromioplasty is performed as needed.
- Remove only that portion of the acromion that extends inferior to the plane of the posterior acromion.
- Avoid decreasing the anteroposterior dimension of the acromion, which can increase the risk of superior escape of the humeral head.
- Keep the coracoacromial ligament at its maximum length and attached to the deep surface of the deltoid.
- At wound closure, place sutures in the acromial end of the coracoacromial ligament and suture this back to the anterior acromion to reconstruct the coracoacromial arch.
Reconstruction of the coracoacromial arch also helps minimize the risk of postoperative superior subluxation of the humeral head.

If degenerative changes are seen in the biceps tendon, it can be tenodesed in the bicipital groove and the intra-articular portion excised to remove it as a potential pain generator.

Complete mobilization of the retracted rotator cuff should be performed on both the intra-articular and extra-articular sides of the tendon.

This is best performed with a scalpel, Cobb or periosteal elevator, and use of electrocautery where necessary on the intra-articular side of the tendons.

Do not exceed 1.5 to 2.0 cm of medial dissection of the rotator cuff muscles within the fossa. Excessive medial dissection could injure the suprascapular nerve (TECH FIG 1D).

Débridement of remaining tissue and light decortication of the greater tuberosity with a rongeur or burr is performed to prepare the site for rotator cuff reattachment or muscle transfer.

Any portion of the cuff that is reparable to the tuberosity should be attached with number 2 or larger nonabsorbable suture to bone.

Bone tunnels or suture anchors are placed in the lateral edge of the greater tuberosity (TECH FIG 1E).

If full mobilization of the rotator cuff will not allow solid repair of the tendon back to the greater tuberosity with the arm at the side, then the decision is made to proceed with the latissimus dorsi transfer.

If a full repair is achieved but the quality of the repair or the tissue quality is fair or poor, we still prefer to perform the latissimus transfer when the likelihood for healing of the primary repair is low and the need for postoperative strength is high and of primary importance to the patient.

SURGICAL APPROACH TO THE LATISSIMUS DORSI

A 15-cm incision is made along the posterolateral border of the latissimus dorsi, extending proximally to the posterior axillary fold (TECH FIG 2A).

The incision can be extended proximally as needed for exposure, being careful to change directions when crossing skin creases in the axilla to avoid webbing and excessive scarring in the skin of the posterior axillary crease.

Skin flaps are raised just superficial to the muscular fascia of the latissimus dorsi, and the upper and lower borders of the muscle are defined (TECH FIG 2B, C).

Identification of the inferior (lateral) border of the latissimus is the most reliable method for correctly identifying the muscle belly, as there is no large muscle inferior (lateral) to the latissimus on the posterior chest wall.

Blunt dissection is used to define and trace the tendon proximally toward its insertion on the proximal humerus (TECH FIG 2D).

Abduction and internal rotation of the arm provides the best visualization of the tendon at its insertion. Careful attention to neurovascular structures is critical at this stage, as the axillary and radial nerves, brachial plexus, and humeral circumflex vessels are all in proximity to the surgical field during this phase of the procedure.

Internal rotation of the arm in abduction is necessary for adequate exposure but also brings the radial nerve closer to the latissimus dorsi tendon along its anterior, medial surface.

The axillary nerve and posterior humeral circumflex artery run along the superior border of the teres
TECH FIG 2 • (continued) D. Exposure of the tendinous insertion of the latissimus dorsi (L) and teres major (TMa) on the proximal, medial humerus is facilitated by abduction and internal rotation of the arm.

- Exposure of the tendinous insertion of the latissimus dorsi (L) and teres major (TMa) just proximal to the latissimus dorsi before exiting the quadrangular space.
- The anterior humeral circumflex vessels run along the superior border of the latissimus dorsi tendon and can be a source of significant bleeding if inadvertently cut.
- Dissection and release of the tendon should be carried out by working from the posterior surface of the humerus, as this keeps all important neurovascular structures anterior (deep) to the tendon.
- A significant number of patients will have latissimus dorsi and teres major tendons that fuse into one tendon along their superior border where they insert on the humerus, a condition that requires sharp dissection to separate the two.
- Once the humeral insertion of the latissimus dorsi has been identified, it should be released directly off the bone on the humeral shaft to ensure adequate tendon length for transfer.

TRANSFER AND FIXATION OF THE LATISSIMUS DORSI TO THE HUMERAL HEAD

- Once released from its insertion, the latissimus dorsi tendon is prepared by weaving number 2 fiberwire (Arthrex, Naples FL) through the tendon with a locking Krackow technique along both its superior and inferior borders (TECH FIG 3A, B).
- These locking sutures should be placed as soon as the tendon is released to minimize extensive handling of the tendon itself, which is easily frayed because it has few crossing fibers.
- These sutures can now be used as traction stitches, and the latissimus is freed from any adhesions on its anterior surface.
  - Be sure to pull the sutures in line with the long axis of the tendon.
  - Do not pull the locking sutures in divergent directions as it will separate the parallel fibers of the tendon.
- The neurovascular pedicle is identified and freed as well to prevent traction and damage to these structures during the transfer.
  - The pedicle is located on the deep surface of the muscle about 13 cm from the musculotendinous junction.
  - It is best seen and dissected after the tendon is released from its insertion and the muscle is flipped posteriorly, thereby exposing the undersurface of the muscle.
- Mobilization of the latissimus dorsi for transfer requires dissection of the deep fascial investments of the muscle from surrounding tissues into the chest wall.
  - If this is not performed, maximum excursion of the transfer will not be achieved and the tendon will not be long enough to reach the top of the humeral head.
Using sharp and scissor dissection and some blunt dissection, the plane underneath the deltoid and superficial to the rotator cuff muscles across the back of the shoulder is developed (about 4 to 6 cm wide) to connect the superior (rotator cuff exposure) and the posterior (latissimus exposure) wounds.

A large Kelly clamp is passed in this plane from the superior to the posterior wounds. Attention must be paid to enlarging this plane (4 to 6 cm) to prevent binding of the latissimus muscle belly within the tunnel, compromising its excursion.

Grasping the previously placed traction sutures with the large curved Kelly clamp, the surgeon then passes the latissimus dorsi deep to the deltoid and into the subacromial space with the arm in adduction and neutral rotation (TECH FIG 3C).

The effectiveness of this transfer depends on achieving a tenodesis effect of the transfer, thereby creating a passive humeral head depressor effect.

To accomplish this, the arm is positioned in 45 degrees of abduction and at least 30 degrees of external rotation.

In this position the transferred tendon is pulled to its maximum length over the top of the humeral head, and the traction sutures placed along the sides of the tendon are passed through the leading edge of the subscapularis tendon and tied. This step establishes the tendon transfer tension and places the tendon over the top of the humeral head (TECH FIG 3D,E).

When the arm is brought to the patient’s side and in internal rotation, the transfer is tensioned further, bringing the humeral head lower within the glenoid fossa.

We believe that this is one of the most important steps in the surgery to achieve proper transfer function.

The lateral border of the latissimus dorsi tendon is now fixed to the greater tuberosity with three number 2 fiberwires passed through bone tunnels or with 5.5-mm biocorkscrew suture anchors (TECH FIG 3F).
The medial edge of the latissimus tendon is sutured to the retracted edge of the supraspinatus and infraspinatus tendons with several nonabsorbable sutures. Although some authors believe that the latissimus tendon should be attached only to the greater tuberosity to act as an external rotator of the humerus, we believe that repair of the leading edge to the upper border of the subscapularis allows the transfer to act as a humeral head depressor (either passively by a tenodesis effect or actively if the patient can learn how to fire the muscle isotonically in phase with external rotation or forward elevation). This suturing of the latissimus to the subscapularis can be done with two heavy, nonabsorbable sutures.

**WOUND CLOSURE**

- The anterior deltoid and middle deltoid are reattached to the acromion with nonabsorbable sutures placed through bone tunnels in the acromion as well as to the intact fascia (TECH FIG 4A).
- A drain is placed in the latissimus dorsi harvest site as needed, and both skin incisions are closed without closure of any deep fascial layers. Before emergence from general anesthesia, the patient is placed in a brace with 20 degrees of abduction and neutral rotation (TECH FIG 4B).

**PEARLS AND PITFALLS**

| Postoperative | Retraining of the latissimus to work in phase with forward flexion and external rotation of the arm                                                                                           |
POSTOPERATIVE CARE

- The patient is placed into a brace postoperatively for 4 to 6 weeks to prevent internal rotation.
- During this time the brace can be removed for dressing and bathing, keeping the arm in neutral rotation.
- Passive forward flexion and external rotation is performed during the first 4 weeks to prevent shoulder stiffness.
- At 4 weeks, bracing is discontinued and passive range of motion in all planes is performed.
- At 7 to 9 weeks, active range of motion is started and physical therapy is begun, focused on retraining the latissimus dorsi to function as an abductor and external rotator of the arm.
- External rotation training: A pillow is placed between the arm and chest wall holding the arm abducted 30 degrees. The patient is told to actively externally rotate the arm while adducting the arm against the pillow.
- Forward elevation training: The patient squeezes a large rubber ball between the palms of the hands while raising both arms forward over the head.
- Biofeedback can also be used to show the patient when he or she is actively contracting the latissimus during external rotation and forward elevation.

OUTCOMES

- Significant improvement in pain scores postoperatively is a consistent finding (80% to 100% of patients) across outcome studies, even for patients less satisfied with their final results.\(^7\)\(^11\)
- Sixty-six to 81% of patients report satisfaction postoperatively. Patient satisfaction tends to be associated more with improved active shoulder function than pain relief.\(^7\)\(^11\)
- Patients with better preoperative function tend to have greater postoperative improvements in range of motion and strength compared to patients starting with greater shoulder dysfunction.
- Based on our experience and that reported in the literature, postoperative range of motion improves by an average of 35 to 50 degrees in forward flexion and 9 to 40 degrees of external rotation.\(^7\)\(^11\)\(^16\)
- Patients undergoing latissimus transfer as the first procedure to treat their rotator cuff pathology can expect better outcomes with regard to satisfaction, pain relief, and active range of motion compared to patients undergoing latissimus transfer who have had prior failed surgery for treatment of their rotator cuff.\(^16\)
- Electromyographic studies show that about 40% to 50% of patients can be retrained to use in-phase latissimus dorsi contraction with active forward flexion or external rotation.\(^7\)\(^11\)
- Female gender and advanced age are associated with worse outcomes.
- Subscapularis tendon tears and superior escape of the humeral head are associated with a higher failure rate.

- Patients with multiple negative preoperative prognostic factors should not undergo isolated latissimus muscle transfer, and other options should be considered either alone or in conjunction with a latissimus transfer.

COMPLICATIONS

- Deltoid detachment
- Wound infection
- Rupture of the transferred tendon
- Decreased active forward flexion

REFERENCES

DEFINITION
- The subscapularis is one of four muscles making up the rotator cuff. Tears can result from chronic attenuation secondary to age or overuse, but more commonly they result from trauma.
- Subscapularis tears commonly occur after a fall on the outstretched arm, traction injuries resulting in a strong external rotation force applied to the arm, or an anterior shoulder dislocation.
- Many tears affect only the upper tendinous portion of the insertion. Other tears result in a complete tear of the tendinous and muscular portions of the insertion.
- Subscapularis tears are often missed early in the course of treatment. Tears older than about 6 months are usually not reparable because of atrophy and degeneration of the muscle, necessitating a pectoralis major muscle transfer.

ANATOMY
- The subscapularis muscle (FIG 1A) arises from the deep, volar surface of the scapular body (the subscapular fossa) and inserts on the lesser tuberosity. The upper two thirds of the insertion is tendinous and the lower third is a muscular insertion.
- The anterior humeral circumflex artery courses laterally along the demarcation between the tendinous and muscular portions of the muscle.
- Tears of the subscapularis differ from tears of the other rotator cuff muscles in that there is often an intact soft tissue sleeve across the front of the shoulder with the torn tendon retracted medially within this “sheath.” In contrast, the supraspinatus and infraspinatus tear leaving exposed humeral head. The remaining soft tissue over the anterior humeral head after a subscapularis tear can be mistaken for an intact or partially torn tendon.
- The pectoralis major muscle is composed of two major heads (FIG 1B).
- The clavicular head originates from the medial third of the clavicle. The sternal head originates from the manubrium, the upper two thirds of the sternum, and ribs 2 to 4. The muscle courses laterally to insert on the lateral lip of the biceps groove.
- The sternal head lies deep to the clavicular head, forming the posterior lamina, and inserts slightly superior to the clavicular head. The clavicular head forms the anterior lamina. The laminae are usually continuous inferiorly.
- Some of the deep muscular fibers from the inferior aspect of the pectoralis major muscle course toward and insert on the more proximal or superior aspect of the muscle insertion. These inferior-to-superior–directed fibers tend to make the muscle “flip” when it is released. The superior corner should be tagged to assist with orientation if used for the transfer.
- The mean width of the pectoralis major insertion is 5.7 cm (range, 4.8 to 6.5 cm).* The undersurface of the insertion has a broad tendinous insertion, whereas the anterior surface is primarily muscular; only the most distal insertion is tendinous.
- The pectoralis major muscle is innervated by the medial and lateral pectoral nerves, which arise from the medial and lateral cords of the brachial plexus, respectively.
- The medial pectoral nerve enters the pectoralis major muscle about 11.9 cm (range, 9.0 to 14.5 cm) from the

Chapter 11 PECTORALIS MAJOR TRANSFER FOR IRREPARABLE SUBSCAPULARIS TEARS

Subscapularis tears result from:
- Anterior shoulder dislocations
- Traction injuries to the arm with extension and external rotation forces to the arm
- Rarely, chronic attenuation from age and overuse
- Possible relationship to coracoid impingement
- The subscapularis muscle is particularly prone to atrophy and degeneration after a tear. With complete, retracted tears of the muscle, there is a window of opportunity for about 6 months when a primary repair can be performed. Beyond that time point, the muscle is increasingly difficult to mobilize and repair is under substantial tension, leading to early failure.

DIFFERENTIAL DIAGNOSIS
- Subscapularis tears result from:
  - Anterior shoulder dislocations
  - Traction injuries to the arm with extension and external rotation forces to the arm
  - Rarely, chronic attenuation from age and overuse
  - Possible relationship to coracoid impingement
- The subscapularis muscle is particularly prone to atrophy and degeneration after a tear. With complete, retracted tears of the muscle, there is a window of opportunity for about 6 months when a primary repair can be performed. Beyond that time point, the muscle is increasingly difficult to mobilize and repair is under substantial tension, leading to early failure.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Lift-off test: The patient will not be able to lift the hand off the back if the subscapularis is deficient.
- Abdominal compression test: With a tear, the patient will not be able to maintain this position and will flex wrist or hand will release from the belly if positive.
- Range-of-motion testing: A subscapularis tear will result in increased external rotation at the side, with a “softer” endpoint.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- A standard shoulder series of radiographs comprising a shoulder anteroposterior (AP) view, a true scapular AP view, an axillary view, and a scapular Y view is obtained to rule out fractures, arthritis, or other injury.
- A subscapularis tear may result in proximal migration of the humeral head relative to the glenoid, depending on the degree of tear and involvement of other rotator cuff muscles.
- In the absence of a subscapularis tear, slight anterior subluxation of the humeral head may be noted on the axillary view.
- An MRI will reveal the tear and also be helpful in assessing the degree of retraction, atrophy, and fatty degeneration of the subscapularis muscle. The proximal portion of the long head of the biceps tendon becomes unstable from the intertubercular groove when the subscapularis tears. An MRI can demonstrate a dislocated or subluxed biceps tendon.
- A CT arthrogram is an alternative to an MRI.
- Subscapularis tears can be diagnosed with ultrasound if performed by a competent, experienced ultrasonographer. Ultrasound is very sensitive for biceps tendon subluxation or dislocation from the groove.

DIFFERENTIAL DIAGNOSIS
- Supraspinatus tears
- Infraspinatus tears
- Biceps tendon pathology
- Anterior instability
- Rotator cuff insufficiency secondary to neurologic etiology

NONOPERATIVE MANAGEMENT
- Physical therapy focusing on strengthening the intact rotator cuff muscles can be beneficial to maximize the function of remaining musculature.
- Range-of-motion exercises focus on any areas of loss of motion or capsular contracture.
- Rotator cuff strengthening with the use of light-resistance Therabands at waist level is an effective initial exercise. Progression to higher-resistance exercises is as tolerated.
- Cortisone injections may give some temporary pain relief but are unlikely to result in permanent resolution of symptoms.
- Nonsteroidal anti-inflammatory medication may be helpful for pain relief of mild to moderate pain.

SURGICAL MANAGEMENT
- An attempt is made at the time of surgery to repair the native subscapularis. Within reasonable limits, the subscapularis is mobilized by releasing surrounding soft tissues. Even a partial repair is recommended in conjunction with a pectoralis major transfer.
- Surrounding soft tissues include the rotator interval and coracohumeral ligament, the anterior capsule of the shoulder (middle and inferior glenohumeral ligaments), and superficial soft tissue adhesions deep to the coracoid and conjoint tendon.
- The subscapularis differs from the other rotator cuff muscles in that it has a fascial sleeve that remains attached to the lesser tuberosity and covers the anterior humeral head. This is in contrast to the other rotator cuff muscles, which leave exposed greater tuberosity and cartilage without soft tissue coverage. This material is easily mistaken for an intact subscapularis, emphasizing the significance of preoperative evaluation.

Preoperative Planning
- Patient history, physical examination, and all imaging studies are reviewed. A soft tissue imaging study such as MRI or ultrasound of the rotator cuff is a necessity.
Plain films should be assessed for proximal migration, anterior subluxation, and deformity secondary to trauma and arthritis. An MRI is useful for assessing the condition of the subscapularis. A high degree of retraction and degeneration of the muscle is highly suggestive of a chronic, irreparable tear that will necessitate a pectoralis major muscle transfer.

Subscapularis tears result in instability of the long head of the biceps tendon with medial subluxation into the joint. The surgeon should be prepared to perform a biceps tenotomy or tenodesis of the tendon if it has not already ruptured from chronic, attritional changes.

Associated tears of the other rotator cuff muscles are addressed concurrently. Isolated arthritic lesions are débrided, as is degenerative labral fraying or tear.

Positioning

The pectoralis major transfer is most easily performed with the patient in the beach chair position. The head of the bed or positioning device is elevated about 60 degrees. The head is secured to avoid cervical injury. The arm is prepared and draped free and held in a commercially available arm holder that allows flexible arm positioning.5

Approach

Several different variations of the pectoralis major transfer have been described.

- Wirth and Rockwood8 described a split pectoralis major muscle transfer superficial to the coracoid.
- Resch and colleagues7 described a split pectoralis major transfer deep to the coracoid.
- Jost and colleagues4 and Gerber and associates3 recommended transfer of the whole pectoralis major muscle superficial to the coracoid.
- Gerber and associates3 described transfer of the sternal head of the pectoralis major with or without the teres major tendon.

The procedure can be performed through a deltopectoral or anterior axillary incision.

- The deltopectoral incision allows a more extensile approach and is recommended in revision cases.
- The anterior axillary incision from the coracoid to the anterior axillary crease is useful in primary cases in smaller patients.
- Both incisions use the deltopectoral interval for deep exposure.

**SPLIT PECTORALIS MAJOR MUSCLE TRANSFER**

- The deltopectoral interval is identified. The cephalic vein is usually retracted laterally with the deltoid. The subdeltoid and subacromial spaces are released of adhesions.
- Regardless of technique, the native subscapularis is examined and mobilized to its full extent. If repair is not possible, a muscle transfer is performed.
- The superior 2.5 to 3 cm of the pectoralis major insertion is identified along the lateral edge of the biceps groove. This contains portions of both the anterior and posterior laminae. The identified portion of the pectoralis major insertion is released sharply from its insertion. Care is taken to avoid injury to the long head of the biceps tendon, which lies directly under the insertion in this case. The distal tendon is tagged with three or four stay sutures.
- Tension is applied to the stay sutures to facilitate the muscle split of the pectoralis major muscle. Muscle dissection is performed bluntly in a medial direction at the inferior portion of the split to mobilize the superior muscle for transfer. Dissection should be limited to 6 to 8 cm to preserve the medial pectoral nerve (TECH FIG 1A).

**TECH FIG 1**

- **A.** The medial pectoral nerve (arrow) arises from the medial cord of the brachial plexus and enters the pectoralis major muscle 6 to 8 cm medial to the muscle insertion. Thus, medial dissection and mobilization is limited to 6 to 8 cm to avoid denervating the muscle. **B.** The superior half of the pectoralis major insertion is freed from the humerus and mobilized. This half is transferred to the humeral head and secured in a small bone trough with drill holes for the sutures.

- The humerus is rotated internally to expose the greater tuberosity and humeral shaft lateral to the biceps groove. An osteotome or burr is used to make a bone trough measuring $5 \times 25$ mm oriented in a vertical position for reinsertion of the transferred pectoralis muscle.
- Three or four holes are drilled just lateral to the edge of the trough and a curved awl is used to connect the drill holes to the trough (TECH FIG 1B).
- The sutures in the tendon are passed into the trough and out through the drill holes. Tension is placed on the sutures, bringing the tendon into the trough. The sutures are then tied over the bone bridges between the holes, securing the tendon.
- A biceps tenotomy or tenodesis is performed as needed.

### TECHNIQUES

#### SUBCORACOID MUSCLE TRANSFER OF THE CLAVICULAR HEAD

- A deltopectoral incision and approach are used (TECH FIG 2A).
- The tendon of the pectoralis major insertion is exposed along its full length (TECH FIG 2B).
- The superior half to two thirds of the clavicular head is detached from the humerus. The muscle fibers corresponding to the detached section of the tendon are split or separated from the remaining muscle using blunt dissection in a medial direction. The blunt dissection is performed between the sternal and clavicular heads so that only the clavicular head muscle is released and preserved for the transfer (TECH FIG 2C). The muscle fibers of the sternal portion that course into the proximal portion of the muscle are transected.
- The space between the medial border of the conjoint tendon and the pectoralis minor is gently dissected bluntly. The musculocutaneous nerve and its entry into the conjoint tendon are identified. The space deep to the conjoint tendon and superficial to the musculocutaneous nerve is developed for the muscle transfer (TECH FIG 2D).
- Stay sutures are attached to the distal pectoralis major tendon. The sutures are grasped with a curved forceps.

---

**TECH FIG 2** • A. This cadaveric dissection illustrates the deltopectoral approach (black arrow, pectoralis major; white arrow, deltoid). The incision should be long enough to allow adequate exposure of the pectoralis major and the proximal humerus for reattachment. B. Cadaveric dissection illustrating the pectoralis major and its insertion (arrow). C. The pectoralis major has two heads, the superficial clavicular head (white arrow) and the deeper sternal head (black arrow). In this photo, the insertion has been released and is reflected medially. (continued)
WHOLE PECTORALIS MUSCLE TRANSFER

- The deltopectoral approach is identical to that described above.
- An attempt is made to mobilize and repair the subscapularis. Releases are performed at the rotator interval, the base of the coracoid, the brachial plexus, and the subscapularis fossa. A partial repair is performed if possible.
- The entire tendon of the pectoralis major tendon is exposed and released from its insertion of the humerus.
- Three nonabsorbable sutures are passed through the tendon using a modified Mason-Allen technique.
- The muscle and tendon is mobilized and brought over (superficial) the coracoid to the medial aspect of the greater tuberosity, where it is secured using anchor fixation or to a bone trough (TECH FIG 3).
- If a bone trough is used, the sutures are routed through the trough and the knots are tied over a small titanium plate to prevent suture pullout. The uppermost corner of the tendon is sutured to the anterolateral supraspinatus. Care is taken not to overtighten the rotator interval.

TECH FIG 3 • The whole pectoralis major muscle is released from its insertion on the humerus and transferred and secured to the humeral head using anchor fixation or a bone trough with tunnels.
SPLIT PECTORALIS MAJOR AND TERES MAJOR TENDON TRANSFER

- Setup and exposure are as described above.
- The plane between the sternal and clavicular heads is located and developed. The sternal head is sharply released from the humerus. Nonabsorbable sutures (no. 2) are placed in the tendon in Mason-Allen fashion.
- The sternal head is mobilized and pulled underneath the clavicular head to the lesser tuberosity, where it is secured (TECH FIG 4A). The transfer is superficial to the coracoid process and should be tight but allow 30 degrees of external rotation.
- If the subscapularis tear is completely irreparable, the authors recommend combining this transfer with the teres major muscle.
- To expose the teres major, the arm is externally rotated.
- The latissimus dorsi insertion is located and the superior and inferior aspects are demarcated. The latissimus is released, leaving a cuff of tissue laterally for repair.
- The teres major insertion is deep to the latissimus. The teres major is tagged and released. Often, the muscle must be released from confluence with the latissimus.
- The axillary nerve and posterior humeral circumflex artery lie at the superior border of the teres major muscle. The radial nerve and brachial artery are in close approximation to the inferior border of the teres major.
- Finally, the teres major is transferred to the inferior portion of the lesser tuberosity, where it is secured with nonabsorbable sutures (TECH FIG 4B).

**TECH FIG 4** • **A.** This transfer uses the sternal head of the pectoralis major muscle. It is released and mobilized underneath the clavicular head to the lesser tuberosity. **B.** The teres major muscle is released from its insertion on the humerus and transferred along with the sternal head of the pectoralis major to the lesser tuberosity. The teres major inserts deep to the latissimus dorsi, which is reattached in its anatomic position.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>

<th>Subscapularis tears are often missed, resulting in a delayed diagnosis.</th>
<th>Elderly patients with generalized atrophy should be considered for a whole muscle transfer, whereas more muscular individuals are better candidates for split or sternal head transfers.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pectoralis major muscle detachment and mobilization</td>
<td>Mobilization of the muscle should not proceed greater than 8 cm from the insertion in order to protect the pectoral nerves.</td>
<td>In whole muscle transfers, the medial pectoral nerve can enter the muscle within 1.2 cm of the inferior edge.</td>
</tr>
</tbody>
</table>
Subcoracoid transfer of the pectoralis major muscle
- The musculocutaneous nerve and its proximal branches are at risk.
- The musculocutaneous nerve is identified.
- Transferred muscle should course deep to the conjoint tendon and superficial to the nerve to avoid excessive traction and neurapraxia.
- Scar in revision cases can make this dissection difficult; an intraoperative nerve stimulator may help identify structures of the brachial plexus if necessary.

Fixation problems
- Mason-Allen or Krackow sutures are used to grasp the tendon securely.

Orientation
- Before release of the muscle, the superior corner is tagged to keep muscle in its anatomic orientation (some inferior muscle fibers course to the superior insertion, so the muscle tends to flip after release).

POSTOPERATIVE CARE
- A drain should always be used because release and transfer of the pectoralis major muscle results in dead space, and hematoma formation is common.
- The operative arm is placed in a sling postoperatively. Passive exercises are started on postoperative day 1.
  - The surgeon should evaluate tension on the transfer intraoperatively before closure to determine the limits of external rotation during early rehabilitation.
  - Forward elevation is performed in internal rotation or neutral rotation to minimize tension on the transfer.
  - Active internal rotation and extension are avoided for 6 weeks.
  - Active assisted and active range-of-motion exercises are started 6 weeks after surgery. Resistance exercises commence as tolerated thereafter. No internal rotation resistance exercises are recommended until 12 weeks postoperatively.

OUTCOMES
- Jost and associates reported a series of 30 transfers in 28 patients. Twelve had isolated subscapularis tears and 18 had concomitant supraspinatus–infraspinatus tears. The mean relative Constant score improved from 47% to 70% at an average of 32 months of follow-up. Thirteen patients were very satisfied, 10 patients were satisfied, 2 patients were dissatisfied, and 3 patients were dissatisfied.
- Resch and colleagues reported on a series of 12 patients with a subcoracoid transfer. The Constant score increased from 26.9% to 67.1%. Nine assessed their final result as good or excellent, three as fair, and none as poor. Four unstable shoulders were stable at the average of 28 months of follow-up.
- Rockwood reported a series of 13 patients. Seven had a pectoralis major transfer and six had a pectoralis minor transfer. Ten of the 13 were satisfied, but the results were not separated between the patients with the pectoralis major and minor transfers.
- Galatz and associates reported on the subcoracoid pectoralis major transfer in 14 patients as a salvage procedure for iatrogenic anterior superior instability. Nine of the 14 had satisfactory results in terms of pain relief, but the functional results are not as predictable for this particular indication.
- Gerber and colleagues reported a combination of sternal head and sternal head plus teres major transfers. In the sternal head patients, 9 of 11 had pain relief. Two had a rupture that required revision. In the sternal head plus teres major group, seven of nine patients had pain relief. One had a rupture discovered at the time of revision surgery (fusion). Final ASES scores were 61 in the sternal group and 55 in the sternal plus teres group.
- In all series, most of the patients had had surgery before the transfer, and in most cases a pectoralis major transfer was performed for revision purposes. This has dramatic implications on outcome.

COMPLICATIONS
- Musculocutaneous nerve injury
- Pectoral nerve injury
- Fixation failure
- Mechanical impingement with the coracoid, either deep or superficial to the conjoint tendon

REFERENCES
Sternoclavicular dislocation is one of the rarest dislocations, but one most shoulder surgeons will encounter several times during a career (more in a practice with significant exposure to high-energy trauma).

Sternoclavicular dislocations represented 3% of a series of 1603 injuries of the shoulder girdle reported by Cave et al.6 The true ratio of anterior to posterior dislocations is unknown, since most reports focus on the rarer posterior type. Estimates range from a ratio of 20 anterior dislocations to each posterior by Nettles and Linscheid,19 in a series of 60 patients (57 anterior and 3 posterior), to a ratio of approximately three to one (135 anterior and 50 posterior) in our series25 of 185 traumatic sternoclavicular injuries.

Not all sternoclavicular dislocations require surgery. Avoiding inappropriate patient selection, preventing hardware-related complications, and repairing or reconstructing the capsule and the rhomboid ligament if the medial clavicle has been resected require special emphasis.

Although this region can be an intimidating one because of the surrounding anatomic structures, a knowledgeable and careful surgeon can treat this joint safely and reliably produce good results.

ANATOMY

The epiphysis of the medial clavicle is the last epiphysis of the long bones to appear and the last to close. It does not ossify until the 18th to 20th year, and it generally fuses with the shaft of the clavicle around age 23 to 25.14,15 For this reason, many sternoclavicular “dislocations” in young adults are in fact physeal fractures.

The articular surface of the medial clavicle is much larger than that of the sternum. It is bulbous and concave front to back and convex vertically, creating a saddle-type joint with the curved clavicular notch of the sternum.14,15

A small facet on the inferior aspect of the medial clavicle articulates with the superior aspect of the first rib in 2.5% of subjects.5

There is little congruence and the least bony stability of any major joint in the body. Almost all of its integrity comes from the surrounding ligaments.

Ligaments

The intra-articular disc ligament is dense and fibrous, arises from the synchondral junction of the first rib to the sternum, passes through the sternoclavicular joint, and divides it into two separate spaces14,15 (FIG 1). It attaches on the superior and posterior medial clavicle and acts as a checkrein against medial displacement of the inner clavicle.

The costoclavicular (rhomboid) ligament attaches the upper surface of the medial first rib to the rhomboid fossa on the inferior surface of the medial end of the clavicle.14,15 It averages 1.3 cm long, 1.9 cm wide, and 1.3 cm thick.5

The anterior fasciculus arises anteromedially, runs upward and laterally, and resists lateral displacement and upward rotation of the clavicle.

The posterior fasciculus is shorter, arises laterally, runs upward and medially, and resists medial displacement and excessive downward rotation1,5,15 (FIGS 1 AND 2).

The interclavicular ligament (see Fig 1) connects the superomedial aspects of each clavicle with the capsular ligaments and the upper sternum. Comparable to the wishbone of birds, it helps the capsular ligaments to produce “shoulder poise”; that is, to hold up the lateral aspect of the clavicle.14

The capsular ligaments cover the anterosuperior and posterior aspects of the joint and represent thickenings of the joint capsule (Figs 1 and 2). The clavicular attachment of the ligament is primarily onto the epiphysis of the medial clavicle, with some blending of the fibers into the metaphysis.3,8

In sectioning studies, the capsular ligaments are the most important structures in preventing upward displacement of the medial clavicle caused by a downward force on the distal end of the shoulder.1

This lateral poise of the shoulder (ie, the force that holds the shoulder up) is attributed to a locking mechanism of the ligaments of the sternoclavicular joint.

Other single ligament sectioning studies26 have shown that the posterior capsule is the most important primary stabilizer to anterior and posterior translation. The anterior capsule is an important restraint to anterior translation. The costoclavicular ligament is unimportant if the capsule remains intact, although it may be an important secondary restraint if the capsular ligaments are torn, much like the coracoclavicular ligament laterally.

Applied Surgical Anatomy

A “curtain” of muscles—the sternohyoid, sternothyroid, and scaleni—lies posterior to the sternoclavicular joint and the inner third of the clavicle and blocks the view of vital structures—the innominate artery, innominate vein, vagus nerve, phrenic nerve, internal jugular vein, trachea, and esophagus.

The anterior jugular vein lies between the clavicle and the curtain of muscles. Variable in size and as large as 1.5 cm in diameter, it has no valves and bleeds like someone has opened a floodgate when nicked.

The surgeon who is considering stabilizing the sternoclavicular joint by running a pin down from the clavicle into the sternum should not do it and should remember that the arch of the aorta, the superior vena cava, and the right pulmonary artery are also very close at hand.

PATHOGENESIS

Most sternoclavicular joint dislocations result from high-energy trauma, usually a motor vehicle accident. They occasionally result from contact sports.
A force applied directly to the anteromedial aspect of the clavicle can push the medial clavicle back behind the sternum and into the mediastinum. More commonly, a force is applied indirectly, from the lateral aspect of the shoulder. If the shoulder is compressed and rolled forward, a posterior dislocation results; if the shoulder is compressed and rolled backward, an anterior dislocation results.

As noted above, many injuries of the sternoclavicular joint in patients under 25 years of age are, in fact, fractures through the medial physis of the clavicle.

NATURAL HISTORY

- Mild or moderate sprain
  - The mildly sprained sternoclavicular joint is stable but painful.
  - The moderately sprained joint may be slightly subluxated anteriorly or posteriorly, and may often be reduced by drawing the shoulders backward as if reducing and holding a fracture of the clavicle.

- Anterior dislocation
  - Although most anterior dislocations are unstable after closed reduction, we still recommend an attempt to reduce the dislocation closed.
  - Occasionally the clavicle remains reduced, but typically the clavicle remains unstable after closed reduction. We usually accept the deformity, because an anteriorly dislocated sternoclavicular joint typically becomes asymptomatic, and we believe that the deformity is less of a problem than the potential complications of operative fixation.

- Posterior dislocation
  - In contrast to anterior dislocations, the complications of an unreduced posterior dislocation are numerous: thoracic outlet syndrome, vascular compromise, and erosion of the medial clavicle into any of the vital structures that lie posterior to the sternoclavicular joint.
  - Closed reduction for acute posterior sternoclavicular dislocation can usually be obtained, and the reduction is generally stable. Often, general anesthesia is necessary. However, when a posterior dislocation is irreducible or the reduction is unstable, an open reduction should be performed.
  - When chronic posterior dislocation is present, late complications may arise from mediastinal impingement, so we recommend medial clavicle resection and ligament reconstruction.

- Physeal injuries
  - The typical history for physeal injuries is the same as for other traumatic dislocations. The difference between these injuries and pure dislocations is that most of these injuries will heal with time, without surgical intervention.
  - In very young patients, the remodeling process can eliminate deformity because of the osteogenic potential of an intact periosteal tube. Zaslav, Rockwood, and Hsu et al have all reported successful treatment of displaced medial clavicle physeal injury in adolescents and provided radiographic evidence of remodeling.
  - Anterior physeal injuries may be reduced, but if reduction cannot be obtained, they can be left alone without problem. Posterior physeal injuries should likewise undergo an attempt at reduction. If a posterior dislocation cannot be reduced closed and the patient is having no significant symptoms, the displacement can be observed while remod-

---

**FIG 1**

A. Normal anatomy around the sternoclavicular joint. The articular disc ligament divides the sternoclavicular joint cavity into two separate spaces and inserts onto the superior and posterior aspects of the medial clavicle. B. The articular disc ligament acts as a checkrein for medial displacement of the proximal clavicle.

**FIG 2**

Normal anatomy around the sternoclavicular and acromioclavicular joints. The tendon of the subclavius muscle arises in the vicinity of the costoclavicular ligament from the first rib and has a long tendon structure.
Plain films, at present they have been replaced with CT scans. In the past, tomograms were useful in distinguishing a sternoclavicular dislocation from a fracture of the medial clavicle and defining questionable anterior and posterior injuries of the sternoclavicular joint. Although they provide more information than plain films, at present they have been replaced with CT scans. Without question, CT scanning is the best technique to study the sternoclavicular joint. It distinguishes dislocations of the joint from fractures of the medial clavicle and clearly defines minor subluxations (FIG 5). The patient should lie supine. The scan should include both sternoclavicular joints and the medial halves of both clavicles so that the injured side can be compared with the normal. If symptoms of mediastinal compression are present or displacement of the medial clavicle is severe, the use of intravenous contrast will aid in the imaging of the vascular structures in the mediastinum.

DIFFERENTIAL DIAGNOSIS

- Arthritic conditions: sternocostoclavicular hyperostosis, osteitis condensans, Friedrich disease, Tietze syndrome, and osteoarthritis
- Atraumatic (spontaneous) subluxation or dislocation: One or both of the sternoclavicular joints may spontaneously subluxate or dislocate during abduction or flexion during overhead motion. Typically seen in ligamentously lax females in their late teens or early 20s, it is not painful, it is almost always anterior, and it should almost always be managed nonoperatively.
- Congenital or developmental or acquired subluxation or dislocation: Birth trauma, congenital defects with loss of bone substance on either side of the joint, or neuromuscular or other developmental disorders can predispose the patient to subluxation or dislocation.
- Iatrogenic instability may be due to failure to reconstruct the ligaments of the sternoclavicular joint adequately or to an excessive medial clavicle resection. History is significant for a prior procedure on the sternoclavicular joint.

NONOPERATIVE MANAGEMENT

- A mild sprain is stable but painful. We treat mild sprains with a sling, cold packs, and resumption of activity as comfort dictates.

FIG 3 • Serendipity view. Positioning of the patient to take the serendipity view of the sternoclavicular joints. The x-ray tube is tilted 40 degrees from the vertical position and aimed directly at the manubrium. The nongrid cassette should be large enough to receive the projected images of the medial halves of both clavicles. In children the tube distance from the patient should be 45 inches; in thicker-chested adults the distance should be 60 inches.

FIG 4 • Interpretation of the cephalic tilt films of the sternoclavicular joints. A. In a normal person, both clavicles appear on the same imaginary line drawn horizontally across the film. (continued)
arm combined with pressure on the medial clavicle will generally reduce the dislocation.

- Posterior dislocation in a stoic patient may possibly be reducible under intravenous narcotics and muscle relaxation. However, general anesthesia is usually required for reduction of a posterior dislocation, because of pain and muscle spasm.
- Our preferred method is the abduction traction technique.

  - The patient is placed supine, with the dislocated side near the edge of the table. A 3- to 4-inch-thick sandbag is placed between the scapulae (FIG 6). Lateral traction is applied to the abducted arm, which is then gradually brought back into extension. The clavicle usually reduces with an audible snap or pop, and it is almost always stable. Too much extension can bind the anterior surface of the dislocated medial clavicle on the back of the manubrium.
  - Occasionally it is necessary to grasp the medial clavicle with one’s fingers to dislodge it from behind the sternum. If this fails, the skin is prepared, and a sterile towel clip is used to grasp the medial clavicle to apply lateral and anterior traction (see Fig 6C). If the joint is stable after reduction, the shoulders should be held back for 4 to 6 weeks with a figure 8 dressing to allow ligament healing.
  - Many investigators have reported that closed reduction usually cannot be accomplished after 48 hours. However, others have reported closed reductions as late as 4 and 5 days after the injury.4

- Physeal fractures are reduced in the same manner as dislocations, with immobilization in a figure 8 strap for 4 weeks to protect stable reductions. Fractures that cannot be reduced and are being managed nonoperatively are treated with a figure 8 strap or a sling for comfort and mobilized as symptoms permit.

**SURGICAL MANAGEMENT**

- A posterior displacement of the medial clavicle that is irreducible or redislocates after closed reduction is a well-accepted surgical indication.
- More controversial is anterior displacement that fails to maintain a stable reduction.

  - The patient is supine on the table, with a 3- to 4-inch-thick pad between the shoulders. Direct gentle pressure over the anteriorly displaced clavicle or traction on the outstretched arm combined with pressure on the medial clavicle will generally reduce the dislocation.
  - Posterior dislocation in a stoic patient may possibly be reducible under intravenous narcotics and muscle relaxation. However, general anesthesia is usually required for reduction of a posterior dislocation, because of pain and muscle spasm.
  - Our preferred method is the abduction traction technique.

  - The patient is placed supine, with the dislocated side near the edge of the table. A 3- to 4-inch-thick sandbag is placed between the scapulae (FIG 6). Lateral traction is applied to the abducted arm, which is then gradually brought back into extension. The clavicle usually reduces with an audible snap or pop, and it is almost always stable. Too much extension can bind the anterior surface of the dislocated medial clavicle on the back of the manubrium.
  - Occasionally it is necessary to grasp the medial clavicle with one’s fingers to dislodge it from behind the sternum. If this fails, the skin is prepared, and a sterile towel clip is used to grasp the medial clavicle to apply lateral and anterior traction (see Fig 6C). If the joint is stable after reduction, the shoulders should be held back for 4 to 6 weeks with a figure 8 dressing to allow ligament healing.
  - Many investigators have reported that closed reduction usually cannot be accomplished after 48 hours. However, others have reported closed reductions as late as 4 and 5 days after the injury.4

- Physeal fractures are reduced in the same manner as dislocations, with immobilization in a figure 8 strap for 4 weeks to protect stable reductions. Fractures that cannot be reduced and are being managed nonoperatively are treated with a figure 8 strap or a sling for comfort and mobilized as symptoms permit.

Chapter 12  ACUTE REPAIR AND RECONSTRUCTION OF STERNOCLAVICULAR DISLOCATION 3163

![Diagram of closed reduction technique](image)

**FIG 6** • Technique for closed reduction of the sternoclavicular joint. A. The patient is positioned supine with a sandbag placed between the two shoulders. Traction is then applied to the arm against countertraction in an abducted and slightly extended position. In anterior dislocations, direct pressure over the medial end of the clavicle may reduce the joint. B. In posterior dislocations, in addition to the traction it may be necessary to manipulate the medial end of the clavicle with the fingers to dislodge the clavicle from behind the manubrium. C. In stubborn posterior dislocations, it may be necessary to prepare the medial end of the clavicle sterilely and use a towel clip to grasp around the medial clavicle to lift it back into position.

- We now consider operative treatment when the entire medial clavicle is torn out of the deltotrapezial sleeve.

**Preoperative Planning**

- Careful review of the history and examination for symptoms of mediastinal compression is crucial.
- Review of the CT scan for the direction and degree of displacement and determination of a very medial fracture versus pure dislocation follows.
- If history or radiographic evidence of mediastinal compromise or potential compromise is present, a cardiothoracic surgeon should be either present or readily available.
- Very medial fractures can occasionally be repaired with independent small-fragment lag screws or orthogonal minifragment plates. For pure dislocations, heavy nonabsorbable suture will sometimes suffice. Suture anchors are useful for augmenting ligament repairs. Allograft tendons may be used if the capsule is irreparable and must be reconstructed.
- Closed reduction under anesthesia is then attempted and the stability of the joint is evaluated after reduction.

**Positioning**

- To begin, the patient is positioned supine on the table, and three or four towels or a sandbag placed between the scapulae.
- The upper extremity should be draped free so that lateral traction can be applied during the open reduction.

- A folded sheet may be left in place around the patient’s thorax so that it can be used for countertraction.
- If there is concern regarding the mediastinum, the entire sternum should be draped into the field.

**Approach**

- An anterior incision that parallels the superior border of the medial 3 to 4 inches of the clavicle and then extends downward over the sternum just medial to the involved sternoclavicular joint is used (FIG 7A).
- As an alternative, a necklace-type incision may be created in Langer’s lines, beginning at the midline and sweeping lateral and up along the clavicle.
- Careful subperiosteal dissection around the medial clavicle and onto the surface of the manubrium allows exposure of the articular surfaces.
- If the medial clavicle is resting posteriorly, it is safer to identify the shaft more laterally and then trace it back medially along the subperiosteal plane (FIG 7B).
- Traction and blunt retractors can then be used to lever the medial clavicle back up into its anatomic location (FIG 7C). These retractors may be used behind the medial clavicle and manubrium to protect the posterior structures.
- If one has chosen to operate on an anterior medial clavicle because of extreme displacement, it may generally be simply pushed back into place.
FIG 7 • A. Proposed skin incision for open reduction of a posterior dislocation. B. Subperiosteal exposure of the medial clavicle shows a posteriorly displaced medial clavicular shaft (left) resting posterior to the medial clavicular physis (arrow, right). C. The medial shaft of the clavicle has been lifted anteriorly with a clamp and now rests adjacent to the medial physis (arrow, right).

PRIMARY REPAIR: MEDIAL FRACTURE

- In children and in young adults, the dislocation of the medial clavicle may occur through the medial physis or as a fracture, leaving a small amount of bone articulating with the manubrium.
- Because much of the capsule remains intact to this medial fragment, it can serve as an anchor for internal fixation of the medial clavicle shaft. Depending on the amount of bone, the type of fixation will vary.
- The smallest fragments will permit only osseous suture fixation, but the medial clavicle is cancellous bone and heals very quickly (TECH FIG 1A).
- As the fragment gets larger, independent lag screw fixation may be possible (TECH FIG 1B,C).
- For very medial shaft fractures, it may even be possible to use two orthogonal minifragment plates.

TECH FIG 1 • A. Heavy nonabsorbable suture has been placed through drill holes in the medial clavicle and through the physis to secure the fracture shown in Figure 7B,C. B, C. A symptomatic medial clavicle nonunion had a medial fragment large enough to allow fixation with three cortical lag screws.
Chapter 12  ACUTE REPAIR AND RECONSTRUCTION OF STERNOCLAVICULAR DISLOCATION

TECH FIG 2
Suture anchors may be used to create a sling to hold the medial clavicle reduced while the capsular ligaments heal.

TECHNIQUES

PRIMARY REPAIR: CAPSULAR LIGAMENTS AND SUTURE AUGMENTATION

- After reduction, the ligaments may be repaired primarily with heavy nonabsorbable suture. This usually allows repair of the anterior and superior capsule, but, for obvious reasons, does not allow repair of the important posterior capsule.
- The reduction is often reinforced with either simple osseous sutures through drill holes in the medial clavicle and manubrium or with suture anchors (TECH FIG 2). The costoclavicular ligament may also occasionally be repaired primarily.
- This technique has generally been employed in children but may also be used in adults.

IMMEDIATE RECONSTRUCTION: CAPSULAR LIGAMENTS

- At times the joint may be reducible but the ligaments are damaged to the point where primary repair is not feasible. In this circumstance, the ligaments may be immediately reconstructed using tendon graft.
- This may be done by passing a tendon from the front of the sternum, through the articular surfaces and intra-articular disc, and out the front of the medial clavicle and tying the tendon to itself anteriorly. Autograft or allograft tendon may be used.
- The capsule may also be reconstructed in the manner described by Spencer and Kuhn (TECH FIG 3).
  - Drill holes 4 mm in diameter are created from anterior to posterior through the medial clavicle and the adjacent manubrium.
  - A free semitendinosus tendon graft is woven through the drill holes so the tendon strands are parallel to each other posterior to the joint and cross each other anterior to it.
  - The tendon is tied in a square knot and secured with no. 2 Ethibond suture.
  - This technique has the advantage of reconstructing both the anterior and the posterior ligament in a very strong and secure manner.

TECH FIG 3 • A. Semitendinosus may be used to reconstruct the capsular ligaments. B,C. The allograft tendon is pulled through the medial clavicle (left) and manubrium (right) and tied. (continued)
If there is concern about the stability of a reconstruction or repair, if the dislocation is subacute and posterior, or if there is a question of impingement on the mediastinal structures, one may elect to resect the medial clavicle entirely. In this situation, it is important to repair or reconstruct the costoclavicular ligament (akin to a modified Weaver-Dunn procedure).

The medullary canal can also be used to create an attachment point for an additional medial tether. We prefer to use the patient’s own tissue, such as the sternoclavicular ligament, whenever possible (TECH FIG 4).

The medial clavicle is resected and the canal curetted and prepared with drill holes on the superior surface.

Grasping suture is woven through the remaining ligament, pulled through the superior drill holes, and tied over bone.

Heavy nonabsorbable sutures are then passed through the remaining costoclavicular ligament and around the clavicle, and the periosteal tube is closed.

If adequate local tissue is not present, an allograft such as Achilles tendon may also be used.2

TECH FIG 4 • The residual capsule may be used to reconstruct a medial clavicular restraint, akin to a medial Weaver-Dunn procedure, as described by Rockwood and Wirth.23
**REDUCTION AND BALSER PLATE FIXATION**

- The use of K-wires around the sternoclavicular joint has been routinely condemned, and they should not be used.
  - There are reports, however, of temporary plate fixation from the medial clavicle to the sternum to maintain a reduced joint while the soft tissues heal.
- The Balser plate is a hook plate used in Europe for treatment of acromioclavicular joint separations and distal clavicle fractures. It has been used for sternoclavicular dislocations by placing the hook into the sternum and using screws to fix the plate onto the medial clavicle (TECH FIG 5).
  - Franck et al.\(^\text{12}\) published good results for 10 patients treated with Balser plates. They thought that the stability of this construct allowed a more rapid rehabilitation. The implant is quite bulky and removal is generally required.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Diagnosis</th>
<th>Conventional studies are unreliable. A high index of suspicion, a thorough examination, and a prompt CT scan will ensure correct diagnosis.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Individualize treatment when necessary</td>
<td>Although anterior dislocations are generally treated nonoperatively, a severely anteriorly displaced medial clavicle may be reduced and fixed acutely, with a low risk of complications, in a reliable patient. Posterior dislocations generally mandate surgery because delayed impingement on mediastinal contents may occur. However, there may be situations where displacement is mild and chronic and the risks of surgery may outweigh the benefits.</td>
</tr>
<tr>
<td>Prepare for complications</td>
<td>Although complications are uncommon, they are spectacular, and not in a good way. The surgeon needs to be ready for both pneumothorax and the unlikely possibility of a vascular injury. A cardiothoracic surgeon should be immediately available.</td>
</tr>
<tr>
<td>Use the medial clavicle</td>
<td>Even a medial epiphysis or a tiny piece of medial clavicle in its anatomic location provides an excellent anchor for heavy suture or lag screws for primary fracture repair.</td>
</tr>
<tr>
<td>Be flexible intraoperatively</td>
<td>Preserving the native joint is an admirable goal, but poor ligament and bone quality sometimes precludes primary repair, especially in the subacute dislocation. If the stability of the joint cannot be ensured, medial clavicle resection and costoclavicular reconstruction should be strongly considered.</td>
</tr>
</tbody>
</table>

**POSTOPERATIVE CARE**

- For sternoclavicular strains and anteriorly dislocated medial clavicles accepted in this position, a sling or figure 8 strap is prescribed and the patient is allowed to mobilize the extremity as function permits.
- Medial clavicle fractures that are stable after reduction are immobilized in a figure 8 strap for 4 to 6 weeks and then mobilized as comfort allows.
- Acute dislocations that have been reduced and are stable or have been surgically repaired receive a sling or figure 8 strap for 6 weeks to protect the reduction and allow ligament healing.
- Patients in the figure 8 strap are allowed use of the elbow and hand with the arm at the side for light activities of daily living, but the strap is conscientiously maintained.
- At 4 to 6 weeks they move to a sling and perform their own mobilization. Because the glenohumeral joint is unaffected, motion usually returns quickly to near full range.
  - When full range of motion has been obtained, gentle progressive strengthening and resumption of normal activities commence.
  - In general, patients treated with joint preservation can return to all activities, including heavy labor, but we have seen traumatic failure of costoclavicular reconstructions and do ask patients who have undergone medial clavicle resection and ligament reconstruction to avoid heavy overhead labor for their lifetimes.

**OUTCOMES**

- A recent Medline search for “sternoclavicular” and “dislocation” yielded 320 citations, most dealing with sternoclavicular instability and its sequelae. Most were case reports, a series of three or four patients, or a discussion of the complications of the injury or its treatment. There are very few large series, which makes discussing outcomes difficult. However, several themes do emerge.
The need for proper patient selection becomes evident when one considers that some forms of sternoclavicular instability generally do well when treated without surgery. Sadr and Swan
tand Rockwood and Odor have both documented the good long-term results obtained with nonoperative treatment of atraumatic sternoclavicular instability. De Jong has documented good long-term results in 13 patients with anterior dislocations treated nonoperatively. Several larger series have reported on about a dozen patients treated with open reduction, ligament repair or reconstruction, and fixation with pins or sternoclavicular wiring. Good results were obtained when the medial clavicle was successfully stabilized. Eskola, however, noted a high failure rate if the remaining medial clavicle was not successfully stabilized to the first rib. In a separate study, Rockwood et al reported on seven patients who had previously undergone medial clavicle resection without ligament reconstruction. Six of the seven had worse symptoms than before their index procedure.

COMPLICATIONS

Complications of injury
- Anterior dislocation: cosmetic “bump” (which may occasionally be pronounced) and late degenerative changes
- Posterior dislocation: Great vessel injuries, including laceration, compression, and occlusion, pneumothorax, rupture of the esophagus with abscess and osteomyelitis of the clavicle, fatal tracheoesophageal fistula, brachial plexus compression, stridor and dysphagia, hoarseness of the voice, onset of snoring, and voice changes from normal to falsetto with movement of the arm have all been reported. These all may occur acutely or in a delayed fashion. Worman and Leagus reported that 16 of 60 patients with posterior dislocations had suffered complications of the trachea, esophagus, or great vessels.

Errors of patient selection
- Operating in unindicated circumstances introduces another set of complications. Rockwood and Odor reviewed 37 patients with spontaneous atraumatic subluxation.
- Twenty-nine managed without surgery had no limitations of activity or lifestyle at over 8 years average follow-up. Eight treated (elsewhere) with surgical reconstruction had increased pain, limitation of activity, alteration of lifestyle, persistent instability, and significant scars. Before surgery, most of these patients had minimal discomfort and excellent motion and complained only of a “bump” that slipped in and out of place with certain motions.

Intraoperative complications
- Little has been written about these, but a veritable jungle of vitally important structures lurks immediately behind the sternoclavicular joint. We always perform these operations with an available, in-house cardiothoracic surgeon on notice and request his or her presence in the operating suite for all but the most routine cases.

Postoperative complications
- Hardware migration: Because of the motion at the sternoclavicular joint, tremendous leverage is applied to pins that cross it; fatigue breakage of the pins is common. Numerous authors have reported deaths and many near-deaths from K-wires and Steinmann pins migrating into the heart, pulmonary artery, innominate artery, aorta, and elsewhere in the mediastinum. Despite numerous admonitions in the literature regarding the use of sternoclavicular pins, there have been continued reports of intrathoracic K-wire migration, most recently in 2005.
- For this reason, we do not recommend the use of any transfixing pins—large or small, smooth or threaded, bent or straight—across the sternoclavicular joint.
- Iatrogenic instability: Failure to preserve the costoclavicular ligament when it is intact and failure to reconstruct it when it is deficient both severely compromise the surgical result. As noted above, both Rockwood and Eskola noted vastly inferior results when the residual medial clavicle was not stabilized to the first rib, and an inability to obtain equivalent results when the costoclavicular ligament was reconstructed in a delayed fashion.

Iatrogenic instability: An excessive resection that removes bone to a point lateral to the costoclavicular ligament is an extremely difficult problem that is best avoided because there is no reconstructive option. In these difficult cases, we have occasionally performed a subtotal claviculectomy to a point just medial to the coracoclavicular ligaments. This leaves the extremity without a “strut” connecting it to the thorax but can produce substantial relief of pain and improvement in motion and activity.

REFERENCES
DEFINITION

- Many pathologic disorders affect the medial clavicle, the most common of which is osteoarthritis.
- Other conditions include rheumatoid arthritis, seronegative spondyloarthropathies, crystal deposition disease, sternoclavicular hyperostosis, condensing osteitis, and avascular necrosis.\(^6\)
- Infection, while rare, must be considered. When suspected, the sternoclavicular joint should be aspirated for culture, Gram stain, and cell counts and then treated with irrigation and débridement.
- Instability of the sternoclavicular joint is rare but potentially fatal.
- Traumatic instability is defined by the direction of displacement of the clavicular head and is superior, anterior, or posterior.
- Posterior instability has been associated with a variety of potentially fatal comorbidities.
- Atraumatic instability is usually anterior and is often seen in people with generalized ligamentous laxity.
- Symptomatic traumatic instability is best treated with closed reduction and possible reconstruction of the joint, not resection of the clavicle head.

ANATOMY

- The sternoclavicular joint is a saddle-shaped joint that is the most unconstrained joint in the human body.
- Important ligamentous restraints to motion include the anterior capsule (restrains anterior and posterior translation), the posterior capsule (restrains posterior translation),\(^10\) and the costoclavicular ligament (which is the pivot point for motion in the axial plane).\(^2\)
- The interclavicular ligament seems to provide little function (FIG 1).

PATHOGENESIS

- Osteoarthritis is the most common disorder affecting the medial clavicle that may require surgical excision.
- Osteoarthritis is most commonly seen in male laborers, in women in the perimenopausal years, and after radical neck dissection.
- Rheumatologic disorders can affect the sternoclavicular joint as part of the systemic disease. Involvement of the sternoclavicular joint is usually late.
- Other atraumatic conditions are less common and the pathogenesis is largely unknown.
- Traumatic instability typically develops from a blow to the shoulder girdle.
- If the force impacts the anterior shoulder, it will push the shoulder girdle posteriorly. The clavicle pivots over the first rib, forcing the head of the clavicle anteriorly.
- If the force impacts the posterior shoulder, it will push the shoulder girdle anteriorly. The clavicle pivots over the first rib, dislocating the head of the clavicle posteriorly.
- Direct blows to the sternoclavicular joint can also dislocate the clavicle head posteriorly.
- Atraumatic instability develops insidiously without a history of trauma.

NATURAL HISTORY

- Many people have asymptomatic sternoclavicular joint arthritis.
- Patients with symptoms may find relief with activity modification and time. This is particularly true with the pain and swelling seen in perimenopausal women.
- Infection may present with a relatively benign clinical picture but will progress and may become serious.
- It is rare for the sternoclavicular joint to be the primary joint involved in rheumatologic conditions or crystal deposition disease.
Traumatic instability may result from high-energy injuries (eg, motor vehicle collision) or may be related to contact in athletics.

Posterior instability may be life-threatening as the clavicular head may compress vascular structures, the trachea, or the esophagus.

Atraumatic instability may have an insidious onset and is often associated with other signs of generalized ligamentous laxity (eg, patellar subluxation, glenohumeral subluxation).

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- **Atraumatic disorders**
  - Pain at the sternoclavicular joint is localized to the joint and may be referred up the sternocleidomastoid and trapezius.\(^5\)
  - Infection typically is unilateral and has significant pain and erythema (Table 1).
  - Osteoarthritis, rheumatoid arthritis, seronegative spondyloarthropathies, and sternoclavicular hyperostosis are typically bilateral, with mild pain, and rare erythema.
  - Crystal deposition diseases, condensing osteitis, and Friedreich’s disease are typically unilateral, and mildly painful.

- **Traumatic disorders**
  - With acute traumatic injuries, patients will have significant pain and will be unwilling to raise the arm. They may describe difficulty with swallowing or breathing in posterior dislocations.
  - The sternoclavicular joint is often swollen and tender.
  - The affected arm may demonstrate circulatory changes with arm swelling.
  - Physical examination may not be helpful in determining if the instability is anterior or posterior.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Special radiographic projections include the Rockwood (serendipity), Hobbs, Heinig, and Kattan views but are somewhat difficult to interpret (Table 2).\(^4\)
- Computed tomography is particularly useful in trauma as it demonstrates displacement of the joint and bony anatomy.\(^4\)
- It is very useful to determine whether a dislocation is anterior or posterior.
- Arteriography should be considered in posterior dislocations if vascular injury is suspected.
- MRI is helpful in atraumatic disorders to evaluate the soft tissues and can delineate marrow abnormalities, joint effusions, and disc and cartilage injury.\(^4\)
- Laboratory findings in atraumatic disorders of the sternoclavicular joint are covered in Table 3.

**Positioning**
- The patient is positioned supine on the operating room table with a small rolled towel behind the middle of the back (FIG 2A).
- The entire chest is exposed for treatment of complications should they occur.
- Important structures, including the clavicle, manubrium, sternocleidomastoid, and costoclavicular ligament, are marked (FIG 2B).
- The ipsilateral hand is prepared and draped as well if the surgeon desires to use palmaris as an interposition graft.
- For reconstructions of the sternoclavicular joint, an ipsilateral hamstring may be used; as such, the knee should be prepared and draped.

**Approach**
- The approach is anterior. Care is taken to protect important structures during dissection, particularly the origin of the sternocleidomastoid muscle and the costoclavicular ligament.

**INCISION AND DISSECTION**
- The incision is made in the lines of Langer, which follow a necklace pattern over the head of the clavicle and manubrium (TECH FIG 1A).
- After undermining in the subcutaneous plane, the platysma is incised in line with the skin incision, exposing the joint capsule and sternocleidomastoid origin (TECH FIG 1B).
- The capsule of the joint is marked. Care must be taken to avoid incising the entire sternal head of the sternocleidomastoid tendon (TECH FIG 1C).

**ATRAUMATIC DISORDERS: REMOVING THE BONE**

- Electrocautery can be used to carefully elevate the capsule from the clavicular head. It is important to avoid straying too far laterally to avoid detaching the capsule and injuring the costoclavicular ligament (TECH FIG 2A).
- The intra-articular disc is removed and the capsule is carefully dissected around the cartilaginous margin of the head of the clavicle (TECH FIG 2B).
- A self-retaining retractor is placed on the capsule, a blunt retractor is placed next to the articular surface, and a small oscillating saw is used to remove between 0.5 and 1.0 cm of the medial clavicle (TECH FIG 2C).
- An osteotome may be used to lever the medial clavicle head out of the joint (TECH FIG 2D).
- Electrocautery is used to carefully dissect the posterior capsule from the back of the clavicular head (TECH FIG 2E).
- The resected head should be between 0.5 and 1.0 cm in size to preserve the costoclavicular ligaments (TECH FIG 2F).^3^
HARVESTING THE TENDON

- The palmaris tendon is isolated with a small incision in the wrist crease (TECH FIG 3A).
- After sutures are passed in the end of the palmaris, the tendon is removed percutaneously with a tendon stripper (TECH FIG 3B).
- The harvested tendon is rolled over a small spool and sutured to itself to create a rolled tendon (TECH FIG 3C,D).
- When resecting the clavicular head for atraumatic disorders, the rolled palmaris tendon is inserted into the defect to create a soft tissue interposition between the cut surface of the clavicle and the manubrial joint surface (TECH FIG 3E).
- Alternatively, the palmaris can be used to augment a reconstruction of an unstable sternoclavicular joint by passing it around the clavicle and first rib (see below).

D E

TECH FIG 3 • A. Palmaris tendon is identified. B. Percutaneous harvesting of palmaris longus tendon. C. Rolling the palmaris tendon graft. D. The rolled palmaris is sutured to itself. E. Insertion of the palmaris as interposition graft.

RECONSTRUCTION OF THE STERNOCLAVICULAR JOINT IN INSTABILITY

- A variety of techniques have been described. A figure 8 reconstruction has the best biomechanical properties.11
- With the assistance of a thoracic surgeon, the plane behind the manubrium is developed by dissecting above the sternal notch (TECH FIG 4A).
- With a ribbon retractor behind the manubrium, two drill holes are made in the manubrium and sutures are passed (TECH FIG 4B).
- Two drill holes are placed in the medial clavicle from anterior to posterior (TECH FIG 4C).
- The semitendinosus autograft is passed in figure 8 fashion and secured to itself (TECH FIG 4D–F).
- Additionally, the palmaris tendon may be passed around the first rib. This dissection behind the first rib should be performed by the thoracic surgeon to avoid injury to the internal mammary artery (TECH FIG 4G).

A B

TECH FIG 4 • A. Development of the surgical plane behind manubrium. B. Drill holes are in manubrium with protection of mediastinal structures with an Army-Navy retractor. (continued)
WOUND CLOSURE

- The capsule is closed with figure 8 interrupted permanent number 2 suture, and the sternal head of the sternocleidomastoid falls into place (TECH FIG 5A).
- The wound is closed in layers with 0 Vicryl in the platysma (TECH FIG 5B), 2-0 Vicryl in the subcutaneous layer, and 3-0 Monocryl in the skin (TECH FIG 5C).

TECH FIG 5 • A. Repair of the joint capsule. B. Repair of the platysma. C. Surgical wound is closed.
CT and MRI imaging will help differentiate arthritis from other less common conditions.

The surgeon must always be diligent for infection, which may have a relatively benign appearance.

If it is unclear whether the sternoclavicular joint is the source of pain, a diagnostic injection with lidocaine can be helpful.

CT is extremely helpful to determine if a dislocation is anterior or posterior.

Preserving the clavicular head is important for reconstructions of unstable sternoclavicular joints.

If the costoclavicular ligament is sacrificed, the intra-articular disc and disc ligament can be passed completely off the clavicle, suture anchors in the clavicle can help restore stability.

Ten of 14 patients reported good to excellent outcomes; six were considered (three of five excellent).

Patients are typically admitted overnight for observation.

Patients wear a sling with pillow support to support the arm when upright for 6 weeks.

Patients are instructed to avoid moving the arm for 6 weeks to allow for capsular healing and preventing instability.

After 6 weeks, patients gradually increase range of motion.

After 12 weeks, patients can begin strengthening activities.

After 16 weeks, patients have unrestricted activity.

POSTOPERATIVE CARE

Patients were graded as good to excellent, and 93% had significant pain relief and would have the procedure again.

Ribin and coworkers1 reported on 15 patients with a variety of pathologies. Sixty percent were graded as good to excellent, and 93% had significant pain relief and would have the procedure again.

Pingsmann and colleagues8 found seven of eight women with sternoclavicular joint arthritis had good to excellent results with medial clavicle excision after 31 months of follow-up.

Meis and coworkers7 modified the technique by interposing the sternal head of the sternocleidomastoid into the intramedullary canal.

A variety of case reports exist for other sternoclavicular joint reconstructions. To date, no reports are in the peer-reviewed literature for the figure 8 reconstruction.

PEARLS AND PITFALLS

CT and MRI imaging will help differentiate arthritis from other less common conditions.

The surgeon must always be diligent for infection, which may have a relatively benign appearance.

If it is unclear whether the sternoclavicular joint is the source of pain, a diagnostic injection with lidocaine can be helpful.

CT is extremely helpful to determine if a dislocation is anterior or posterior.

General surgery

It is wise to have a thoracic surgeon available should complications develop in the mediastinum.

POSTOPERATIVE CARE

Patients are typically admitted overnight for observation.

Patients wear a sling with pillow support to support the arm when upright for 6 weeks.

Patients are instructed to avoid moving the arm for 6 weeks to allow for capsular healing and preventing instability.

After 6 weeks, patients gradually increase range of motion.

After 12 weeks, patients can begin strengthening activities.

After 16 weeks, patients have unrestricted activity.

OUTCOMES

There is little reported on the outcomes after this procedure. All reports are level 4 case series.

Rockwood and colleagues9 reported that outcomes were improved if the costoclavicular ligament remained intact (eight of eight excellent with complete satisfaction). If the costoclavicular ligament was disrupted, however, the results were less predictable (three of five excellent).

Arcus and associates1 reported on 15 patients with a variety of pathologies. Sixty percent were graded as good to excellent, and 93% had significant pain relief and would have the procedure again.

Pingsmann and colleagues8 found seven of eight women with sternoclavicular joint arthritis had good to excellent results with medial clavicle excision after 31 months of follow-up.

Heterotopic ossification has been reported in about half of the patients but seems to be asymptomatic.1

Although not reported to date, complications involving the great vessels, trachea, and other mediastinal contents are possible. A thoracic surgeon should be available for assistance if required.

REFERENCES

DEFINITION
- Displaced, comminuted fractures of the clavicle are at risk for nonunion and malunion and can be considered for open reduction and internal fixation with a plate and screws.

ANATOMY
- The clavicle and scapula are tightly linked through the strong coracoclavicular and acromioclavicular ligaments and link the axial skeleton to the upper extremity.
- Clavicles are present only in brachiating animals and apparently serve to help hold the upper limb away from the trunk to enhance more global positioning and use of the limb.
- The clavicle is named for its S-shaped curvature, with an apex anteromedially and an apex posterolaterally, similar to the musical symbol clavicula. The larger medial curvature widens the space for passage of neurovascular structures from the neck into the upper extremity through the costoclavicular interval.
- The clavicle is made up of very dense trabecular bone lacking a well-defined medullary canal. In cross section, the clavicle changes gradually between a flat lateral aspect, a tubular midportion, and an expanded prismatic medial end.
- The clavicle is subcutaneous throughout its length and makes a prominent aesthetic contribution to the contour of the neck and upper part of the chest.
- The supraclavicular nerves run obliquely across the clavicle just superior to the platysma muscle and should be identified and protected during operative exposure to offset the development of hyperesthesia or dysesthesia over the chest wall.

PATHOGENESIS
- Clavicle fractures usually result from a direct blow to the point of the shoulder.
- This is usually a moderate- to high-energy injury in younger adults but can result from a low-energy fall from a standing height in an older individual.

NATURAL HISTORY
- The overall nonunion rate for diaphyseal clavicle fractures is 4.5%. 7
- The risk of nonunion increases with age, female gender, displacement, and comminution. 7
- The risk of nonunion for completely displaced (no apposition) and comminuted fractures is between 10% and 20% (FIG 1). 9
- Malunion of the clavicle can result in shoulder girdle deformity and weakness. 3,5,9
- Malunion and nonunion of the clavicle can result in brachial plexus compression.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The mechanism and date of injury should be elicited.
- A careful neurologic examination should be performed.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- An anteroposterior (AP) radiograph can be supplemented by a 20- to 60-degree cephalad-tilted view.
- The so-called apical oblique view (tilted 45 degrees anterior and 20 degrees cephalad) may facilitate the diagnosis of minimally displaced fractures (eg, birth fractures, fractures in children).
- The abduction lordotic view taken with the shoulder abducted above 135 degrees and the central ray angled 25 degrees cephalad is useful in evaluating the clavicle after internal fixation. Abduction of the shoulder results in rotation of the clavicle on its longitudinal axis, which causes the plate to rotate superiorty and thereby expose the shaft of the clavicle and the fracture site under the plate.
- Computed tomography with 3D reconstructions can help understand 3D deformity.

DIFFERENTIAL DIAGNOSIS
- Lateral or medial clavicle fracture
- Acromioclavicular or sternoclavicular dislocation

NONOPERATIVE MANAGEMENT
- Closed reduction of clavicular fractures is rarely attempted because the reduction is usually unstable and no reliable means of providing external support is available.
- A simple sling provides comfort and limits activity during healing. A figure 8 bandage leaves the arm free, but it cannot improve alignment.

FIG 1 • An AP radiograph shows greater than 100% displacement and comminution with a vertical fracture fragment. The clavicle is shortened. (Copyright David Ring, MD.)
There is no need to be concerned about shoulder stiffness, and patients should be encouraged to keep the arm at the side and limit activity for the first 4 to 6 weeks.

**SURGICAL MANAGEMENT**
- Intramedullary fixation is an option when comminution is limited, but otherwise plate-and-screw fixation is preferred.
- The plate can be placed on either the superior or the anterior aspect of the clavicle.

**Preoperative Planning**
- Planning of the surgery using tracings of radiographs helps limit intraoperative decision making and helps the surgeon anticipate problems and contingencies.

**Positioning**
- The patient is supine with a variable amount of flexion of the trunk according to surgeon preference (FIG 2).

**Approach**
- A longitudinal incision is made in line with the clavicle.

**SUPERIOR PLATE-AND-SCREW FIXATION**
- An incision is made parallel and just inferior to the long axis of the clavicle (TECH FIG 1A). Infiltration with dilute epinephrine can help limit bleeding.
- The crossing supraclavicular nerves are identified under loupe magnification and preserved (TECH FIG 1B).
- Muscle attachments and periosteum are preserved as much as possible.
- Realignment and provisional fixation may be facilitated by the use of a small distractor or temporary external fixator (TECH FIG 1C).
- A 3.5-mm limited-contact dynamic compression plate (LCDC plate, Synthes) or a precontoured plate is applied to the superior aspect of the clavicle (TECH FIG 1D). A minimum of three screws should be placed in each major fragment. If the fracture pattern is amenable, placement of an interfragmentary screw greatly enhances the stability of the construct.
- When the vascularity of the fragments has been preserved, no bone graft is needed (TECH FIG 1E). When extensive stripping or gaps have occurred in the cortex...

**TECH FIG 1**
- **A.** A straight incision in line with the clavicle and just inferior to it is infiltrated with dilute epinephrine. **B.** The supraclavicular nerves cross the clavicle at the level of the platysma, and an effort should be made to protect them. **C.** A small distractor or temporary external fixator can be used to facilitate realignment and provide provisional fixation. **D.** In this patient, a superior 3.5-mm LC-DCP is applied. An oscillating drill is used to limit the risk to nerves. **E.** Final plate placement. (continued)
opposite the plate, one might consider adding a small amount of autogenous iliac crest cancellous bone graft.

- Close the platysma (TECH FIG 1F).

- If the skin condition is suitable, wound closure is accomplished in atraumatic fashion with a subcuticular suture (TECH FIG 1G,H).

ANTERIOR PLATE-AND-SCREW FIXATION

- The technique is identical for an anterior plate placement with the exception that the origins of the pectoralis major and deltoid are partially extraperiosteally elevated off the anterior clavicle (TECH FIG 2).

- The anterior plate placement may help to decrease hardware prominence, and the drill and screws are directed posterior rather than directly inferior to the clavicle, which may increase the margin of safety.

TECH FIG 2 • An alternative is to place the plate on the anterior surface of the clavicle. This limits plate prominence but requires greater stripping and muscle elevation. (Copyright David Ring, MD.)

POSTOPERATIVE CARE

- Confident use of the hand at the side is encouraged immediately.
- Shoulder abduction and handling of more than 15 pounds is delayed until early healing is established.
- Shoulder stiffness is unusual and usually responds quickly to exercises. Shoulder exercises can therefore be delayed until healing is established.

OUTCOMES

- Plate loosening and nonunion occur in 3% to 5% of cases.6
- Healing leads to good function.

COMPLICATIONS

- Infection and wound complications occur but are uncommon.
- Neurovascular injury is very uncommon and pneumothorax has not been described.
REFERENCES

DEFINITION
- The clavicle is one of the most commonly fractured bones.
- The site on the clavicle most often fractured is the middle third. The midclavicular region is the thinnest and narrowest portion of the bone.
- It is the only area not supported by ligament or muscle attachments.
- It represents a transitional region of both cross-sectional anatomy and curvature.
- It is the transition point between the lateral part, with a flatter cross section, and the more tubular medial.
- Because of the clavicle’s S shape, an axial load creates a very high tensile force along the anterior midcortex. (Axial load makes a virtual right angle at midclavicle.)

ANATOMY
- The clavicle is the only long bone to ossify by a combination of intramembranous and endochondral ossification.
- Its configuration is S-shaped, a double curve; the medial curve is apex anterior and the lateral curve is apex posterior (FIG 1A).
- The larger medial curvature widens the space for the neurovascular structures, providing bony protection.
- The clavicle is made up of very dense trabecular bone, lacking a well-defined medullary canal.
- The cross-sectional anatomy gradually changes from flat laterally, to tubular in the midportion, to expanded prismatic medially.
- The clavicle is subcutaneous throughout, covered by the thin platysma muscle.
- The supraclavicular nerves that provide sensation to the overlying skin of the clavicle are found deep to the platysma muscle.
- Very strong capsular and extracapsular ligaments attach the medial end to the sternum and first rib and the lateral end to the acromion and coracoid.
- Proximal muscle attachments include the sternocleidomastoid, pectoralis major, and subclavius. Distal muscle attachments include the deltoid and trapezius (FIG 1B).
- The clavicle functions by providing a fixed-length strut through which the muscles attached to the shoulder girdle can generate and transmit large forces to the upper extremity.

PATHOGENESIS
- The mechanism of clavicle fractures in the vast majority is a direct injury to the shoulder. Stanley and associates studied 106 injured patients; 87% had fallen onto the shoulder, 7% were injured by a direct blow on the point of the shoulder, and only 6% reported falling onto an outstretched hand.
- Stanley suggests that in the patients who described hitting the ground with an outstretched hand, the shoulder became the next contact point with the ground, causing the fracture. Stanley
stated that a compressive force equivalent to body weight would exceed the critical buckling load to cause the clavicle fracture.

**NATURAL HISTORY**

- In the 1960s, both Neer and Rowe published large series of midclavicle fractures, showing very low nonunion rate (0.1% and 0.8%) with closed treatment and a higher nonunion rate (4.6% and 3.7%) with operative treatment.
- More recent studies have shown that nonunion is more common than previously recognized and that a significant percentage of patients with nonunion are symptomatic.
- Malunion with shortening greater than 15 to 20 mm has also been shown to be associated with significant shoulder dysfunction.
- McKee and colleagues identified 15 patients with malunion of the midclavicle after closed treatment. All patients had shortening of more than 15 mm, all were symptomatic and unsatisfied, and all underwent corrective osteotomy. Postoperatively all 15 patients improved in terms of function and satisfaction.
- Hill and associates reviewed 52 completely displaced mid-shaft clavicle fractures and found that shortening of more than 20 mm had a significant association with nonunion and unsatisfactory results.
- Eskola and coworkers reported on 89 malunions of the midclavicle, showing that shortening of more than 15 mm was associated with shoulder discomfort and dysfunction.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The diagnosis is usually straightforward and is based on obtaining the mechanism of injury from a good history.
- On visual inspection the examiner will frequently see notable swelling or ecchymosis at the fracture site and possibly deformity of the clavicle, with drooping of the shoulder downward and forward if the fracture is significantly displaced. The skin is inspected for tenting at the fracture site and characteristic bruising and abrasions that might suggest a direct blow or seatbelt shoulder strap injury (FIG 2A,B).
- Palpation over the fracture site will reveal tenderness, and gentle manipulation of the upper extremity or clavicle itself may reveal crepitus and motion at the fracture site.
- The amount of shortening is identified by clinically measuring the distance of a straight line (in centimeters) from both acromioclavicular joints to the sternal notch and noting the difference (FIG 2C).
- It is important to perform a complete musculoskeletal and neurovascular examination of the upper extremity and auscultation of the chest to identify the rare associated injuries; these are more closely related to high-energy injuries.
  - Rib and scapula fracture
  - Brachial plexus injury (usually traction to upper cervical root)
  - Vascular injury (subclavian artery or vein injury associated with scapulothoracic dissociation)
  - Pneumothorax and hemothorax

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Two orthogonal radiographic projections are necessary to determine the fracture pattern and displacement, ideally 45-degree cephalic tilt and 45-degree caudad tilt views.
- Usually a standard anteroposterior (AP) view and a 45-degree cephalic tilt view (FIG 3) view are adequate.
- In practice, a 20- to 60-degree cephalic tilt view will minimize interference of thoracic structures.
- The film should be large enough to include the acromioclavicular and sternoclavicular joints, the scapula, and the upper lung fields to evaluate for associated injuries.
- An AP view of bilateral clavicles on a wide cassette to include the acromioclavicular joints and sternum is fairly helpful in determining the amount of shortening; however, this is a multiplanar deformity and a CT scan would have greater accuracy, although it is rarely required.
DIFFERENTIAL DIAGNOSIS
- Sprain of acromioclavicular joint
- Sprain of sternoclavicular joint
- Rib fracture
- Muscle injury
- Contusion
- Hematoma
- Kehr sign: referred pain to the left shoulder from irritation of the diaphragm, signaled by the phrenic nerve. Irritation may be caused by diaphragmatic or peridiaphragmatic lesions, renal calculi, splenic injury, or ectopic pregnancy.

NONOPERATIVE MANAGEMENT
- If the clavicle fracture alignment is acceptable, generally a simple configuration with less than 15 mm of shortening, then any of a number of methods of supporting the upper extremity are adequate, including a figure 8 bandage, sling, sling and swathe, Sayre bandage, Velpeau dressing, and benign neglect, just to name a few.
- Nordqvist and colleagues\(^8\) reported on 35 clavicle fracture malunions with shortening of less than 15 mm. They were all treated nonoperatively in a sling. All 35 had normal mobility, strength, and function compared to the normal shoulder.
- A prospective, randomized study\(^2\) comparing sling versus figure 8 bandage showed that a greater percentage of patients were dissatisfied with the figure 8 bandage, and there was no difference in overall healing and alignment. The study concluded that the figure 8 bandage does little to obtain reduction.

SURGICAL MANAGEMENT
- Indications for operative treatment of acute midshaft clavicle fractures are as follows:
  - Open fractures
  - Fractures with neurovascular injury
  - Fractures with severe associated chest injury or multiple trauma: patients who require their upper extremity for transfer and ambulation
  - “Floating shoulder”
  - Impending skin necrosis
  - Severe displacement: possibly 15 to 20 mm of shortening
- In a multicenter, randomized, prospective clinical trial of displaced midshaft clavicle fractures, Altamimi and McKee\(^1\) showed that operative fixation compared to nonoperative treatment improved functional outcome and had a lower rate of both malunion and nonunion.
- Potential advantages of intramedullary fixation of the clavicle are as follows:
  - Less soft tissue stripping and therefore potentially better healing
  - Smaller incision
  - Better cosmesis
  - Easier hardware removal
  - Less weakness of bone after hardware removal
- Potential disadvantages of intramedullary fixation of the clavicle are as follows:
  - Less ability to resist torsional forces
  - Skin breakdown from prominence distally
  - Pin breakage
  - Pin migration
- Newer designs and techniques prevent pin migration by placing a locking nut on the lateral end and technically avoiding penetration of the medial fragment cortex.

Preoperative Planning
- After the decision has been made to fix a clavicle fracture, one must evaluate whether the fracture pattern is amenable to intramedullary pin fixation.
- A simple fracture pattern in the middle third of the bone is ideal.
- The fracture should not extend past the middle third of the bone.
- Comminution and butterfly fragments (usually anterior) are common and do not preclude intramedullary fixation as long as the medial and distal main fragments have cortical contact.

Positioning
- There are two good options for patient positioning that facilitate use of an image intensifier or C-arm device, which will aid you during pin placement.
- The patient can be placed supine on a Jackson radiolucent surgical table so the C-arm can be brought in perpendicular from the opposite side of the table, which is out of the way of the surgeon (FIG 4A,B).

FIG 4 • A,B. The patient is placed supine on a Jackson radiolucent surgical table. A 1-L bag is placed under the affected shoulder, medial to the scapula, and the arm is prepared free and placed in an arm holder to aid in fracture reduction. The C-arm can be brought in perpendicular from the opposite side of the table, which is out of the way of the surgeon and facilitates getting orthogonal radiographic views of the fracture: 45-degree caudad tilt view (A) and 45-degree cephalic tilt view (B). C,D. Alternatively, the patient is placed in the beach chair position on the OR table, using a radiolucent shoulder-positioning device. C. The arm is prepared free and placed in an arm holder to facilitate fracture reduction. The C-arm is brought in from the head of the bed with the gantry rotated upside down and slightly away from the operative shoulder and oriented with a cephalic tilt. D. The same beach chair positioning shown steriley draped.
- A 1-L bag is placed under the affected shoulder, medial to the scapula, to aid in fracture reduction.
- The arm is also prepared free and placed in an arm holder to facilitate fracture reduction.
- This is our preferred method due to the ease and speed of the set-up and the ease of getting orthogonal radiographic views of the fracture (45-degree cephalic and caudad tilt views).

The other option is placing the patient in the beach chair position on the OR table, using a radiolucent shoulder-positioning device (FIG 4C,D).
- The C-arm is brought in from the head of the bed with the gantry rotated upside down and slightly away from the operative shoulder and oriented with a cephalic tilt.
- The arm is also prepared free and placed in an arm holder to facilitate fracture reduction.

### INCISION AND DISSECTION

- Mark out the clavicle, fracture site, and surrounding anatomy (TECH FIG 1A).
- Use the C-arm to identify the appropriate position for the incision, which should be over the distal end of the medial fragment, in the Langer lines of the normal skin crease around the neck (TECH FIG 1B).
- Make an incision of about 2 to 3 cm over the fracture site.
- Divide the subcutaneous fat down to the platysma muscle using electrocautery (TECH FIG 1C).
- Although there is usually very little subcutaneous fat, gently make full-thickness flaps to include skin and subcutaneous tissue around the entire incision to facilitate exposure.
- Bluntly split the platysma muscle in line of its fibers to identify, protect, and retract the underlying supraclavicular nerves; its middle branches are frequently found near the midclavicle (TECH FIG 1D,E).
- The fracture site is then usually easily identifiable in acute injuries because the periosteum is disrupted and usually requires no further division.
- Remove any debris, hematoma, or interposed muscle from the fracture site.
- If there are butterfly fragments, be careful to keep any soft tissue attachments.

**TECH FIG 1**  
A. Displaced right clavicle fracture, showing the clavicle and fracture site marked out. B. A skin incision of about 2 to 3 cm is made over the distal end of the medial clavicular fragment, in the Langer lines of normal skin creases around the neck. C. Incision over a clavicle fracture site, showing full-thickness flaps to include skin and subcutaneous tissue around the entire incision. This exposes the fascia that covers the platysma muscle. D. Skin incision over a displaced clavicle fracture, with underlying platysma muscle and the middle supraclavicular nerves. E. Intraoperative photo showing the platysma muscle bluntly split in the line of its fibers to identify an underlying supraclavicular nerve, which is under the clamp. The fracture site is usually easily identifiable in acute injuries because the periosteum is disrupted and usually requires no further division; as shown here, the medial clavicular fragment is easily seen. (B, D: Courtesy of Steven B. Lippitt, MD.)
CLAVICLE PREPARATION

- The following technique uses a modified Hagie pin called the Rockwood Clavicle Pin (DePuy Orthopaedics, Warsaw, IN) (TECH FIG 2A).
- Use a bone-reducing clamp or towel clip to grab and elevate the medial clavicular fragment through the incision (TECH FIG 2B).
- Size the diameter of the canal with the appropriate-size drill bit; the C-arm can be useful to judge canal fill and orientation of the drill.
  - The fit should be snug to maximize fixation, but not too tight, to prevent splitting the bone.
- Attach the chosen drill to the T-handle and ream out the intramedullary canal without penetrating the anterior cortex (TECH FIG 2C–E).
- Next, attach the appropriate-sized tap (that corresponds to the drill size) to the T-handle and tap the intramedullary canal to the anterior cortex (TECH FIG 2F,G).
- Elevate the lateral clavicular fragment through the incision; this can be facilitated by externally rotating the arm.
- Use the same drill bit attached to the T-handle to ream out the lateral fragment, but this time, under C-arm guidance, penetrate the posterolateral cortex of the clavicle (TECH FIG 2H,I).
  - The drill should exit posterior and medial to the acromioclavicular joint capsule (TECH FIG 2J).
  - To prevent the pin nuts from being too prominent, make sure the drill does not exit in the upper half of the posterolateral clavicle.
- Attach the appropriate-sized tap to the T-handle and tap the intramedullary canal of the lateral fragment (TECH FIG 2K).

**TECH FIG 2 • A.** The Rockwood Clavicle Pin instrument set by DePuy Orthopaedics, Warsaw, IN, which is a modified Hagie pin. **B.** A bone-reducing clamp is used to elevate the medial clavicular fragment through the incision. **C–E.** The chosen drill is attached to a T-handle and the intramedullary canal of the medial clavicular fragment is reamed without penetrating the anterior cortex. **F,G.** An appropriate-sized tap is attached to a T-handle and the intramedullary canal of the medial clavicular fragment is tapped to the anterior cortex. **H,I.** The chosen drill is attached to a T-handle and the intramedullary canal of the lateral clavicular fragment is reamed out, penetrating the posterolateral cortex under direct C-arm guidance. (continued)
J. When drilling out the posterolateral cortex of the lateral clavicular fragment, the drill should exit posterior and medial to the acromioclavicular joint capsule. To prevent the pin nuts from being too prominent, the drill should not exit in the upper half of the posterolateral clavicle. K. The appropriate-sized tap is attached to the T-handle and the intramedullary canal of the lateral fragment is tapped. (C,H,J,K: Courtesy of Steven B. Lippitt, MD.)

PIN INSERTION AND FRACTURE REDUCTION

- Remove the nuts from the pin assembly and attach the T-handle using a Jacobs chuck to the medial end of the clavicle pin.
  - This is the end with the large threads.
  - Never tighten the chuck over the machined threads at either end.
- Continue firmly holding the lateral fragment while passing the trocar end (lateral end) of the clavicle pin into the intramedullary canal, out the previously drilled hole in the posterolateral cortex (TECH FIG 3A).
- Once you are just through the cortex, make a small incision over the palpable tip.
- Bluntly dissect the subcutaneous tissue with a hemostat until the tip of the pin can be felt, and then place the hemostat or a small elevator under the tip of the pin to facilitate the pin’s passage through the incision (TECH FIG 3B).
- Drill the pin out laterally until the large medial threads engage the lateral fragment.
- Now switch the T-handle to the lateral end of the pin and retract the pin into the lateral fragment (TECH FIG 3C,D).
- Reduce the fracture by lifting the arm, and pass the pin into the medial fragment.
- Use the C-arm to ensure that the pin advances correctly down the line of the medial fragment and that all the medial threads cross the fracture site.

TECH FIG 3 • A. The surgeon continues firmly holding the lateral fragment while passing the trocar end (lateral end) of the clavicle pin into the intramedullary canal, out the previously drilled hole in the posterolateral cortex. Once just through the cortex, the surgeon makes a small incision over the palpable tip. (continued)
**FINAL POSITIONING OF PIN AND FRACTURE COMPRESSION**

- Cold-weld the two nuts onto the lateral end of the pin.
  - First place the medial nut onto the pin, followed by the smaller lateral nut.
  - Grasp the medial nut with a needle-nose pliers and then tighten the lateral nut against the medial nut using the lateral nut wrench (TECH FIG 4A,B).
- Using the lateral nut wrench and C-arm guidance, now advance the pin assembly into the medial fragment until it contacts the anterior cortex (TECH FIG 4C).
- Break the cold weld by grasping the medial nut with needle-nose pliers and then loosen the lateral nut by turning it counterclockwise using the lateral nut wrench.
- Advance the medial nut against the posterolateral cortex of the clavicle to get desired compression across the fracture site.
- Cold-weld the lateral nut back onto the medial nut again.
- Use the medial nut wrench to back the pin assembly out of the soft tissues far enough to expose the nuts, usually about 1 cm. This will enable the pin to be cut flush to the lateral nut (TECH FIG 4D,E).
- Finally, use the lateral nut wrench to advance the pin assembly back into the medial fragment with the same desired fracture site compression (TECH FIG 4F,G).

**TECH FIG 3 • (continued)** B. The subcutaneous tissue is bluntly dissected with a hemostat until the tip of the pin can be felt, and then the hemostat or a small elevator is placed under the tip of the pin to facilitate the pin’s passage through the incision. C,D. The T-handle is switched to the lateral end of the pin and the pin is retracted into the lateral fragment. (A,C: Courtesy of Steven B. Lippitt, MD.)

**TECH FIG 4 • A.** The lateral end of the pin with the larger medial nut is placed first, closest to the skin, followed by the smaller lateral nut, in preparation for cold welding. B. To cold weld the joint, the medial nut is grasped with a needle-nose pliers, and then the lateral nut is tightened against the medial nut using the lateral nut wrench. C. Using the lateral nut wrench and C-arm guidance, the surgeon advances the pin assembly into the medial fragment until it contacts the anterior cortex. (continued)
If an anterior butterfly fragment exists, cerclage is done using no. 0 or no. 1 absorbable suture.
- Pass an elevator under the clavicle to deflect the sutures (TECH FIG 5A).
- Then pass the suture in a figure 8 manner through the periosteum of the butterfly fragment and around the fragment and the clavicle (TECH FIG 5B).
- Close the periosteum overlying the fracture site with no. 0 absorbable suture in an interrupted figure 8 manner.
- Reapproximate the fascia of the platysma muscle using 2-0 absorbable suture in an interrupted figure 8 manner.
- Close the subcutaneous tissue and skin of both incisions.
**POSTOPERATIVE CARE**

- A sling is worn for 4 weeks. During this time the sling is removed at least five times a day for active range of motion of the elbow and active assisted range of motion of the shoulder to 90 degrees of forward flexion.
- The sling is discontinued and full active range of motion of the shoulder is started at 4 weeks.
- Progressive resistance exercises are started at 6 weeks if the patient achieved full range of motion and there is clinical and radiographic evidence of healing.
- Once the clavicle fracture has healed, the pin is removed at 10 to 12 weeks, as described in the Techniques section (FIG 5).

**PEARLS AND PITFALLS**

| Avoid splitting the clavicular fragments and aid in pin insertion | If tapping the medial or lateral clavicular fragments is too tight, the surgeon should redrill with the next larger drill size. |
| Achieve a more anatomic fracture reduction | When advancing the pin into the medial clavicular fragment, the surgeon should avoid starting too superior and anterior, which can lead to malreduction. Instead, the pin should be inserted more inferior and posterior to achieve a more anatomic reduction. |

**PIN REMOVAL**

- The pin is removed at 10 to 12 weeks if the fracture has healed.
- The patient is positioned on his or her side and a local anesthetic is delivered (TECH FIG 6A).
- An incision is made over the same previous lateral incision and the subcutaneous tissue is dissected using the hemostat until the medial nut is identified.
- The medial nut wrench is used to extract the pin assembly (TECH FIG 6B,C).
- If the nut is stripped, the T-handle and chuck can be used to extract the pin assembly.

**TECH FIG 6**

A. The patient is positioned on his or her side and the lateral incision is infiltrated with local anesthesia. B,C. The surgeon makes an incision over the same previous lateral incision, dissecting through the subcutaneous tissue using the hemostat until the medial nut is identified and freed up. The medial nut wrench is then used to extract the pin assembly. (B: Courtesy of Steven B. Lippitt, MD.)

**FIG 5**

Radiograph showing a healed clavicle fracture after pin assembly removal.
OUTCOMES

- One of the authors (C.B.) has performed intramedullary fixation of some 300 acute fractures; there have been 60 malunions and 30 nonunions of the clavicle, with a nonunion rate of 1.2%.
- Most of the nonunions occurred in older, sick patients with polytrauma.

COMPLICATIONS

- Pin migration is rare with this technique because of the locking nut on the lateral end of the pin, the blunt tip on the medial end of the pin, and technically avoiding penetration of the medial fragment cortex.
- The risk of skin breakdown from pin prominence laterally can be minimized by making sure the drill exits the posterolateral clavicle in the lower half.
- Neurovascular complications are rare.
  - There is no drilling toward the neurovascular structures with this technique.
  - When exposing the fracture site, the surgeon should stay on bone at all times.
- Nonunion rates are low as long as general fracture principles are maintained, soft tissue stripping of the fracture site is minimized, the technique is followed to get adequate fracture site compression and alignment, and the patient is compliant with the postoperative protocol.
- Malunion can rarely occur, especially in fractures with large butterfly fragments. Good imaging with the C-arm allows the surgeon to start inserting the pin more inferior and posterior down the line of the medial clavicular fragment to achieve a more anatomic reduction.
- Infection is rare, especially with this technique, which has a relatively short surgical time and small exposure. Preoperative antibiotics, meticulous handling of the soft tissues, and adequate irrigation should be part of any surgical technique.

REFERENCES

DEFINITION
- **Proximal humerus fractures** are defined as those of the proximal portion of the humerus involving the shoulder joint.
- **Fracture lines** divide the proximal humerus into parts defined by anatomic structures that arise from early centers of ossification.
  - These “parts” first were described by Codman, and led to development of the Neer classification, which is commonly used today.
  - The parts refer to the head of the humerus, the greater tuberosity, the lesser tuberosity, and the shaft (FIG 1).
  - Proximal humerus fractures are classified as two-, three-, or four-part fractures according to the Neer classification.
  - Displacement of a “part” is classically defined as 1 cm of displacement or 45 degrees of angulation. Importantly, displacement is not necessarily an indication for surgery, but only a criterion for classification.
  - The type of fracture and degree of displacement, as well as patient considerations, all factor into surgical decision-making.

ANATOMY
- The proximal humerus arises from four distinct centers of ossification: the humeral head, the greater tuberosity, the lesser tuberosity, and the shaft.
  - The greater tuberosity has three distinct facets for the insertion of the supraspinatus, the infraspinatus, and the teres minor muscles of the rotator cuff.
  - The lesser tuberosity is the insertion site for the subscapularis muscle.
  - The rotator interval lies between the upper subscapularis and the anterior border of the supraspinatus.
  - The long head of the biceps tendon lies in a shallow groove on the anterior proximal humerus and enters the glenohumeral joint at the rotator interval.
  - The proximal 3 cm of the long head of the biceps tendon lies deep to the interval tissue intra-articularly.
  - The anterior humeral circumflex artery (FIG 2) courses laterally along the inferior subscapularis.
  - The anterolateral branch of the anterior humeral circumflex artery travels superiorly along the lateral aspect of the biceps groove and enters the humeral head at the proximal-most aspect of the groove, providing about 85% of the blood supply to the humeral head.
  - The posterior humeral circumflex artery gives off several small branches that run adjacent to the inferior capsule of the shoulder, providing most of the remaining blood supply.
  - The pectoralis major muscle inserts on the proximal shaft of the humerus lateral to the long head of the biceps tendon. The latissimus dorsi muscle inserts onto the proximal shaft medial to the biceps groove.

![FIG 1](image1.png) Fractures of the proximal humerus are classified as two-, three-, or four-part fractures based on fracture and degree of displacement of the greater tuberosity, the lesser tuberosity, the humeral head, and the humeral shaft.

![FIG 2](image2.png) The rotator interval lies between the upper border of the subscapularis and the anterior border of the supraspinatus. The biceps tendon runs deep to the rotator interval tissue. Importantly, the fracture line between the greater and lesser tuberosities lies just posterior to the biceps groove. The ascending branch of the anterior humeral circumflex artery provides 85% of the blood supply to the humeral head.
PATHOGENESIS

- Proximal humerus fractures occur in a bimodal distribution.
  - Most proximal humerus fractures are “fractures of senescence” in older individuals with age-related osteopenia. They commonly result from low-energy injuries such as tripping and falling.
  - They also occur in younger individuals as the result of high-energy injuries such as motorcycle or automobile accidents.
  - Associated nerve injuries can occur and usually resolve spontaneously. Axillary nerve neurapraxia is the most common.

NATURAL HISTORY

- Eighty-five percent of proximal humerus fractures can be treated nonoperatively.6
  - Displacement at the surgical neck is better tolerated than displacement at the greater tuberosity.
  - Because of the vast range of motion (ROM) of the shoulder in multiple planes, the arm can compensate for translational displacement or angulation at the surgical neck.
  - Displacement of the tuberosities, however, affects the mechanics of the rotator cuff and is very poorly tolerated.

- Four-part fractures have an extremely high incidence of avascular necrosis—45% in Neer’s classic series—with the exception of valgus impacted four-part fractures, in which the incidence is only 11%.7
  - In most four-part fractures, the blood supply from the anterior humeral circumflex artery is disrupted, contributing to the high incidence of avascular necrosis.
  - The blood supply is maintained in most valgus impacted fractures by the branches from the posterior humeral circumflex artery along the intact medial periosteal hinge (FIG 3), making this particular fracture configuration very amenable to fixation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete history of injury is important to determine the mechanism of injury. It is helpful to differentiate low-energy from high-energy injuries.
  - Elderly individuals often sustain proximal humerus fractures as the result of low-energy injuries such as slipping and falling. These injuries often are very amenable to minimally invasive fixation techniques, because the displacement is manageable and the periosteal sleeve between fracture fragments often is intact. The rotator cuff often is intact as a sleeve. All these qualities facilitate minimally invasive reduction and fixation techniques.
  - In younger individuals, proximal humerus fractures often result from higher-energy injuries. These fractures commonly have greater fracture fragment displacement, rotator cuff tears between the tuberosities, and disruption of the periosteal sleeve. These factors do not necessarily preclude percutaneous pinning, but make it more challenging and should be considered in preoperative planning.

- Other important aspects of the history include:
  - Previous history of injury to the affected shoulder
  - Previous shoulder function
  - History of numbness or tingling in the affected extremity
  - Rule out elbow and wrist fractures, especially in osteoporotic patients with injuries resulting from a fall on an outstretched arm.
  - Patients often hold the shoulder inferior on the affected side.
  - Examination should include skin integrity, presence of ecchymosis, downward carriage of shoulder girdle, and deformity consistent with shoulder dislocation or acromioclavicular joint separation.
  - Examine for possible associated nerve injury (usually neurapraxia) by testing sensation to light touch in individual nerve distribution, two-point discrimination, and muscle strength (testing is limited to isometric at shoulder because of limited ROM and pain).
  - Possible associated vascular injury can be determined by testing radial pulse and capillary refill.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A trauma series of radiographs of the shoulder should be obtained (FIG 4).
  - The series includes an AP view of the shoulder, a scapular AP view, a scapular Y view, and an axillary view.
  - A complete series with these views allows the fracture configuration to be determined in sufficient detail.
  - A CT scan is helpful in many cases and should be obtained if there is any question regarding the extent of fracture involvement or the level of displacement of the fragments. It also is helpful if there is any question of joint dislocation or glenoid fracture.
  - Radiographs are used to determine whether the fracture is a two-, three-, or four-part fracture and to assess the degree of displacement.

FIG 3 • Valgus impacted fractures maintain blood supply to the articular surface via ascending branches off the posterior humeral circumflex artery along the intact medial periosteal hinge.
Three-dimensional reconstructions of the CT scan can be helpful in fracture evaluation, but are not routinely required.

DIFFERENTIAL DIAGNOSIS
- Acromioclavicular joint separation
- Glenohumeral joint dislocation
- Humeral shaft fracture
- Scapulothoracic dissociation
- Elbow and wrist fractures (may coexist)

NONOPERATIVE MANAGEMENT
- Minimally displaced fractures can be treated nonoperatively.
- Displacement at the surgical neck is well tolerated.
  - An AP view of the shoulder can be misleading in the case of a surgical neck fracture.
  - The pectoralis major muscle exerts an anterior force on the shaft, resulting in anterior displacement of the shaft relative to the humeral head.
  - A scapular Y or axillary view can exhibit this angular deformity.
- Displacement of the greater tuberosity is less well tolerated.
  - Historically, 1 cm of displacement has been used as the criterion for clinically significant tuberosity displacement.
  - Recently, however, even 5 mm of displacement has been considered an operative indication.
- Patients wear a sling for 2 to 3 weeks or until the proximal humerus feels stable with gentle internal or external rotation of the arm.
  - Patients should be instructed to remove the sling for elbow and hand ROM to avoid stiffness of these joints.
  - Early signs of healing (eg, callus formation) also are helpful indicators of when it is safe to commence ROM exercises.
  - In borderline instances, it is better to err toward a longer period of immobilization to ensure healing, because shoulder stiffness is easier to address than a nonunion.
- Therapy begins with passive stretching until 6 weeks when active ROM and strengthening can be started, progressing as tolerated.

SURGICAL MANAGEMENT
Preoperative Planning
- All imaging studies should be reviewed carefully to determine the type of fracture, the degree of displacement, fracture configuration, and bone quality.
- Certain radiographic findings that can suggest that minimally invasive fracture fixation is not appropriate for a given fracture are as follows:
  - Poor bone quality. The bone may not hold the pins and screws well and may be better treated with a more stable construct.
  - Commination of the greater tuberosity. A comminuted bone fragment is not amenable to fixation with screws. Fractures with a comminuted greater tuberosity require suture fixation through the tendon–bone junction (required open approach).
  - Commination of the medial calcar region leads to unstable reduction of the head onto the shaft.
- Fractures amenable to minimally invasive fixation are two-part, three-part, and valgus impacted four-part fractures with:
  - Good bone quality
  - Substantial fracture fragments with minimal comminution of the tuberosities
  - Minimal or no comminution at the medial calcar region
  - Minimally invasive fixation is not appropriate for noncompliant or unreliable patients. This procedure should be performed only in patients committed to consistent follow-up in the postoperative period.
    - The pins require close surveillance in the early postoperative period.
    - Pin migration is possible and must be caught early in order to avoid potential injury to thoracic structures.
Positioning
- Percutaneous pinning is performed with the patient in the straight supine or 10- to 15-degree beach chair position (FIG 5).
- This allows easy intraoperative evaluation with C-arm fluoroscopy.
shoulder can be imaged in the anteroposterior plane without the table obstructing the view.
  ▪ This image should be checked before prepping and draping to confirm adequate visualization.
  ▪ The entire upper extremity is draped free.

Approach
  ▪ Closed fracture reductions are performed with the aid of a “reduction portal” (FIG 6).^2
  ▪ The reduction portal is a portal (analogous to that of an arthroscopic portal) or small incision used to access the fracture fragments.
  ▪ Instruments can be introduced through this portal to lever fracture fragments or pull fragments into reduced position.
  ▪ The surgeon also can insert a finger through this portal to palpate fragments.
  ▪ Medially, the biceps tendon can be palpated.
  ▪ The surgical neck fracture is located just deep to the portal.
  ▪ By sweeping posterior and superior, the greater tuberosity and its extent of displacement can be palpated.
  ▪ The location of the reduction portal is critical (FIG 6B).
  ▪ In three- and four-part fractures, the fracture line of the greater tuberosity is reliably 0.5 to 1 cm posterior and lateral to the biceps groove.
  ▪ Therefore, the reduction portal is located at the level of the surgical neck and 1 cm posterior to the biceps groove.

FIG 5 • The patient is placed in the supine or gently upright position. The C-arm is brought in parallel to the patient, leaving the lateral aspect of the arm free for instrumentation. The patient should be positioned laterally on the table such that an adequate fluoroscopic view can be obtained.
  ▪ The C-arm fluoroscope is placed parallel to the patient, extending over the shoulder from the cephalad direction.
  ▪ This position leaves the lateral shoulder completely accessible for instrumentation and pin fixation.
  ▪ The patient must be positioned far lateral on the table or on a specialized shoulder surgery positioning device such that the shoulder can be imaged in the anteroposterior plane without the table obstructing the view.

FIG 6 • A. The reduction portal is established off the anterolateral corner of the acromion. Instruments can be introduced through this portal to help reduce the fracture. B. The reduction portal is located at the level of the surgical neck fracture approximately 0.5 to 1 cm posterior to the biceps groove. The reduction portal is definitively localized using C-arm imagery. A hemostat is applied to the skin (C) and then imaged (D) to confirm that this portal will be directly at the level of the surgical neck fracture. E. A small incision is made in the skin, and the deltoid is spread bluntly to avoid injury to the underlying axillary nerve.
Reduction

- The pectoralis major muscle provides the major deforming force resulting in displacement of surgical neck fractures. The shaft usually is displaced anteriorly and medially with respect to the head.
- An axillary or scapular Y radiograph is necessary to evaluate the extent of this displacement.
- The reduction maneuver involves flexion, adduction, and possibly some slight internal rotation to relax the pull of the pectoralis major muscle3 (TECH FIG 1).
- Longitudinal traction is applied to the arm, and a posteriorly directed force is applied to the proximal shaft of the humerus.
- A blunt instrument can be inserted into the fracture at the surgical neck to lever the head back onto the shaft. This maneuver can be a powerful reduction tool, but care should be used to avoid further damage or fracture to the humeral head during this maneuver, especially on osteopenic patients.
- The long head of the biceps tendon can become interposed between the fracture fragments, precluding reduction. Therefore, if reduction is not achieved, check the biceps tendon through the reduction portal (or consider open reduction).

Fixation

- Two or three retrograde pins are placed from the shaft into the humeral head (TECH FIG 2).
- The starting point for the pins is approximately 5 to 6 cm distal to the surgical neck fracture line.
- The pins must angle steeply to enter the head fragment and not cut out posteriorly (TECH FIG 2B,C).
- Pins should be smooth to avoid injury to soft tissue upon insertion, and terminally threaded to avoid backing out.
- 2.5- or 2.7-mm smooth, terminally threaded pins commonly are found in external fixation or 7.3-mm cannulated screw sets of instruments.
- The pins should enter at different directions to enhance stability of fixation construct.
- One pin should enter lateral to the biceps in a primarily anterior-to-posterior direction.
- Another pin should enter further laterally in a primarily lateral-to-medial direction.
- Stability should be checked under fluoroscopic imaging with live, gentle internal and external rotation.

Fixation

- The arm is held in neutral rotation.
- The level of the surgical neck is located using fluoroscopic imagery (FIG 6C,D).
- The location of the biceps tendon is estimated based on surface anatomic landmarks.
- A 2-cm incision is made in the skin (FIG 6E).
- Subcutaneous tissues and the deltoid muscle are spread bluntly using a straight hemostat to avoid injury to the axillary nerve on the deep surface of the deltoid. Subdeltoid adhesions are gently released by sweeping finger if necessary.

Surgical Neck Fracture

Reduction

- The pectoralis major muscle provides the major deforming force resulting in displacement of surgical neck fractures. The shaft usually is displaced anteriorly and medially with respect to the head.
- An axillary or scapular Y radiograph is necessary to evaluate the extent of this displacement.
- The reduction maneuver involves flexion, adduction, and possibly some slight internal rotation to relax the pull of the pectoralis major muscle3 (TECH FIG 1).
- Longitudinal traction is applied to the arm, and a posteriorly directed force is applied to the proximal shaft of the humerus.
- A blunt instrument can be inserted into the fracture at the surgical neck to lever the head back onto the shaft. This maneuver can be a powerful reduction tool, but care should be used to avoid further damage or fracture to the humeral head during this maneuver, especially on osteopenic patients.
- The long head of the biceps tendon can become interposed between the fracture fragments, precluding reduction. Therefore, if reduction is not achieved, check the biceps tendon through the reduction portal (or consider open reduction).

Fixation

- Two or three retrograde pins are placed from the shaft into the humeral head (TECH FIG 2).
- The starting point for the pins is approximately 5 to 6 cm distal to the surgical neck fracture line.
- The pins must angle steeply to enter the head fragment and not cut out posteriorly (TECH FIG 2B,C).
- Pins should be smooth to avoid injury to soft tissue upon insertion, and terminally threaded to avoid backing out.
- 2.5- or 2.7-mm smooth, terminally threaded pins commonly are found in external fixation or 7.3-mm cannulated screw sets of instruments.
- The pins should enter at different directions to enhance stability of fixation construct.
- One pin should enter lateral to the biceps in a primarily anterior-to-posterior direction.
- Another pin should enter further laterally in a primarily lateral-to-medial direction.
- Stability should be checked under fluoroscopic imaging with live, gentle internal and external rotation.
Reduction

- Deforming forces influencing displacement of three-part fractures include the pectoralis major, as described earlier, and the rotator cuff muscles. The rotator cuff pulls the tuberosity medially (to a certain extent) and posteriorly. Posterior displacement and rotation often are underappreciated and must be considered.
- The surgical neck component is addressed first. (See Surgical Neck Fractures earlier in this section).
- The greater tuberosity fracture is reduced using the “reduction portal.” A dental pick or small hooked instrument is inserted through the portal to engage the tuberosity and pull it inferior and anterior into a reduced position.

Fixation

- 4.5-mm cannulated screws are used to fix the tuberosity fragment.
- The screw is placed through the tuberosity fragment distal to the cuff insertion through bone on the lateral cortex (TECH FIG 3A).
- The proper location is confirmed with fluoroscopic imaging.
- The guidewire is first passed through a small incision in the skin just large enough to pass the drill guide and screw through the deltoid (TECH FIG 3B,C).
- The guidewire is passed through the tuberosity, across the surgical neck fracture, and engages the medial cortex of the proximal humeral shaft.

Pins are cut below the skin to prevent pin site infection (TECH FIG 2D).

Any suggestion of instability or motion at the fracture is an indication for open reduction and plate fixation at that point.

The reduction portal is closed with interrupted nylon sutures.

A soft dressing and sling are applied.

THREE-PART GREATER TUBEROSITY FRACTURES

TECH FIG 2 • (continued) C. Fluoroscopic view of two retrograde pins in place. D. The pins should be cut below the skin after insertion to prevent pin site infection. They are easily removed a couple of weeks later with a small procedure in the office or operating room.
Valgus impacted fractures are recognized by the 90-degree angle between the long axis of the humeral shaft and the articular surface of the humeral head with loss of the normal neck shaft angle. The tuberosities are displaced laterally from the head of the humerus and slightly proximally.

This fracture configuration results in a low incidence of avascular necrosis compared to that of other four-part fractures, because the medial periosteal hinge of soft tissues is intact along the medial and posterior anatomic neck, preserving the blood supply provided by the posterior humeral circumflex artery and its ascending vessels.

The reduction maneuver for this fracture requires raising the humeral head back into its anatomic position.

The reduction portal described previously is created, and an instrument such as a blunt elevator or small bone tamp is inserted beneath the humeral head.

The instrument passes through the surgical neck fracture and through the fracture line between the tuberosities, which reliably exists 0.5 to 1 cm posterior and lateral to the biceps groove.

After the guidewire is overdrilled, the screw is passed over the guidewire. We use a partially threaded screw with a washer (TECH FIG 3D–F).

If the greater tuberosity fragment is large enough, a second cancellous screw is directed through the tuberosity fragment, engaging cancellous bone of the humeral head.

Pins are cut beneath the skin.

Incisions are closed with nylon interrupted sutures.

A dressing and sling are applied.
POSTOPERATIVE CARE

- The operative arm is immobilized in a sling.
- The patient is instructed to begin active elbow, wrist, and hand ROM exercises.
- Radiographs are checked weekly to monitor for pin migration or loss of fixation.
- Pins are removed as a short procedure in the office or operating room about 3 to 4 weeks postoperatively or when early signs of healing are evident radiographically.
- Pendulum exercises are initiated 2 to 3 weeks postoperatively, and passive stretching (forward elevation in scapular plane), external rotation, and internal rotation (all in supine position) is initiated when pins are removed.
- Ideally, pins should be out and motion started no later than 4 weeks postoperatively.
- Active ROM progressing as tolerated to resistance exercises commences at 6 weeks postoperatively.

OUTCOMES

- Jaberg et al. reported good to excellent results in 38 of 48 fractures. There were 29 surgical neck, 3 anatomic neck, 8 three-part, and 5 four-part fractures.
Resch et al\textsuperscript{8} reported results of 9 three-part fractures and 18 four-part fractures. In the four-part fractures, the incidence of avascular necrosis was 11%. Good results correlated with anatomic reconstruction.

Keener et al\textsuperscript{5} reported a multicenter study of 35 patients—7 two-part, 8 three-part, and 12 valgus impacted fractures. Average duration of follow-up was 35 months. All fractures healed. American Shoulder and Elbow Surgeons and Constant scores were 83.4 and 73.9, respectively. Four patients had some residual malunion, and four developed posttraumatic arthritis. Neither of these affected outcome at this early follow-up period, however.

Most studies report very satisfactory results with this procedure. Patient selection is critical. In published studies, patients are not randomized to percutaneous pinning, but, rather, careful patient selection is left to the treating surgeon. Therefore, it can be concluded that this is an appropriate technique in certain patients who meet the outlined criteria.

**COMPLICATIONS**

- Nerve injury\textsuperscript{9}
- Pin migration
- Loss of fixation
- Malunion
- Nonunion
- Infection
- Glenohumeral joint stiffness

**REFERENCES**

DEFINITION

- Proximal humerus fractures may involve the surgical neck, the greater tuberosity, or the lesser tuberosity.
- The Neer classification, which is most commonly used, categorizes fractures based on the number of displaced parts ([FIG 1](#)), This classification system involves four segments: the articular surface, the greater tuberosity, the lesser tuberosity, and the humeral shaft. Fracture fragments displaced 1 cm or angulated 45 degrees are considered displaced.\(^\text{17,18}\)
- The AO/ASIF (Arbeitsgemeinschaft fuer Osteosynthese-fragen–Association for the Study of Internal Fixation) broadly classifies fractures into three types: type 1, unifocal extra-articular; type 2, bifocal extra-articular, and type 3, intra-articular.
  - Each type is then further divided into groups and subgroups.\(^\text{16}\)
  - This system places more emphasis on the vascular supply to the humerus, with intra-articular fracture patterns having the highest risk of avascular necrosis.\(^\text{26}\)
- Studies have demonstrated that interobserver reliability for both classification systems is not high.\(^\text{1,23,24}\)

- Although not included in Neer’s original classification, valgus impacted fractures are a unique entity that is important to recognize:
  - Four-part fractures in which the humeral articular surface is impacted upon the shaft segment
  - Often minimally displaced owing to an intact rotator cuff\(^\text{5}\)
  - Have a lower incidence of avascular necrosis, because the blood supply to the head is less likely to be disrupted

ANATOMY

- The osseous anatomy of the proximal humerus consists of the greater tuberosity, the lesser tuberosity, and the articular surface.
- The subscapularis inserts onto the lesser tuberosity, whereas the supraspinatus, infraspinatus, and teres minor insert onto the greater tuberosity.
- Knowledge of deforming forces associated with humerus fracture allows the surgeon to better treat proximal humerus fractures by both operative and nonoperative means.
- In a two-part surgical neck fracture, the pectoralis major pulls the humeral shaft anteromedial.
- In a two-part greater tuberosity fracture, the pull of the supraspinatus, infraspinatus, and teres minor tendons displace the greater tuberosity superiorly and/or posteriorly.

[FIG 1](#) • Simplified Neer classification for fractures of the proximal humerus.
With a three-part fracture involving the lesser tuberosity, the attachment site of these tendons into the greater tuberosity is intact, and the articular surface of the humeral head rotates externally to face anteriorly.

Three-part fractures involving the greater tuberosity result in unopposed subscapularis function, and the humeral articular surface rotates posteriorly.

Four-part fractures result in displacement of the shaft and both tuberosities, leaving a free head fragment with little soft tissue attachment.

An understanding of the vascular anatomy is crucial to treat fractures of the proximal humerus effectively.

The main blood supply to the humeral head is the anterolateral ascending branch of the anterior circumflex artery.

This branch of the axillary artery runs just lateral to the bicipital groove, entering the humeral head at the proximal portion of the transition from bicipital groove to greater tuberosity.

The intraosseous portion of this vessel, known as the arcuate artery, has been shown to supply the entire epiphyseal portion of the proximal humerus except for a small portion of the greater tuberosity and the posteroinferior humeral head, which is supplied by the posterior humeral circumflex artery.

**PATHOGENESIS**

- In older patients, proximal humerus fractures usually result from a ground-level fall. Younger patients may sustain such an injury from a higher-energy mechanism such as an automobile collision or from sports.
- The presence of an associated glenohumeral dislocation also must be determined.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- On presentation, patients with proximal humerus fractures complain of pain in the shoulder that is made worse with attempted movement. Palpation of the proximal humerus results in diffuse pain.
- Visual inspection reveals ecchymosis and swelling of the arm.
- It is necessary to determine the stability of the fracture. If the shaft and the proximal portion move as a unit when taken through internal and external rotation, the fracture usually is stable. Unstable fractures will not move as a unit, and crepitus often is appreciated.
- If there is an associated dislocation, it may be possible to palpate the humeral head as an anterior fullness.
- It is crucial to perform a thorough neurovascular examination to determine the presence of associated injuries.
- Patients over 50 years of age are more prone to nerve injuries. One study demonstrated nerve injury, usually of the axillary nerve, in nearly 40% of patients in this age group who sustained shoulder dislocations or surgical neck fractures.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Initial imaging studies consist of anteroposterior, scapular Y, and axillary views.
- Additional views also may include internal and external rotation views if the fracture pattern is stable. Internal rotation views help to visualize the lesser tuberosity, whereas external rotation shows the greater tuberosity.
- Traction views also may prove helpful if tolerated by the patient.
- A CT scan may be helpful if radiographs do not demonstrate the fracture pattern adequately.
- Studies have shown that the addition of a CT scan improves intraobserver reproducibility only minimally and does not affect interobserver reliability. However, CT scanning may prove valuable in determining the method of fixation as well as identifying associated injuries such as Hill-Sachs fractures and bony Bankart lesions.
- Indications for MRI are limited, although it may prove useful if there is any concern regarding soft tissue injuries, including the glenoid labrum and rotator cuff.

**DIFFERENTIAL DIAGNOSIS**

- Glenohumeral dislocation
- Scapula fracture
- Head-splitting fracture
- Clavicle fracture
- Humeral shaft fracture
- Neurovascular injury
- Neuropathic arthropathy

**NONOPERATIVE MANAGEMENT**

- Historically, conservative treatment usually is recommended for fractures with less than 1 cm of displacement and 45 degrees of angulation. About 85% of proximal humerus fractures can be treated nonoperatively. With newer fixation devices, however, indications for surgical management have been expanded. Whether a more aggressive approach leads to improved outcomes remains to be seen.
- There is less tolerance for displacement in isolated greater tuberosity fractures. It has been suggested that more than 5 mm of displacement leads to poor functional results.
- For proximal humerus fractures not involving the humeral head, patients initially are immobilized in a simple sling.
- When pain improves and the fracture moves as a unit, passive range of motion (ROM) is started. Patients begin with pendulum exercises, usually 2 to 3 weeks after injury, then progress to ROM in all planes.
- Between 6 and 10 weeks, the fracture usually has healed enough that strengthening exercises may be started.
- Physical therapy is very important when treating proximal humerus fractures conservatively. Koval et al showed significant improvement with one-part fractures when physical therapy was initiated before 2 weeks.
- Several studies have shown that nonoperative management can lead to acceptable results with proximal humerus fractures.
- Studies comparing patients treated surgically and nonsurgically have shown no difference in outcome with two-part surgical neck fractures and displaced three- and four-part fractures, although these studies were done before the advent of anatomic proximal humeral plating.

**SURGICAL MANAGEMENT**

- It is imperative that patients have reasonable expectations of their outcome following surgery. Patients also must be aware of the importance of physical therapy postoperatively.
Preoperative Planning

- Acceptable imaging studies, either plain radiographs or a CT scan, are necessary before proceeding to surgery.
- Each proximal humerus fracture is unique, and in most cases a planned method of fixation is chosen before entering the operating room. However, the definitive choice of fixation is not made until the fracture is visualized at surgery. Consequently, the surgeon should be prepared with an arsenal of different fixation techniques.
- If the fracture is not deemed suitable for internal fixation intraoperatively, the surgeon must be prepared to perform a hemiarthroplasty.
- Multiple techniques can be employed for surgical fixation of the proximal humerus. In this chapter, we describe several current techniques. The final choice of appropriate manner of fixation should be based on the individual patient, the fracture pattern, and the surgeon’s own comfort level.

Positioning

- The techniques discussed in this section are easiest to perform with the patient in the beach chair position. With the patient nearly seated, the hips and knees are flexed. The patient is moved as far laterally as possible on the table to allow full ROM of the shoulder. A lateral buttress is used to help keep the patient in position on the table.
- C-arm fluoroscopy is helpful in determining the quality of reduction. The C-arm is best positioned with the intensifier posterior to the shoulder and the arm over the patient (FIG 2).

Approach

- The approach depends on the surgical technique to be used and is discussed further in the Techniques section.
- The deltopectoral approach is most commonly employed.

FIXATION OF ISOLATED TUBEROSITY FRACTURES

- The patient is placed in the beach chair position.
- An incision is made from the tip of the acromion extending laterally down the arm.
- Alternatively, an incision can be made parallel to the lateral border of the acromion, as used in open rotator cuff repair.
- Skin flaps are then raised.
- The deltoid is split in line with its fibers, and the anterior portion of the deltoid may be detached from the acromion.
- A deltopectoral approach also could be used.
- The deltoid fibers should not be split further than 5 cm below the acromion, to prevent damage to the axillary nerve. A suture at the distal aspect of the split can help prevent inadvertent extension.10
- As with all open procedures described in this chapter, the fracture should be cleaned of hematoma to facilitate reduction.
- The greater tuberosity usually is displaced posteriorly or superiorly. Abducting and externally rotating the shoulder will take tension off the posterosuperior rotator cuff, allowing the greater tuberosity fragment to be more easily reduced.
- Traction sutures in the rotator cuff may prove valuable in obtaining reduction.
- Provisional fixation can then be obtained with a K-wire (TECH FIG 1A,B).
- Cannulated screws placed over the wire may then be used for definitive fixation if placed in an acceptable location.
- Screws should be of the appropriate length to gain adequate purchase (TECH FIG 1C,D) but not so long that they are symptomatic.
- The use of washers may prove beneficial.
- Alternatively, suture fixation of the greater tuberosity back to the humerus may provide better fixation than cannulated screws in those patients with poor bone quality.
- This can be accomplished by placing two suture anchors into the fracture bed (TECH FIG 1E).
- Both limbs of each anchor can then be brought through drill holes in the fragment and tied over the top (TECH FIG 1F).
- Suture also can be placed at the bone–tendon interface of the tuberosity fragment and then through bone tunnels in the shaft, as discussed later in this section.
- If the anterior deltoid was detached during the approach, it must be repaired back to the acromion using nonabsorbable sutures.
TECH FIG 1 • A. Traction sutures are placed through the rotator cuff tendon to aid in reduction of the displaced greater tuberosity. B. Wires may be used to maintain reduction of the tuberosity. C. Screw fixation with 4.5-mm cannulated screws. D. Final fixation. Screws should obtain purchase in the far cortex, but they must not be long enough to damage the axillary nerve. E. Placement of suture anchors into the fracture bed. F. Reduced fracture with sutures tied over the greater tuberosity.
OPEN REDUCTION AND SUTURE FIXATION

- The patient is placed in the beach chair position. Depending on the pattern, the fracture may be approached via the deltopectoral interval or a deltoid-splitting approach.
- The rotator interval tissue may be incised. This "interval split" allows visualization of the humeral head articular surface, if needed, in the setting of intact tuberosities and rotator cuff, as with head split patterns.
- Multiple sutures are placed through the tendons of the rotator cuff, preferably no. 5 nonabsorbable sutures or 1-mm tapes.
  - Both the subscapularis tendon and the posterosuperior cuff tendons should be incorporated (TECH FIG 2A).
- Drill holes should be placed distal to the fracture site. The bone on either side of the bicipital groove is of excellent quality and should hold sutures well (TECH FIG 2B,C).
- In most cases, anatomic reduction is desired.
- With three-part fractures involving the greater tuberosity, the head fragment should first be secured to the shaft, followed by reduction of the greater tuberosity.20
- For high surgical neck fractures, sutures should be placed into any remaining tuberosity on the head fragment to help maintain fixation.

OPEN REDUCTION AND INTERNAL FIXATION USING ANATOMIC PLATING

Exposure

- Anatomic plating of the proximal humerus commonly is performed through the deltopectoral interval.
- With the patient in the beach chair position, an incision is made starting from above the coracoid process and extending distally as needed along the deltopectoral groove (TECH FIG 3A).
- The plane between the deltoid and pectoralis major is developed, mobilizing the cephalic vein.
- Cobb elevators can be used to develop this plane, making it easier for the surgeon to identify
AB C

TECH FIG 4 • A. Traction sutures through the tendinous attachments of the rotator cuff may be helpful in correcting varus deformity.
B. Reducing the fracture by elevating the proximal fragment.
C. Correct placement of the plate is lateral to the biceps tendon (not seen here). Suture fixation has been used to help maintain fixation and supplement the plate.

and ligate branches of the cephalic vein (TECH FIG 3B,C).
■ The underlying clavipectoral fascia is identified and incised laterally to the conjoined tendon.10
■ The conjoined tendon is carefully retracted medially with the pectoralis major and the deltoid retracted laterally.

Reduction
■ The fracture and rotator cuff are now visible. With fractures involving displaced tuberosities, we recommend obtaining control of the tuberosities with sutures placed at the bone–tendon interface (TECH FIG 4A).
■ Heavy sutures may be placed through the insertions of the cuff tendons and later used as supplemental fixation if necessary.
■ For fractures with minimally displaced tuberosities, sutures may not be needed before a reduction maneuver.
■ A Cobb elevator placed in the fracture site will aid in reducing the fracture (TECH FIG 4B).
■ The pectoralis major insertion is elevated in a subperiosteal fashion if necessary. The plate should be placed lateral to the biceps tendon so as not to disrupt the blood supply to the humeral head (TECH FIG 4C).
■ Often, it may be necessary to release a small portion of the anterior deltoid insertion before placing the plate.

Plate Fixation
■ Fluoroscopy should be used to confirm the reduction before placement of the plate, especially in regard to the superior aspect of the plate.
■ A plate positioned too high or a fracture fixed in varus may result in the plate impinging on the undersurface of the acromion. K-wires may be used to temporarily maintain fixation proximally and distally.
■ Alternatively, multiple guidewires may be placed into drill sleeves (TECH FIG 5A). Confirm plate location

TECH FIG 3 • A. The incision is made extending from the coracoid process distally along the deltopectoral groove.
B. Identifying the interval between the deltoid and pectoralis major.
C. Using two Cobb elevators to develop the interval, bringing the cephalic vein laterally.
again, both proximally and distally, before placing screws.

- Locking screws usually are placed proximally into the head first, and multiple configurations of screws are possible.
- Once the head is secured to the shaft, distal screws can be placed (TECH FIG 5B).
- Final plate placement should be confirmed fluoroscopically (TECH FIG 5C,D).
- Sutures placed through the cuff tendons also may be secured to the plate, shaft, or other tuberosity.
- At the completion of the procedure, the pectoralis major may be secured with sutures through holes in the plate.

In osteoporotic bone, the tuberosities can first be attached to the shaft with sutures, following which a locking plate may be placed along the lateral aspect of the proximal humerus.

- Fixation of displaced two-part proximal humerus fractures also can be performed using a locking plate in a percutaneous fashion. With this technique, great care must be taken to prevent injury to the axillary nerve.
- A recent cadaveric study demonstrated that the axillary nerve was an average of 3 mm from the second most proximal diaphyseal screw hole, and an average of 7 mm from the third most proximal screw hole. All other screw holes were more than 1 cm from the nerve.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>An understanding of the neurovascular anatomy as well as the deforming forces present in proximal humerus fractures is vital to treating these injuries effectively.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exposure</td>
<td>Avoid devascularizing fracture fragments by stripping pieces minimally. Development of the “interval split” aids in fracture visualization and reduction and does not require detachment of the rotator cuff tendons. This is especially helpful when trying to fix a head-splitting fracture in a young patient.</td>
</tr>
<tr>
<td>Maintaining fixation</td>
<td>K-wires are useful for maintaining initial fixation. With suture fixation, the strong bone along the bicipital groove of the distal fragment will hold sutures the best.</td>
</tr>
<tr>
<td>Poor bone quality</td>
<td>With osteoporotic three-part fractures, consider suture fixation first, followed by a proximal humeral locking plate. Anatomic plating is very helpful when medial comminution is present.</td>
</tr>
<tr>
<td>Superior impingement</td>
<td>Avoid placing the locking plate too high on greater tuberosity.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE
- Stable fixation must be obtained to allow for immediate ROM.
- A physical therapy regimen should be established based on the stability of fixation, the fracture pattern, the quality of the bone, and individual patient factors.
- Ideally, the fixation should allow pendulum exercises on the first postoperative day and 130 degrees of passive forward flexion and 30 degrees of passive external rotation.
- Between 4 and 6 weeks after surgery, an overhead pulley can be added, with stretching and active motion added at 6 to 8 weeks.
- Formal strengthening with elastic bands is not started until 10 to 12 weeks after surgery.3
- As with nonoperative treatment, participation in physical therapy is key to a successful outcome.
- In a recent study looking at fixation of two- and three-part fractures, the only patients with unsatisfactory outcomes were those who were noncompliant with physical therapy.20

OUTCOMES
- Neer’s original description called for fixation of greater tuberosity fractures when there was more than 1 cm of displacement.17
- One recent study had excellent or good results in 12 of 16 patients with fixation of greater tuberosity fractures displaced more than 1 cm.7 Forward elevation averaged 170 degrees, and external rotation averaged 63 degrees.
- Some authors believe that greater tuberosity displacement of greater than 5 mm may lead to poor outcomes.
- McLaughlin14 first suggested that patients in whom a greater tuberosity healed with residual displacement of more than 5 mm had longstanding pain with poor function. Displacement of less than 5 mm does not appear to warrant surgery.
- Platzer et al13 looked at minimally displaced fractures of the greater tuberosity and found no statistical significance with varying degrees of displacement less than 5 mm.
- Open reduction with suture or wire fixation can achieve acceptable fixation, especially in older patients with osteoporotic bone. The technique can be used reliably in two- and three-part fractures.
- One study showed nearly 80% excellent results with average motion of 155 degrees of average forward flexion, 46 degrees average external rotation, and internal rotation to T11. Furthermore, there were no reported cases of osteonecrosis of the humeral head.20
- Early open reduction and internal fixation with a laterally placed T-plate failed to yield consistently good results, especially for four-part fractures.12,19 Other early osteosynthesis techniques include the cloverleaf and the blade-plate, but the current trend is toward anatomic plating technology.
- Recent studies show promise with the use of such locking plates, although this technique is not without complications.6

COMPLICATIONS
- Infection
- Nonunion
- Malunion
- Avascular necrosis
- Nerve injury
- Impingement secondary to fixation or residual tuberosity displacement
- Failure of fixation, including varus malposition and plate fracture with proximal humeral anatomic plating6

REFERENCES

DEFINITION

■ From 50% to 80% of proximal humerus fractures are nondisplaced or minimally displaced and stable. Early range of motion after a short period of immobilization usually is sufficient to treat these fractures and has been shown to result in satisfactory outcomes. The remaining 20% to 50% of patients with proximal humerus fractures may benefit from operative management.

■ Numerous techniques of internal fixation for proximal humerus fractures have been described and reported, including cloverleaf and blade plating, Rush pinning, spiral pinning, Kirschner wire and tension band fixation, and intramedullary nail fixation.

■ Extensive dissection and inadequate biomechanical fixation in the context of severe soft tissue injury and devascularization associated with these complex fracture types are the commonly cited reasons for failure of internal fixation devices.

■ Prosthetic arthroplasty traditionally has been the recommended treatment for three-part fractures with osteoporosis, four-part fractures, head-splitting fractures, and articular compression fractures that involve more than 40% of the articular surface. Recent studies have reported satisfactory results with various types of osteosynthesis for four-part fractures, leading them to recommend an attempt at internal fixation in younger patients. The basis of this recommendation is that subsequent published series have been unable to reproduce Neer’s results with early hemiarthroplasty for four-part fractures.

■ Various reports have been made on the use of intramedullary nails in the proximal humerus. We prefer to use an intramedullary nail that permits stable fixation of the head to the shaft of the humerus using a minimally invasive rotator cuff-splitting approach (DePuy Inc., Warsaw, IN).

■ The method for treatment of proximal humeral fractures described in this chapter involves a minimally invasive anterior acromial surgical approach, an indirect method of reduction, and a unique intramedullary rod designed to permit a variety of proximal interlocking configurations.

ANATOMY

Osteology

■ The proximal humerus includes the humeral head, the lesser tuberosity, the greater tuberosity, and the proximal humeral metaphysis.

■ The position of the head is higher than the tuberosities, and changes in this relationship will cause impingement. The humeral head is slightly medial (3 mm) and posterior (7 mm) in relation to the humeral shaft (FIG 1).

■ The humeral head is retroverted approximately 30 degrees (range 20 to 60 degrees).

Vascular Supply of the Proximal Humerus

■ The anterior and posterior humeral circumflex arteries are branches of the axillary artery.

■ The arcuate artery, the terminal vessel of the ascending branch of the anterior humeral circumflex artery, supplies most of the humeral head.

■ Avascularity of the humeral head can occur if this vessel is disrupted during a fracture of the anatomic neck.

■ The posterior circumflex artery becomes important in patients with proximal humerus fractures.

■ It may be the primary source of blood supply to the fractured head, so care should be taken to prevent additional devascularization.

■ Traumatic and iatrogenic vascular insult may lead to devascularization of the fracture fragments, resulting in delayed union, nonunion, and avascular necrosis. Traumatic injury cannot be predicted; well-planned minimally invasive procedures should reduce the risk of further damage, however.

Innervation

■ The brachial plexus is at risk in patients with upper extremity injury, and thorough neurologic evaluation is mandatory.
The axillary nerve courses through the quadrilateral space, where it is at risk during fracture dislocation.

The lateral entry site for locking screw fixation (4–5 cm distal to the tip of the acromion) places the axillary nerve at risk.

PATHOGENESIS

A blow to the anterior, lateral, or posterolateral aspect of the humerus typically is the cause.

Axial load transmitted to the humerus may cause impacted fracture in osteoporotic bone.

Violent muscle contractures, as in grand mal seizures and electric shock, are associated with posterior dislocation due to overpowering internal rotators and adductors.

Pathologic causes include tumor, multiple myeloma, and metastatic or metabolic disorders.

Osteoporosis is associated with fractures of the proximal humerus (more than any other fracture).

In a three-part fracture with intact greater tuberosity, the humeral head is pulled by the supraspinatus and infraspinatus tendons; if the tendons are intact, the humeral head is externally rotated. The inverse is seen when the greater tuberosity is avulsed: the intact subscapularis internally rotates the humeral head (FIG 2).

NATURAL HISTORY

Epidemiology

4% to 5% of all fractures

Increased incidence in osteoporosis, older middle-aged and elderly persons (third most common fracture in elderly)

In persons older than 50 years of age, the female: male ratio is 4:1 (osteoarthritis). Minor falls and trauma may cause comminuted fracture.

In patients younger than 50 years of age, violent trauma, contact sports, and falls from heights are responsible for fractures.

Surgical neck fracture is common.

Consequences of Injury

Nondisplaced fractures may heal without major consequences.

Acute, recurrent, or chronic dislocation

Rotator cuff tears

Neurovascular injury: axillary nerve, brachial plexus

Avascular necrosis of the humeral head often results from disruption of the arcuate artery. The axillary artery also may be damaged, but less commonly, in fracture-dislocations.

Malunion: loss of humeral length may cause deltoid weakness

Posttraumatic arthrosis

Adhesive capsulitis

Chronic pain

PATIENT HISTORY AND PHYSICAL FINDINGS

Associated injuries:

Rotator cuff tears

Dislocation

Forearm fractures

Brachial plexus, axillary, radial and ulnar nerve injuries (5%–30% of complex proximal humerus fractures)

IMAGING AND OTHER DIAGNOSTIC STUDIES

Trauma series

Scapular anteroposterior (glenoid view)

Trans-scapular

Axillary

Rotational views

CT scan

SURGICAL MANAGEMENT

Indications

Two-part proximal humerus fracture

Three-part proximal humerus fracture

Certain four-part proximal humerus fractures

Prerequisites

Shoulder table, image intensification, and experienced radiology technician

Be aware of the learning curve (do not attempt nailing of a four-part fracture before acquiring adequate experience with two- and three-part fractures).

FIG 2 • A. Fracture pattern and deforming forces. The muscular attachments of the greater and lesser tuberosities will cause abduction, external rotation, and internal rotation, respectively. The head will follow whichever tuberosity is intact. B, C. In four-part fractures, the head often is in a neutrally rotated position. (Copyright J. Dean Cole, MD.)
When treating patients with complex fractures, obtain the patient’s consent for a hemiarthroplasty if that is determined to be the best treatment, and have the implant available in case it is found to be necessary.

Contraindication: head-splitting, comminuted displaced humeral head fragment devoid of soft tissue attachment

Preoperative Planning

- Successful intramedullary nailing of the proximal humerus fracture depends on consistent integration between image intensification and the surgical steps.
- Patient positioning on a radiolucent table will allow the surgeon to use a minimally invasive approach.
- Any error on the entry site will cause inevitable problems with the rest of the procedure.
- It is crucial that the surgeon follow the surgical technique precisely.

Positioning

- Positioning on the table must allow orthogonal and overhead axillary views.

The patient is placed supine in the beach chair position on a radiolucent table tilted at 60 to 70 degrees. The C-arm should be positioned on the opposite side of the table to allow the surgeon easy access to the proximal humerus (FIG 3).

A bolster is used to elevate the shoulder from the table and to allow shoulder extension. Extension of the shoulder is necessary to expose the entry site in the humeral head. Flexion of the shoulder will result in the acromion overlying the center of the humeral head in the sagittal plane, obscuring the entry site or errantly directing an entry angle. Anterior cutout of the nail in the head fragment can easily occur in an osteoporotic humeral head with an associated greater tuberosity fracture.

Approach

- Intramedullary nailing for isolated surgical neck fractures may be performed completely percutaneously using most of the techniques described in the following paragraphs. However, when tuberosity reduction and fixation are required, a wider approach often is necessary.
- The timing of the open approach depends on the sequencing of head, shaft, and tuberosity fixation. In the technique we describe in this chapter, head–shaft fixation is accomplished percutaneously using nailing and interlocking screws before tuberosity fixation. Alternatively, an open approach with tuberosity reduction and fixation can be performed before nail insertion.
- The surgical approach for viewing tuberosity fractures that require fixation is a lateral deltoid-splitting approach made just below the acromion, approximately 4 cm long, that does not extend distally, to avoid injury to the axillary nerve (FIG 4A).
- For a lesser tuberosity approach, a separate, small deltopectoral incision is centered just over the lesser tuberosity, and the lesser tuberosity fixation or fixation to the subscapularis tendon is performed in that plane (FIG 4B).
- The rotator cuff is incised longitudinally away from the lateral watershed area of the rotator cuff and away from Sharpey’s fibers and the connection of the tendon to the bone.
- Significant rotator cuff defect is not created with this approach, as confirmed in cadaver dissection. The longitudinal incision on the rotator cuff does not weaken the cuff.
K-WIRE PLACEMENT

Placement of K-wires allows fragment reduction and helps dictate placement of the skin incision and surgical approach. Hence, the first step involves placement of a K-wire in the subacromial space; it is inserted through the anterolateral aspect of the shoulder using the image intensifier (C-arm) and directed posteromedial toward the glenoid (TECH FIG 1A,B).

- This initial pin will serve as a guide for the retroversion of the humeral head.
- Next, two K-wires are placed in the humeral head, directed lateral to medial, one anterior and one posterior to the central aspect of the head (TECH FIG 1C,D). The wires should be separated by enough distance to allow insertion of the nail between them (1.5 cm).

The K-wires should be directed in the longest axis of the humeral head in the axial plane. Allowing for retroversion is important. Confirmation of the correct placement in the axial plane is done by the overhead axillary view. Then the C-arm is positioned to view the advancement of the pins in the coronal plane projection.

With longer K-wires, the surgeon’s hand can be kept out of radiographs. Unfortunately, with internal rotation, extension also occurs in the humerus and the humeral head, depending on the soft tissue attachments.

TECH FIG 1 • A,B. AP and axial views of initial K-wire insertion: This initial pin will serve to orient the humeral head, specifically the desired degree of retroversion. C,D. AP and axial views of pins to control head fragment. These pins are inserted to control the head fragment in a joystick fashion. (Copyright J. Dean Cole, MD.)
## Fragment Reduction

- The K-wires can then be used in a joystick fashion to adduct and extend the head, exposing the supraspinatus tendon and optimal entry site in the head from beneath the anterior edge of the acromion (TECH FIG 2A,B).
- Image intensification can be used to place a K-wire through the head in line with intramedullary axis of the humerus. This maneuver includes two important aspects:
  - The first is to use the joysticks to extend and adduct the proximal humeral head, exposing the anterolateral portion of the head from under the acromion while simultaneously distracting the distal shaft, thereby aligning the longitudinal intramedullary axis of the proximal and distal fragments (TECH FIG 2C,D).
  - The second is to drive the K-wire into the head in a central position with reference to the medullary canal in the sagittal plane and lateral to central in reference to the canal in the frontal or coronal plane (TECH FIG 2E).
- To achieve fracture reduction, the joysticks in the proximal fragment must be used to rotate the head while simultaneously rotating the distal shaft manually to obtain true orthogonal views of the head in reference to the shaft.

![TECH FIG 2 • Fragment reduction maneuver. A,B. Combining rotation of the head fragment (K-wires) with the shaft (arm) is used to assist in fracture reduction. C,D. AP and axial views of humeral head reduction maneuver. Manipulation of the fracture fragments with the K-wires allows disimpaction of the fracture, improving the varus or valgus alignment. E. Pin entry site in humeral head. (Copyright J. Dean Cole, MD.)](image)

## Guidewire Placement

- The nail can be placed percutaneous just anterior to the anterior edge of the acromion.
- The anterior edge may be difficult to palpate and to differentiate from the humeral head because of edema and hematoma from the fracture. Therefore, it is helpful to locate the anterior edge of the angle of the acromion under image intensification with a K-wire where it intersects the longitudinal axis of the humerus.
ENTRY SITE REAMING

- Reaming of the entry site should be performed carefully, as the percutaneous incision is small.
- The reamer is inserted over the guidewire, and the soft tissues are retracted and protected. The reamer is advanced through the rotator cuff in “reverse” until bone contact, then on “forward” through the humeral head. The reamer is left in place.
- The guidewire that was used to initiate the entry site is removed, and a longer guidewire is passed to the shaft fragment. Manipulation of the shaft fragment sometimes is necessary. The reamer’s sound must be used to gauge the canal diameter. It is necessary to ream 1 mm greater than the anticipated nail size.
- On some occasions, even external fixator placement from the scapular spine to the distal humerus is necessary. The external fixator is applied and distraction accomplished with manipulation of the proximal aspect of the shaft; guidewire passage usually is simple.

NAIL INSERTION

- Once the nail is inserted, confirm the rotation of the humerus in the axial plane; it is necessary to ensure proper alignment before impaction (TECH FIG 3).
- Usually, impaction of the distal fragment by blows against the olecranon, while supporting the proximal humeral head indirectly through the soft tissues, is adequate.
- Large gaps are not acceptable, and it may be necessary to use filler substance.

INTERLOCKING SCREW FIXATION

- We recommend that the oblique distal screw be the initial locking screw (TECH FIG 4). The goal of this screw is to attach the head to the shaft before fixation of the tuberosities.
- Screw placement puts the axillary nerve at risk. Careful blunt dissection to bone, drilling within the sheath, and placing the screw within the confines of the sheath are necessary. Drilling should be done very carefully, although it certainly does not completely negate the risk of drilling through the humeral head. Careful observation is important.
- It is occasionally helpful to remove the drill and then use a blunt guidewire and assure good humeral head subchondral bone contact before further drilling or screw placement.
- Central placement of the distal oblique screw in the humeral head is important. This step should flow very smoothly if the initial K-wires have been placed in the correct axial plane alignment.
- Errant placement or acceptance of poorly positioned K-wires will result only in further deviation. If the distal oblique screw is not placed at the appropriate
angle, the radiographs may be deceptive and may result in screw penetration.

- Screw placement on the subchondral bone is important for fixation. However, patients with osteoporosis do have a risk of the fracture fragment settling.

- A and B screws are placed depending on goals of fixation.
- Overdrilling to countersink the more proximal screw usually is necessary to avoid impingement.
- These screws rarely are helpful in tuberosity fixation.

The sequence of fixation should involve passing sutures through the musculotendinous junction of the subscapularis, infraspinatus, and supraspinatus. Sutures passed over the superior aspect of the head from the infraspinatus and subscapularis and sutures passed laterally around the head provide helpful, reliable fixation points. With practice, these maneuvers can be performed in a minimally invasive manner.

Comminuted tuberosity fixation is challenging. It is difficult to achieve consistent fixation with screws. A headless screw has been used with some success in limited cases.

| Contraindication             | Head-splitting, comminuted displaced humeral head fragment devoid of soft tissue attachment |

| Positioning                  | Beach chair position to allow clear fluoroscopic images. Chair with metal extensions positioned to allow overhead axillary C-arm views. |
## Postoperative Care

- The postoperative regimen depends on the stability of the fixation and the soft tissues.
  - Sling with abduction pillow that allows the proximal humerus to rest in neutral rotation and slight abduction (relax the rotator cuff and decrease tension on the greater tuberosity)
  - Gentle passive, pendulum, and active-assisted exercises of the shoulder
  - Active elbow and wrist exercises
  - Once fracture healing is detected on radiographic imaging, range of motion can be increased; weight lifting restrictions must be maintained until healing is complete.

## Complications

- **Early**
  - Injury to axillary nerve
  - Joint penetration
  - Loss of reduction
  - Infection

- **Late**
  - Nonunion
  - Posttraumatic arthrosis
  - Avascular necrosis of humeral head
  - Prominent hardware

## References

**DEFINITION**

- Proximal humerus fractures involve isolated or combined injuries to the greater tuberosity, lesser tuberosity, articular segment, and proximal humeral shaft.
- Overall, proximal humerus fractures account for 4% to 5% of all fractures. \(^8,^13\)

**ANATOMY**

- The proximal humerus consists of four segments: the greater tuberosity, lesser tuberosity, articular segment, and humeral shaft (FIG 1).
- The most cephalad surface of the articular segment is, on average, 8 mm above the greater tuberosity. \(^16\) Humeral version averages 29.8 degrees (range 10 to 55 degrees). \(^5^3\)
- The intertubercular groove lies between the tuberosities and forms the passageway for the long head of the biceps as it traverses from the intra-articular origin into the distal arm.
- The tuberosities attach to the articular segment at the anatomic neck. The greater tuberosity has three facets for the corresponding insertions of the supraspinatus, infraspinatus, and teres minor tendons; the lesser tuberosity has a single facet for the subscapularis.
- The deltoid, pectoralis major, and latissimus dorsi all insert on the humerus distal to the surgical neck. These soft tissue attachments contribute to the deforming forces sustained with proximal humerus fractures.
- The anterolateral branch of the anterior humeral circumflex artery (the arcuate artery of Laing) is the major blood supply to the humeral head. This vessel courses parallel to the lateral aspect of the long head of the biceps and enters the humeral head at the interface between the intertubercular groove and the greater tuberosity. Injury to the arcuate artery can result in osteonecrosis of the articular segment. \(^10,^18\)

**PATHOGENESIS**

- The incidence of proximal humerus fractures is increasing with an aging population and associated osteoporosis.
- The mechanism of injury may be indirect or direct and secondary to high-energy collisions in younger patients (eg, motor vehicle accidents, athletic injuries) or falls from standing height in elderly patients.
- Pathologic fractures from primary or metastatic disease should be included in the differential diagnosis.
- Risk factors for the development of proximal humerus fractures in the elderly patient population include low bone density, lack of hormone replacement therapy, previous fracture history, three or more chronic illnesses, and smoking. \(^15\)

**NATURAL HISTORY**

- Neer’s classic study in 1970 compared the results of nonoperative treatment with hemiarthroplasty for three- and four-part displaced proximal humerus fractures. No satisfactory results were found in the nonoperative group owing to inadequate reduction, nonunion, malunion, and humeral head osteonecrosis with collapse. \(^20\)
- Stableforth \(^24\) reaffirmed this in a study in which patients were randomized to nonoperative management or prosthetic replacement. The patients with displaced fractures treated nonoperatively had worse overall results for pain, range of motion, and activities of daily living.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- A thorough history and complete physical examination should be performed. History should include mechanism of injury, pre-morbid level of function, occupation, hand dominance, history of malignancy, and ability to participate in a structured rehabilitation program. \(^14\)
- A review of systems should involve queries regarding loss of consciousness, paresthesias, and ipsilateral elbow or wrist pain.
- On physical examination, the orthopaedic surgeon should look for swelling, soft tissue injuries, ecchymosis, and deformity. Posterior fracture-dislocations will demonstrate flattening of the anterior aspect of the shoulder with an associated posterior prominence. Anterior fracture-dislocations present with opposite findings. \(^14\)

**FIG 1 • Neer classification of proximal humerus fractures:**

1. greater tuberosity; 2. lesser tuberosity; 3. articular surface; 4. shaft.
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Appropriate radiographs include anteroposterior and axillary views of the shoulder (FIG 2). If the axillary view cannot be obtained because of patient discomfort, alternate views such as the Velpeau trauma axillary view can be used to evaluate and classify the glenohumeral articulation.2
- The Neer classification is based on the four anatomic segments of the proximal humerus: the humeral head, the greater and lesser tuberosities, and the humeral shaft (see Fig 1).11 Number of parts is based on 45 degrees of angulation or 1 cm of displacement from neighboring segments.
- The AO/ASIF/OTA Comprehensive Long Bone Classification system distinguishes the valgus impacted four-part proximal humerus fracture from other four-part fractures with partial preservation of the vascular inflow to the articular segment through an intact medial capsule.17,22
- The current fracture classification systems have fair interobserver reliability, even with the addition of CT scans. Despite the limitations of these systems, they remain clinically useful when deciding on nonoperative versus operative treatment.2,11
- CT scans may be helpful in evaluating tuberosity displacement and articular surface involvement.14

DIFFERENTIAL DIAGNOSIS

- Acute hemorrhagic bursitis
- Traumatic rotator cuff tear
- Simple dislocation
- Acromioclavicular separation
- Calcific tendinitis 2

NONOPERATIVE MANAGEMENT

- Nonoperative treatment usually is reserved for minimally displaced fractures of the proximal humerus, which account for nearly 80% of these injuries.
- The characteristics of the fracture (ie, bone quality, fracture orientation, concurrent soft tissue injuries), the personality of the patient (eg, compliant, realistic expectations, mental status), and surgeon experience all affect the decision to proceed with operative intervention.
- Moribund individuals and patients unable to cooperate with a postoperative rehabilitation program (eg, closed head injury) are not appropriate candidates for operative intervention.
- In general, nonoperative management of complex, displaced proximal humerus fractures has not proven as successful.
- Initial immobilization with a sling and axillary pad may be helpful. Gentle range-of-motion exercises may be started by 7 to 10 days after the fracture when pain has decreased and the patient is less apprehensive.2
- Intermittent biplanar radiographs are essential to determine additional displacement and the interval stage of healing.2
- Active and active assisted range-of-motion exercises are initiated with evidence of radiographic union. Inform the patient that he or she may never attain symmetric range of motion or strength when comparing the affected versus the uninjured side.

SURGICAL MANAGEMENT

- The goal of surgery is to anatomically reconstruct the glenohumeral joint with restoration of humeral length, placement of appropriate prosthetic retroversion, and establishment of secure tuberosity fixation.
- Prosthetic replacement is the preferred treatment of most four-part fractures, three-part fractures and dislocations in elderly patients with osteoporotic bone, head-splitting articular segment fractures, and chronic anterior or posterior humeral head dislocations with more than 40% of the articular surface involved.25
- Several studies have indicated that the outcome of primary hemiarthroplasty for acute proximal humerus fractures is superior to that from late reconstruction.6,21

Preoperative Planning

- Although some studies have suggested urgent intervention (ie, within less than 48 hours), most authors recommend preoperative planning with a careful neurovascular assessment of the injured shoulder, medical optimization of the patient, and preoperative templating with standard radiographs of the contralateral uninjured shoulder.12
- An interscalene block (regional anesthesia) may be used to supplement general anesthesia.
- Endotracheal intubation is recommended to allow for intraoperative muscle relaxation, but laryngeal mask intubation may be used.12,14
Positioning
- The patient is placed on an operating table in the beach chair position with the arm positioned in a sterile articulating arm holder or draped free if an appropriate number of assistants are available (FIG 3).

Approach
- The surgical prep site should include the entire upper extremity and shoulder region, including the scapular and pectoral regions.
- Appropriate prophylactic intravenous antibiotics are given to the patient before skin incision.
- A standard deltopectoral incision is used. Care is taken to minimize injury (eg, surgical detachment, contusion secondary to retractors) to the deltoid muscle. The musculocutaneous and axillary nerves are identified and protected during the procedure.

DE尔TOPECTORAL APPROACH
- The incision begins superior and medial to the coracoid process and extends toward the anterior aspect of the deltoid insertion (TECH FIG 1A).
- The cephalic vein is identified, preserved, and retracted laterally with the deltoid muscle. The pectoralis major is mobilized medially. If additional exposure is necessary, the proximal 1 cm of the pectoralis major insertion is released (TECH FIG 1B).
- Fracture hematoma usually is encountered once the clavipectoral fascia is incised. At this time, fracture fragments and the rotator cuff musculature become evident. The axillary and musculocutaneous nerves can be identified through digital palpation of the anteroinferior aspect of the subscapularis muscle and the posterior aspect of the coracoid muscles respectively. External rotation of the humerus results in reduced tension on the axillary nerve.

TUBEROSITY MOBILIZATION
- The tendon of the long head of the biceps is identified as it courses in the bicipital groove toward the rotator interval. The tendon serves as a key landmark when re-establishing the anatomic relationship between the greater and lesser tuberosities.
- The rotator interval and coracohumeral ligament are both released to allow for mobilization of the tuberosities (TECH FIG 2A,B).
- If the fracture does not involve the bicipital groove, an osteotome or saw may be used to create a cleavage plane for tuberosity mobilization. Preservation of the coracocromial ligament is advisable to maintain the coracocromial arch.
- Heavy, nonabsorbable traction sutures (eg, 1-mm cottony Dacron) are placed through the rotator cuff insertions on the tuberosities. Two or three sutures should be placed through the subscapularis tendon, and three or four sutures through the supraspinatus.
- Tuberosity fragments vary in size and may require trimming for reduction and repair (TECH FIG 2C,D).
With the tuberosities retracted on their muscular insertions, the humeral head and shaft fragments are removed.

The native articular surface is removed and sized with a template for trial humeral head replacement (TECH FIG 2E).

The glenoid must be examined for concomitant pathology. Hematoma and cartilaginous or bony fragments are removed with sterile saline irrigation.

Glenoid fractures should be stabilized with internal fixation. If the glenoid exhibits significant degenerative wear or irreparable damage, a glenoid component must be used.
HUMERAL SHAFT PREPARATION

- The proximal end of the humeral shaft is delivered into the incisional wound. Loose endosteal bone fragments and hematoma are removed from the canal of the humeral shaft.
- Axial reamers, preferably without power, are used to prepare the humeral shaft for trial implantation.
- The trial humeral implant is placed with the lateral fin slightly posterior to the bicipital groove, and with the medial aspect of the trial head at least at the height of the medial calcar.
- Formerly, we used a sponge to anchor the trial stem within the intramedullary canal of the humerus. We currently use a commercially available fracture jig that can maintain the height and retroversion of the trial component through a functional range of motion (TECH FIG 3).12,14

DETERMINATION OF HUMERAL RETROVERSION

- Correct humeral retroversion is critical when recreating the glenohumeral articulation. Most techniques suggest 30 degrees as a guide during reconstruction, although native retroversion may vary from 10 to 50 degrees.
- Several methods are employed to gauge this angle:
  - External rotation of the humerus to 30 degrees from the sagittal plane of the body with the humeral head component facing straight medially
  - An imaginary line from the distal humeral epicondylar axis that bisects the axis of the prosthesis
  - Positioning of the lateral fin of the prosthesis about 8 mm posterior to the biceps groove (TECH FIG 4).

DETERMINATION OF PROSTHETIC HEIGHT

- The prosthetic height also is critical in re-establishing appropriate muscle tension and shoulder mechanics.
- Preoperative templating may be helpful.
- Intraoperative examination of soft tissue tension, including the deltoid, rotator cuff, and the long head of the biceps, combined with fluoroscopic imaging aids in prosthetic height placement.
- Common errors involve placing the prosthesis too low, resulting in poor deltoid muscle tension and no room for the tuberosities (TECH FIG 5).
- Drill holes are placed in the proximal humerus medial and lateral to the bicipital groove, with 1-mm cottony Dacron sutures subsequently passed for fixation of the tuberosity to the shaft (TECH FIG 6A).

- A trial reduction is then performed with the mobilized tuberosities fitted below the head of the modular prosthesis.

- A towel clip can be used to hold the tuberosities for fluoroscopic examination and assessment of glenohumeral stability.

- Intraoperative fluoroscopy is helpful in confirming appropriate implant height and glenohumeral stability (TECH FIG 6B).

- The humeral head should not subluxate more than 25% to 30% of the glenoid height inferiorly.

**TECH FIG 5** Height adjustment. A commercially available fracture jig permits intraoperative height adjustment. Similarly, a sponge may be placed holding the trial stem at a determined level, allowing for intraoperative assessment. (Copyright Steven B. Lippitt, MD.)

**TECH FIG 6** • A. Humeral shaft preparation. Drill holes are placed in the proximal humerus medial and lateral to the bicipital groove with 1-mm cottony Dacron sutures. B. Trial reduction. A trial reduction may be performed with the fracture jig in place, allowing assessment of the functional range of motion. (Copyright Steven B. Lippitt, MD.)

**FINAL IMPLANT PLACEMENT**

- The final humeral component should be cemented in all fracture patients.
  - A cement restrictor is placed to prevent cement extravasation distally.

- Pulsatile lavage and retrograde injection of cement with suction pressurization also is used (TECH FIG 7A). Excess cement is removed during the curing phase.
- Spaces between the tuberosities, prosthesis, and shaft are packed with autogenous cancellous bone graft from the resected humeral head (TECH FIG 7B).
- A second trial reduction may be performed with a trial head after cement fixation of the humeral stem.
- The final head may be impacted before stem implantation or after the repeat trial reduction.
- A cerclage suture is placed circumferentially around the greater tuberosity and through the supraspinatus insertion, and then medial to the prosthesis and through the subscapularis insertion (lesser tuberosity). Several authors have indicated superior fixation with the cerclage suture when compared to tuberosity-to-tuberosity and tuberosity-to-fin fixation alone.\textsuperscript{23}
- Overreduction of the tuberosities should be avoided to prevent limitations in external (lesser tuberosity) and internal (greater tuberosity) rotation.
- Sutures are then tied, beginning with tuberosity-to-shaft reapproximation, followed by tuberosity-to-tuberosity closure using the previously placed suture limbs (TECH FIG 7C).
- The lateral portion of the rotator interval is closed with the arm in approximately 30 degrees of external rotation.

**TECH FIG 7**  
A. A cement restrictor is placed to prevent cement extravasation distally. Pulsatile lavage and retrograde injection of cement with suction pressurization is also used.  
B. Morselized cancellous bone graft is placed between the tuberosities and shaft.  
C. Tuberosity fixation. Previously placed suture limbs through the tuberosities and shaft are reapproximated. Not shown: a medial cerclage suture is placed circumferentially around the greater tuberosity and through the supraspinatus insertion, and then medial to the prosthesis and through the subscapularis insertion (lesser tuberosity) and tied.  
D. The rotator interval is closed with no. 2 nonabsorbable suture with the arm in about 30 degrees of external rotation. (A, C, D: Copyright Steven B. Lippitt, MD. B: Courtesy of DePuy Orthopaedics.)

**SURGICAL WOUND CLOSURE**

- The deltopectoral interval usually is not closed. Drain suction is recommended in both acute and chronic injuries to prevent hematoma formation.
- A commercially available pain pump may be used to augment postoperative analgesia and to reduce narcotic medication use.
- The subcutaneous tissues are reapproximated with 2-0 absorbable suture. Subcuticular closure is performed with 2-0 monofilament suture.
- The patient is then placed in a sling or shoulder immobilizer with 45 degrees of abduction for comfort.
PEARLS AND PITFALLS

</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Physician-directed therapy is initiated on postoperative day 1 with gentle, gravity-assisted pendulum exercises, as well as passive pulley-and-stick exercises to maintain forward flexion and external rotation (motion limits placed by surgeon based upon intraoperative stability).
- After discharge, the patient’s wound is re-examined and sutures removed at 10 to 14 days. Gentle range-of-motion exercises are continued.
- At 6 weeks, repeat radiographs are obtained to evaluate tuberosity healing. When tuberosity healing is evident, phase 2 exercises are initiated with isometric rotator cuff exercises and active assisted elevation with the pulley.
- At 3 months, strength training with graduated rubber bands (phase 3) is implemented. Maximal motion and function are obtained at about 12 months from date of surgery.

OUTCOMES

- About 90% of patients treated with hemiarthroplasty demonstrate minimal pain, despite a wide range of function, motion, and strength.
- Factors that portend a poor outcome after hemiarthroplasty for fractures include tuberosity malposition, superior migration of the humeral prosthesis, stiffness, persistent pain, poor initial positioning of the implant (excessive retroversion, decreased height), and age over 75 years in women.4
- When comparing acute intervention versus late reconstruction, most authors report poorer outcomes with delayed surgical intervention (more than 2 weeks), particularly with functional results.20,25,26

COMPLICATIONS

- Complications include delays in wound healing, infection, nerve injury, humeral fracture, component malposition, instability, nonunion of the tuberosities, rotator cuff tearing, regional pain syndrome, periarticular fibrosis, heterotopic bone formation, component loosening, and glenoid arthritis.3,7,19
- The most common problems in acute fracture treatment involve stiffness, nonunion, malunion or resorption of the tuberosities.7,19
- In patients with chronic fractures treated with hemiarthroplasty, the most common problems encountered were instability, heterotopic ossification, tuberosity malunion or nonunion, and rotator cuff tears.19

REFERENCES

DEFINITION
- Humeral shaft fractures, which account for about 3% of adult fractures, usually result from a direct blow or indirect twisting injury to the brachium.
- These injuries are most commonly treated nonoperatively with a prefabricated fracture brace. The humerus is the most freely movable long bone, and anatomic reduction is not required.
- Patients often can tolerate up to 20 degrees of anterior angulation, 30 degrees of varus angulation, and 3 cm of shortening without significant functional loss.
- There are, however, several indications for surgical treatment of humeral shaft fractures:
  - Open fracture
  - Bilateral humeral shaft fractures or polytrauma; floating elbow
  - Segmental fracture
  - Inability to maintain acceptable alignment with closed treatment (ie, angulation greater than 15 degrees)—seen more commonly with transverse fractures
  - Humeral shaft nonunion
  - Pathologic fractures
  - Arterial or brachial plexus injury
- Open reduction with internal plate fixation requires extensive dissection and operative skill. However, it offers advantages over intramedullary fixation because the rotator cuff is not violated, which leads to improved postoperative shoulder function.

ANATOMY
- The humeral shaft is defined using Key’s landmarks: the area between the upper margin of the pectoralis major tendon and the supracondylar ridge.
- The blood supply of the humeral shaft comes from the posterior humeral circumflex vessels and branches of the brachial and profunda brachial arteries.
- The radial nerve and profunda brachial artery pass through the triangular interval (bordered superiorly by the teres major, medially by the medial head of the triceps, and laterally by the humeral shaft). The nerve then transverses from medial to lateral behind the humeral shaft and travels distally to a location between the brachialis and brachioradialis muscles.
- The musculocutaneous nerve lies on the undersurface of the biceps muscle and terminates distally as the lateral antebrachial cutaneous nerve.
- The humeral shaft has anteromedial, anterolateral, and posterior surfaces. Proximal and midshaft fractures are more amenable to plating on the anterolateral surface, whereas distal fractures often require posterior plate fixation.

PATHOGENESIS
- Humeral shaft fractures occur after both direct and indirect injuries. Direct blows to the brachium can fracture the humeral shaft in a transverse pattern, often with a butterfly fragment. Injuries with high degrees of energy often result in a greater degree of fracture comminution.
- Indirect injuries, such as those that can occur with activities such as arm wrestling, often involve a twisting mechanism and result in a spiral fracture pattern. Higher-energy injuries may result in muscle interposition between the fracture fragments, which can inhibit reduction and healing.
- A study of 240 humeral shaft fractures revealed radial nerve palsies in 42 patients, for an overall rate of 18% (17% in closed injuries). Fractures in the midshaft were more likely to have concomitant radial nerve palsy. Twenty-five of these patients had complete recovery in a range of 1 day to 10 months. Ten patients did not have radial nerve recovery. Median and ulnar nerve palsies were seen very rarely in patients with open fractures.
- Concomitant vascular injuries are present in about 3% of patients with humeral shaft fractures.

NATURAL HISTORY
- Almost all humeral shaft fractures heal with nonoperative management. The most common treatment method is initial splinting from shoulder to wrist, followed by application of a prefabricated fracture brace when the patient is comfortable, usually within 2 weeks of the injury.
- Studies by Sarmiento and coauthors have shown the effectiveness of functional bracing in the treatment of humeral shaft fractures. Nonunion rates with this method of treatment are in the 4% range, lower than seen when treating with external fixators, plates, or intramedullary nails.
- Closed fractures with initial radial nerve palsy can be observed, with expected recovery over a period of 3 to 6 months. Late-developing radial nerve palsies require surgical exploration.
- Angulation of the humeral shaft after fracture healing is expected and is well tolerated when it is less than 20 degrees. Varus deformity is most common.
- Adjacent joint stiffness of the shoulder and elbow also is common. If the situation dictates treatment, physical therapy reliably restores joint motion in these patients.
- Relative contraindications to closed treatment include bilateral humeral shaft fractures or patients with polytrauma who require an intact brachium to ambulate. Transverse fractures and those with significant muscle imposition also are more amenable to operative fixation.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The examining physician must perform a complete examination of the affected limb to rule out concomitant injuries.
- The skin should be thoroughly evaluated for evidence of an open fracture. This includes examination of the axilla.
and exit wounds are sought in gunshot victims. Swelling is common, and the patient may have an obvious deformity.

- The patient often braces the affected limb to his or her side, making evaluation of shoulder and elbow range of motion difficult. Bony prominences should be gently palpated to evaluate for other injuries, such as an olecranon fracture.
- Evaluate the appearance and skeletal stability of the forearm to rule out the presence of a co-existing both-bone forearm fracture (“floating elbow”). This finding necessitates operative fixation of humeral, radial, and ulnar fractures.
- Determine the vascular status of the upper extremity by palpating the radial and ulnar pulses at the wrist. Compare these findings with the unaffected limb. Selected cases may require Doppler arterial examination.\(^2\)
- A complete neurologic assessment is necessary, with particular attention focused on the status of the radial nerve. This structure is at risk proximally as it passes posterior to the humeral shaft after emerging from the triangular interval, as well as distally, as it lies adjacent to the supracondylar ridge (near the location of the Holstein-Lewis distal one-third spiral humeral shaft fracture).
- Examine sensory function in the first dorsal web space, wrist extension, and thumb interphalangeal joint extension to determine the functional status of the radial nerve.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- At least two plain radiographs at 90-degree angles to each other are necessary to evaluate the displacement, shortening, and comminution of the humeral shaft fracture.
- Radiographic views of the shoulder and elbow are necessary to rule out proximal extension of the shaft fracture or concomitant elbow injury (ie, olecranon fracture). This is especially important in high-energy injuries
- If swelling or evidence of skeletal instability about the forearm is present, dedicated forearm radiographs can determine the presence of a floating elbow (ie, ipsilateral humeral shaft fracture plus both-bone forearm fractures).

**DIFFERENTIAL DIAGNOSIS**

- Distal humerus fracture
- Proximal humerus fracture
- Elbow dislocation
- Shoulder dislocation

**NONOPERATIVE MANAGEMENT**

- Most isolated humeral shaft fractures can be treated nonoperatively. Initial treatment can vary with fracture location and involves splinting in either a posterior elbow or coaptation splint. The elbow is positioned in 90 degrees of flexion. An isolated humeral shaft fracture rarely necessitates an overnight hospital stay.
- In the past, definitive nonoperative treatment involved coaptation splinting or the use of hanging arm casts. Currently, functional fracture bracing provides adequate bony alignment, while local muscle compression and fracture motion promote osteogenesis. These braces provide soft tissue compression and allow functional use of the extremity.\(^11\)
- Timing of brace application depends on the degree of swelling and patient discomfort. On average, the brace is applied about 2 weeks after the injury. A collar and cuff help with initial patient comfort and should be worn during recumbency until the fracture heals.
- The brace often requires frequent retightening over the first 2 weeks as swelling subsides. Elbow and wrist range-of-motion exercises out of the sling are encouraged.
- Functional bracing requires that the patient be able to sit erect, and weight bearing on the humerus is not allowed. The level of humeral shaft fracture does not preclude the use of functional bracing, even if the fracture line extends above or below the brace.
- Anatomic alignment of the humerus rarely is achieved, with varus deformity most common. However, patients often are able to tolerate the bony angulation and still perform activities of daily living after injury. A cosmetic deformity rarely exists.
- Pendulum exercises are encouraged as soon as possible post-injury. Active elevation and abduction are avoided until bony healing has occurred, to prevent fracture angulation. The surgeon obtains radiographs after brace application and again 1 week later. If alignment is acceptable, repeat radiographs are obtained at 3- to 4-week intervals until fracture healing occurs.\(^10,11\)

**SURGICAL MANAGEMENT**

- Certain humeral shaft fractures are not amenable to conservative treatment. Open fractures or high-energy injuries with significant axial distraction are treated with open reduction and internal fixation. Patients with polytrauma, bilateral humeral shaft fractures, vascular injury, or an inability to sit erect are best treated with operative fixation. Unacceptable fracture alignment requires abandonment of nonoperative treatment. Finally, humeral shaft nonunion is a clear indication for open reduction and internal fixation with bone grafting.\(^4,9\)

**Preoperative Planning**

- The surgeon must review all radiographic images and must rule out ipsilateral elbow or shoulder injury.
- Preoperative radiographs help the surgeon estimate the required plate length. Higher-energy injuries with comminution may benefit from plating and supplemental bone grafting. The surgeon must plan for various scenarios based on these studies: moderate comminution or bone loss can be addressed with cancellous allograft or autograft bone, whereas more extensive bone defects may require strut grafting.
- Proximal and middle-third humeral shaft fractures are addressed using an anterolateral approach. Distal-third humeral shaft fractures often are treated via a posterior approach, because the distal humeral shaft is flat posteriorly, making it an ideal location for plate placement.
- Fracture patterns with extension into the proximal humerus can be exposed with a deltopectoral extension to the anterolateral humeral dissection.
- The surgeon notes any pre-existing scars that may affect the desired surgical approach, and neurovascular status is documented, with particular attention to radial nerve function.

**Positioning**

- Positioning depends on the intended surgical approach. For an anterolateral or medial approach, the patient is brought to the edge of the bed in the supine position. A hand table is attached to the bed and the patient’s injured arm is placed on the hand table in slight abduction (FIG 1A).
For a posterior approach, the patient can be placed prone or in the lateral decubitus position. A stack of pillows can support the brachium during the procedure (FIG 1B).

**Approach**

- The approach depends on fracture location and the presence of any previous surgical incisions. The anterolateral and posterior approaches to the humerus are used most commonly, for proximal two-third and distal third fractures, respectively.
- In patients who have already undergone multiple procedures to the affected extremity, Jupiter recommends consideration of a medial approach to take advantage of virgin tissue planes.

**ANTEROLATERAL APPROACH TO THE HUMERUS**

- The incision courses over the lateral aspect of the biceps, beginning proximally at the deltoid tubercle and terminating just proximal to the antecubital crease (TECH FIG 1).
- A tourniquet rarely is used, because it often limits proximal exposure.
- The lateral antebrachial cutaneous nerve lies in the distal aspect of the incision and must be protected during exposure.
- Bluntly enter the interval between the biceps and brachialis by sweeping a finger from proximal to distal.

---

TECH FIG 1 • A. Anterolateral incision. B. Skin and subcutaneous tissue incised. C. Retractor on brachialis muscle, forceps on brachioradialis. D. Musculocutaneous nerve on undersurface of biceps muscle. E. Radial nerve in interval between brachialis and brachioradialis. (continued)
At the level of the midhumerus, identify the musculocutaneous nerve on the undersurface of the biceps muscle. Trace this nerve out distally to protect its terminal branch, which forms the lateral antebrachial cutaneous nerve.

Distally, the interval between the brachialis and brachioradialis is dissected to expose the radial nerve. Protect the radial nerve with a vessel loop so that it can be identified at all times.

The brachialis is split in line with its fibers between the medial two thirds and lateral one third. This is an intermuscular plane between the radial nerve medially and the musculocutaneous nerve laterally.

Identify the fracture site and proceed with reduction and fixation.

**POSTERIOR APPROACH TO THE HUMERUS**

Make a generous incision over the midline of the posterior arm extending to the olecranon fossa (TECH FIG 2).

Identify the interval between the long and lateral heads of the triceps proximally. Bluntly dissect this interval, taking the long head medially and the lateral head laterally.

Distally, several blood vessels cross this plane; they require coagulation before transection.

Identify the radial nerve proximal to the medial head of the triceps in the spiral groove. Protect the radial nerve throughout the case.

Split the medial head of the triceps in its midline from proximal to distal to expose the fracture site.
FRACTURE REDUCTION

- Sharp periosteal dissection exposes the fracture site. Evaluate the degree, if any, of comminution.
- Limit periosteal stripping to adequately expose the fracture. Make every attempt to leave some soft tissue attached to each fragment so as not to devascularize the fragments.
- Gentle traction and rotation often can bring the fracture fragments into better alignment.
- Anatomically reduce the fracture with one or more reduction clamps. It is advisable to reduce the fracture completely before definitive fixation, and this often requires the use of multiple reduction clamps (TECH FIG 3).
- After the fracture is reduced, the fragments can be provisionally fixed with Kirschner wires. Place the wires so as not to interfere with plate fixation.
- Alternatively, 3.5- or 4.5-mm interfragmentary screws can be used to hold the fracture aligned until plate fixation.
- Transverse fractures with minimal comminution often can be directly reduced with the plate and Faberge clamps.

TECH FIG 3 • A. Fracture reduction maintained temporarily. B. Hold the plate over the reduced fracture with a plate-holding clamp.

EXPOSURE OF FRACTURE NONUNION

- Exposure of the radial nerve is more challenging, but it is very important in this situation. In many cases it is best to dissect out the nerve distally in the interval between the brachialis and brachioradialis and proximally medial to the spiral groove. The nerve is then carefully dissected free from the nonunion site.
- Pinpoint the exact location of the nonunion with a no. 15 scalpel.
- The ends of the nonunion can be brought out through the wound, and all fibrous material is extracted.
- After thorough fracture débridement, the amount of bone loss becomes clear. The surgeon can now determine whether standard cancellous bone grafting or strut grafting is necessary.
PLATE FIXATION OF HUMERAL SHAFT FRACTURES

**PLATE APPLICATION**

- After fracture reduction, the plate length is determined.
- Humeral shaft fractures require at least six cortices of fixation above and below the fracture site.
- In larger bones, a broad 4.5-mm dynamic compression plate can provide optimal fixation. In smaller bones, a 4.5-mm limited contour dynamic compression plate often provides a better fit.
- Provisionally place the plate on a flat surface of the humerus and hold it in place with a plate-holding clamp.
- 4.5-mm cortical screws are placed through the plate holes proximal and distal to the fracture. Compression techniques can be used, where appropriate.
- Ensure that no soft tissue, especially nerve, is trapped between the plate and the bone.
- Make sure to obtain screw purchase in at least six cortices above and below the fracture (TECH FIG 4).
- Cerclage wiring over the plate can add supplemental fixation, especially in weak bone.
- Rotate the arm and flex and extend the elbow to evaluate fracture stability.
- Apply cancellous bone graft into defects as needed.

**TECH FIG 4**

**A.** Plate spanning the fracture site with at least six cortices of fixation proximally and distally. **B.** Anterior plate with a probe pointing to the radial nerve as it exits the spiral groove posteriorly (proximal is to the right, distal to the left). **C.** Supplemental cerclage wire fixation can augment stability in weak bone.

**MEDIAL APPROACH**

- Positioning is similar to the anterolateral approach.
- Make an incision over the medial intermuscular septum from the axilla to 5 cm proximal to the medial epicondyle (TECH FIG 5).
- Mobilize the ulnar nerve.
- Resect the medial intermuscular septum; identify and coagulate the adjacent venous plexus with bipolar electrocautery.
- Mobilize the triceps posteriorly and the biceps/brachialis anteriorly.
- Expose the fracture site.
- The axillary incision raises concern for infection; there is also concern that the ulnar nerve can scar to the plate.

**TECH FIG 5**

**A.** Incision for the medial approach. (continued)
PEARLS AND PITFALLS

Indications
■ Operative treatment is reserved for open fractures, patients with multiple fractures, and fractures with inadequate reduction.

Preoperative planning
■ Review all radiographs and determine the best surgical approach.
■ Estimate potential plate length and prepare for possible bone grafting.

Surgical exposure
■ Locate and protect the radial nerve.
■ Expose and reduce fracture fragments and temporarily hold them in place with pins or clamps.
■ Alternatively, fix larger fragments with interfragmentary screws.

Plate fixation
■ Ensure that plate length allows six cortices of fixation proximal and distal to the fracture.
■ Use 4.5-mm dynamic compression plates or limited contact dynamic compression plates.
■ Use compressive techniques when indicated.

Radial nerve function
■ Preoperatively, document a detailed neurovascular examination.
■ Ensure that the radial nerve is not trapped within the plate before closure.

POSTOPERATIVE CARE
■ Postoperative radiographs ensure proper fracture alignment and plate placement (FIG 2).
■ Initially, the patient can be placed in a sling or posterior elbow splint. This is removed and range-of-motion exercises are started when patient comfort allows (usually 1 to 2 days postoperative).
■ Weight bearing on the affected upper extremity is allowed based on patient comfort.12
■ Initial therapy consists of elbow range-of-motion and shoulder pendulum and passive self-assist exercises.
■ The patient can come out of the sling after 2 weeks and start waist-level activities with the operative arm.
■ At 6 weeks, elbow motion should be near normal range, and shoulder strengthening is added to the patient’s physical therapy.
■ At 3 months, radiographs should reveal some callus formation. If no callus is evident, radiographs are repeated every 6 weeks until evidence of healing appears.
OUTCOMES

- Plate fixation leads to union in 90% to 98% of cases.
- Plating offers decreased complication rates compared to intramedullary nailing, especially in terms of shoulder dysfunction.8
- Iatrogenic radial nerve palsy occurs in about 2% to 5% of cases and usually resolves in 3 to 6 months. Electromyography helps monitor return of nerve function in patients with prolonged palsy. Radial nerve exploration is indicated when no nerve function returns by 6 months.
- Elbow and shoulder range of motion usually return to normal postoperatively.

COMPLICATIONS

- Infection
- Nonunion
- Malunion
- Hardware failure
- Radial nerve palsy
- Shoulder impingement
- Elbow stiffness

REFERENCES

DEFINITION
- Incidence: 3% to 5% of all fractures
- The AO/ASIF classification of humeral shaft fractures is based on increasing fracture comminution and is divided into three types according to the contact between the two main fragments:
  - Type A: simple (contact > 90%)
  - Type B: wedge/butterfly fragment (some contact)
  - Type C: complex/comminuted (no contact)
- Intramedullary nailing (IMN) can be used to stabilize fractures 2 cm distal to the surgical neck to 3 cm proximal to the olecranon fossa.
- The precise role of IMN is not defined. Proponents offer the following benefits over formal open reduction with internal fixation (ORIF): it is minimally invasive, causing limited soft tissue damage and no periosteal stripping (preservation of vascular innervation); it is biomechanically superior; it is cosmetically advantageous (smaller incision); it is capable of indirect diaphyseal fracture reduction and metaphyseal fracture approximation.
- Complications such as shoulder pain, delayed union or nonunion, fracture about the implant, iatrogenic fracture comminution, and difficulty in the reconstruction of failures, raise questions regarding the usefulness of intramedullary nailing over ORIF.
- Biomechanically, intramedullary nails are closer to the normal mechanical axis; consequently they act as a load-sharing device if there is cortical contact.
- Unlike plate-and-screw fixation, a load-bearing construct, intramedullary nails are subjected to lower bending forces, making fatigue failure and cortical osteopenia secondary to stress shielding less likely.

ANATOMY
- Comparatively, there are several anatomic differences between the long bones of the upper extremity versus the long bones of the lower extremity (femur, tibia):
  - The medullary canal terminates at the metaphysis (versus diaphysis).
  - Isthmus: junction is at the middle-distal third (versus proximal-middle third).
  - Trumpet shape: the proximal two thirds of the humeral canal is cylindrical; distally, the medullary canal rapidly tapers to a prismatic end at the diaphysis (hard cortical bone) versus the wide flare of the metaphysis (soft cancellous bone).
  - Because of the funnel shape of the humeral shaft, a true interference fit is difficult to obtain; therefore, proximal and distal static locking has become the standard of care for IMN of humeral fractures.
- Neurovascular considerations include average distances of key structures from notable bony landmarks:
  - Axillary nerve to proximal humerus, 6.1 ± 0.7 cm (range 4.5 to 6.9 cm)

PATHOGENESIS
- Biomodal distribution
- Young, male 21 to 30 years old: high-energy trauma
- Older, female 60 to 80 years old: simple fall/rotational injury
- 5% open
- 63% AO/ASIF type A fracture patterns
- Various loading modes and the characteristic fracture patterns they create
  - Tension: transverse
  - Compression: oblique
  - Torsion: spiral
  - Bending: butterfly
  - High-energy: comminuted
- Red flags:
  - Minimal trauma indicates a pathologic process
  - Disconnect between history and fracture type suggests domestic abuse.

NATURAL HISTORY
- The humerus is well enveloped in muscle and soft tissue, hence its good prognosis for healing in most uncomplicated fractures.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with humeral shaft fractures present with arm pain, deformity, and swelling.
- Demographics, medical history, and information regarding the circumstance and mechanism of injury should be obtained.
- Particularly significant in upper extremity trauma: hand dominance, occupation, age, and pertinent comorbidities must be solicited from the patient. All of these factors play a major role in determining whether to pursue surgical versus nonsurgical treatment.
- On physical examination, the arm is typically shortened, angulated, or grossly deformed, with motion and crepitus on manipulation.
- Document the status of the skin (open versus closed fracture) and perform a careful neurovascular evaluation of the limb.
Chapter 21  INTRAMEDULLARY FIXATION OF HUMERAL SHAFT FRACTURES

NONOPERATIVE MANAGEMENT

- Most non- or minimally displaced humeral shaft fractures can be successfully treated nonoperatively, with union rates of more than 90% often reported.12
- Common closed techniques include hanging arm cast; coaptation splint; Velpeau dressing; abduction humeral/shoulder spica cast; functional brace; and traction.
  - Each of these modalities has been successfully employed, but most commonly either a hanging arm cast or coaptation splint is used for 1 to 2 weeks, followed by a functional brace, tightened as the swelling decreases.
  - Hanging arm casts are a very good option for displaced, midshaft humeral fractures with shortening, especially oblique or spiral fracture patterns, if the cast is able to extend 2 cm or more proximal to the fracture site.
  - For nonoperative treatment to be effective, the patient should remain upright, either standing or sitting, and avoid leaning on the elbow for support. This allows for gravitational force to assist in fracture reduction.
  - As soon as possible, the patient should begin range-of-motion exercises of the fingers, wrist, elbow, and shoulder to minimize dependent swelling and joint stiffness.
  - Acceptable alignment of humeral shaft fractures is considered to be 3 cm of shortening, 30 degrees of varus/valgus angulation, and 20 degrees of anterior/posterior angulation.10
  - Varus/valgus angulation is tolerated better proximally, and more angulation may be tolerated better in patients with obesity.
  - Patients with large pendulous breasts are at increased risk for varus angulation if treated nonsurgically.
  - No set values for acceptable malrotation exist, but compensatory shoulder motion allows for considerable tolerance of rotational deformity.10
  - Low-velocity gunshot wounds act as closed injuries after initial treatment. Following irrigation and débridement of skin at entry and exit sites, tetanus status confirmation, and prophylactic antibiotic initiation, nonoperative treatment modalities are commonly employed.10

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Initial studies must always include orthogonal views (anteroposterior [AP] and lateral radiographs) of the fracture site, shoulder, and elbow (FIG 1). To obtain these radiographs, move the patient rather than rotating the injured limb through the fracture site.
  - Traction radiographs may be helpful with comminuted or severely displaced fractures, and comparison radiographs of the contralateral side may be helpful for determining preoperative length.
  - CT scans rarely are indicated. Rare situations in which they should be obtained include significant rotational abnormality, precluding accurate orthogonal radiographs, and suspicion of possible intra-articular extension or an additional fracture or fractures at a different level.
  - Doppler pulse and compartment pressures should be checked if indicated following a thorough physical examination.
  - Suspicion of vascular injuries warrants an angiogram.

DIFFERENTIAL DIAGNOSIS

- Osteoporosis
- Pathologic fractures
- High- or low-energy trauma
- Open or closed fractures
- Domestic abuse

FIG 1 • AP and lateral radiographs of a displaced humeral shaft fracture, shortened and in varus angulation.
Polytrauma
- Spinal cord or brachial plexus injuries
- Poor soft tissue over the fracture site(s), such as thermal burns
- The most commonly cited overall best indication for IMN from this extensive list is a pathologic or impending pathologic fracture.
- The need for operative intervention secondary to radial nerve dysfunction after closed manipulation is controversial.
- There are advocates for both early nerve exploration and observation.
- This condition was once thought to be an automatic indication for surgery; however, this assumption has since been called into question.  
- Isolated comminution is not an indication for operative treatment. However, if surgical fixation is chosen over nonoperative management, antegrade IMN currently is favored over plate fixation for comminuted fractures.  

Relative contraindications include:
- Open epiphyses
- Narrow intramedullary canal (ie, < 9 mm)
- Prefracture deformity of the humeral shaft
- Open fractures with obvious radial nerve palsy and neurologic loss after penetrating stab injuries
- The last two conditions require nerve exploration with subsequent plate-and-screw fixation.
- Chronically displaced fractures should be treated with ORIF rather than IMN to prevent traction-induced brachial plexus palsy and radial nerve injury.

Preoperative Planning
- When selecting implant size, consider canal diameter, fracture pattern, patient anatomy, and postoperative protocol.
- Nail length and diameter should take into account the distal narrowing of the humerus.
- Estimations of the nail diameter, length, and necessity of reaming can be made using preoperative roentgenograms of the uninjured humerus.
- Alternatively, the length and diameter of the medullary canal can be ascertained intraoperatively using a radiopaque gauge and C-arm imaging of the intact humerus. Use of a radiolucent table top will substantially improve the quality of the image as well as the ability to obtain accurate C-arm images.
- Position the gauge anterior to the unaffected humerus with its distal end 2.5 cm or more proximal to the superior edge of the olecranon fossa and 1 cm distal to the superior edge of the articular surface.
- Move the C-arm to the proximal end of the humerus and read the correct length directly from the stamped measurements on the nail length gauge. The IMN should end approximately 1 to 2 cm proximal to the olecranon fossa.
- Measure the length of the IMN to allow the proximal end to be buried. This will reduce the incidence of subacromial impingement if an antegrade technique is used, or encroachment on the olecranon fossa and blocked elbow extension if a retrograde approach is chosen.
- In comminuted fractures, carefully chose the length to avoid distracting the humerus, which predisposes the patient to delayed union or nonunion.
- Measure the diameter of the medullary canal at the narrowest part that will contain the nail.

- In retrograde nailing, it is important to determine the relation between alignment of the humeral canal and the entry point of the nail by measuring the anterior deviation/distal humeral offset of the distal canal on the preoperative lateral radiograph.
- Based on these calculations, if the deviation is small, make a distal, long entry portal that includes the superior border of the olecranon fossa.
- If the anterior deviation is large, however, make the entry portal more proximal and shorter in length.

Positioning
- The patient’s position for surgery is determined based on the method chosen for fixation.

Antegrade Intramedullary Nailing
- Place the patient in either a beach chair or supine position on a radiolucent table with the head of the bed elevated 30 to 40 degrees (FIG 2).
- Put a small roll between the medial borders of the scapula and rotate the head to the contralateral side to increase exposure of the shoulder.
- Certain fracture patterns may call for skeletal traction.
- If it is used, place an olecranon pin and apply intermittent traction to avoid brachial plexus palsy.
- Clinically assess the rotational alignment by placing the shoulder in an anatomic position and rotating the distal fragment of the fracture humerus so that the arm and hand point toward the ceiling and the elbow is flexed 90 degrees.
- Prepare the affected extremity and drape the arm free in the typical manner. The operative area should encompass the shoulder proximal to the nipple line, the midline of the chest to the nape of the neck, and the entire affected extremity to the fingertips.
- Bring the patient to the edge of the radiolucent table to improve the ability to obtain orthogonal C-arm images of the affected extremity.
- It may be necessary to have the patient lying partially off the table on a radiolucent support.
- Cover the C-arm imager with a sterile isolation drape. Most commonly, the C-arm is brought in directly lateral on the injured side, although some surgeons favor coming in from the contralateral side.
- Regardless of which direction the C-arm is brought into the field, it is imperative to obtain orthogonal views of the entire humerus before the first incision is made.

Retrograde Intramedullary Nailing
- Put the patient in the lateral decubitus or prone position with dorsum placed near the edge of the operating table.
- If the patient is in the prone position, the affected arm may be supported on a radiolucent arm board, or placed over a bolster or paint roller upper extremity support. The latter two options facilitate access to the olecranon fossa and prevent a traction injury to the brachial plexus. The arm should be positioned in 80 degrees of abduction with the elbow flexed at least 90 degrees.
- If the lateral decubitus position is used, suspend the fractured extremity, taking care not to distract the fracture site or cause neurovascular compromise. Suspension can be aided by an olecranon pin.
Prepare the affected extremity and drape the arm free in the typical manner. Include the distal clavicle, the acromion, the medial scapula, and the entire arm and hand in the operative field.

Cover the C-arm imager with a sterile isolation drape.

Bring the C-arm from the ipsilateral side and make sure that adequate orthogonal C-arm images are possible before making the surgical approach.

**Approach**

- Standard locked intramedullary humeral nails can be inserted either antegrade or retrograde.

## Antegrade Intramedullary Nailing

**Approach**

- The antegrade approach, which has been the traditional method of IMN, typically involves a starting point at the proximal humerus—either through the rotator cuff, where the tissue is less vascular, or just lateral to the articular surface, where the blood supply is higher (TECH FIG 1).

- Palpate and outline the surface anatomy of the acromion, clavicle, and humeral head.
  - Feel the anterior and posterior borders of the humeral head to locate and mark the midline.
  - Make a small longitudinal incision at the anterolateral corner of the acromion centered over the top of the greater tuberosity. Extend it distally 3 cm.

- The C-arm can be used to locate the exact entry point before performing the anterior acromial approach.
  - Place a K-wire into the ideal entry point under C-arm imaging guidance. Confirm the location on orthogonal images.
  - Leave the K-wire intact while making an anterior acromial approach.
  - Split the deltoid fibers in line with the longitudinal cutaneous incision.
  - Do not extend the incision distally more than 4 or 5 cm in the deltoid muscle, to avoid damage to the axillary nerve.

**TECH FIG 1** Postoperative AP and lateral radiographs of antegrade intramedullary nailing for a midshaft humerus fracture.
Excise any visible subdeltoid bursae to improve your visualization of the rotator cuff.

Longitudinally incise the supraspinatus in line with the deltoid/cutaneous incision for 1 to 2 cm, just posterior to the bicapital tuberosity.

Placing suture tags at the margins of the supraspinatus will help retract its edges during the remainder of the procedure and assist in achieving an optimal rotator cuff repair during wound closure.

There is insufficient evidence to indicate that a larger incision, in cases in which the rotator cuff is identified and purposely incised, is superior to a smaller incision made with the aid of C-arm imaging.\(^{13}\)

**Entry Hole**

Make the entry hole medial to the tip of the greater tuberosity, just lateral to the articular margin and approximately 0.5 cm posterior to the bicipital groove to minimize damage to the supraspinatus.

Linear access to the humeral medullary canal is possible only though an entry portal made in this sulcus between the greater tuberosity and the articular surface.

Make sure the entry portal is centered on AP and lateral C-arm images to ensure the nail will be in the midplane of the humerus.

If the entry hole is too medial, it will violate the supraspinatus; if the entry portal is too lateral, it will cause some degree of varus angulation (in proximal fractures) or substantially increase the risk of an iatrogenic fracture during nail insertion.

Proximal third fractures may require a more medially located entry hole to avoid varus angulation at the fracture site.

**Entrance into Medullary Canal**

After establishing the entry hole, insert a K-wire through the portal into the medullary canal to the level of the lesser tuberosity.

Next, to open the medullary canal, either use a cannulated awl or pass a cannulated drill bit over the K-wire, through a protection sleeve, and drill to the depth of the lesser tuberosity.

Adduct the proximal component of the fractured humerus and extend the shoulder to improve clear ance of the acromion and facilitate awl or starter reamer access to the correct portal location.

Once the medullary canal has been opened, remove the guidewire and insert a long, ball-tipped guidewire. Bending the tip of the guidewire may aid in its passage across the fracture site.

**Provisional Reduction/ Guidewire Passage**

Manipulate the extremity to reduce the fracture. In many cases, reduction is obtained through a combination of adduction, neutral forearm rotation, and longitudinal traction.

While advancing the guidewire down the canal, rotate the arm about its longitudinal axis and take several C-arm images to confirm that the guidewire remains contained in the canal.

This is especially important if the humerus is substantially comminuted.

Slowly and deliberately pass the guidewire across the fracture site.

Difficult passage may be a tip-off that soft tissue may be interposed (possibly the radial nerve).

An open fracture is advantageous in this situation because it provides the opportunity to directly visualize and clear the fracture site of any problematic soft tissue.

After crossing the fracture site, advance the ball-tipped guidewire into the center of the distal fragment until the tip is 1 to 2 cm proximal to the olecranon fossa.

Avoid shortening or distracting the fracture site while firmly securing the guidewire into the distal fragment.

**Determined Nail Length**

Determine the correct nail length by one of two methods:

- **Guide rod method:** with the distal end of the rod 1 to 2 cm proximal to the olecranon fossa, overlap a second guide rod extending proximally from the humeral entry portal. Subtract the length in mm of the overlapped guide rod from the total length of an identical guidewire to determine the correct nail length.

- **Nail length gauge:** position the radiopaque gauge anterior to the fractured humerus. Move the C-arm to the proximal end of the humerus and read the length from the stamped measurements on the gauge.

The ideal length of an IMN should be measured 1 cm distal to the articular surface of the humeral head to a point 1 to 2 cm proximal to the olecranon fossa.

If the calculated length falls between two standardized nail lengths of the chosen implant, always choose the smaller size.

Long nails are a risk factor for subacromial impingement and fracture site distraction.

- Burying a long nail proximally below the subcondral surface has the potential to iatrogenically split the distal humerus or create a supracondylar fracture when the tip of the nail is wedged too close to the olecranon fossa.

**Reaming the Humeral Shaft**

Reaming the humeral shaft usually is avoided, especially in comminuted fractures, to avoid reaming injury to the radial nerve or the rotator cuff.

If it is warranted, slowly ream the entire humerus over the ball-tipped reamer guidewire in 0.5-mm increments.

Exercise greater caution when reaming the humerus than when reaming the long bones of the lower extremity, because the cortical thickness of the humerus is substantially less than that of the tibia or femur.

Ream 0.5 mm to 1 mm larger than the selected nail diameter. Ream minimally until the sound of cortical chatter becomes audible.

Choose a nail 1 mm smaller in diameter than the last reamer used.

Some implant systems require that the ball-tipped guidewire be replaced with a rod that does not have a tip.

Use the medullary exchange tube when replacing the guidewire to maintain fracture reduction.
Inserting the Nail

- Once the correct nail length and the diameter of the selected implant have been verified, attach the nail adapter, place the nail-holding screw through the nail adapter, and then attach the radiolucent targeting device onto the nail adapter.
- Verify that this assembly is locked in the appropriate position and that its alignment is correct by inserting a drill bit through the assembled tissue protection/drill sleeve placed in the required holes of the targeting device.
- Insert the nail with sustained manual pressure.
  - Aggressive placement can result in iatrogenic fractures or displacement of the fracture fragments.
  - Use the C-arm image intensifier to identify the source of the problem if the IMN does not easily advance.
- Insert the nail at least to the first circumferential groove on the nail adapter but no deeper than the second groove.
- Ideally, the IMN should be countersunk about 5 mm below the articular surface to avoid subacromial impingement.
- Sinking the nail more than 1 cm below the articular surface may place the proximal interlocking screws at the level of the axillary nerve.
- If the proximal end of the nail is properly countersunk, the incidence of shoulder pain is reportedly less than 2%.4
- Attach a strike plate to the targeting device and use a mallet to impact the proximal jig assembly to eliminate any fracture gap or advance the IMN.
- Do not hit the targeting device or the nail-holding screw directly.
- The distal end of the IMN should come to lie about 2 cm proximal to the olecranon fossa.
- Remove the guidewire.

Compression

- Before proximal interlock insertion, make sure that optimal fracture site compression is present.
- Proximal compression locking can be used for transverse or short oblique fracture patterns. Severe osteopenia is a contraindication to its use.
  - Explore the radial nerve before compression locking if any possibility of radial nerve entrapment exists.
  - The nail must be overinserted by the same distance of anticipated interfragmentary travel because otherwise, during compression, the nail will back out and cause subacromial impingement.
- Additionally, if the fracture is suitable for compression, the chosen implant should be 6 to 10 mm shorter than the calculated measurement to avoid proximal migration of the nail beyond the insertion site.
- Proximal locking screw placement
  - Oblique proximal locking screws are preferred because their insertion point is cephalad to axillary nerve.
  - Only lateral-to-medial placement is recommended for proximal interlocking screws.
  - It is important to make sure that these screws are inserted above the level of the humeral neck to avoid axillary nerve injury.

Determining Rotation

- Confirm rotational alignment before placing distal interlocking screws. Rotational alignment can be ascertained clinically and radiographically.
  - Magnified C-arm AP images of the fracture site can be used to judge the medial and lateral cortical width of the most proximal and most distal aspects of the fracture site.
  - Proper rotation is achieved when these widths are identical.

Distal Locking Screws

- Place anterior, then posterior and/or lateral, then medial directed distal interlocking screws.
- Insert distal interlocking screws using a freehand technique.
  - To place AP-directed screws, advance the C-arm over the distal humerus until the oval slot is seen to be in maximal relief—that is, “perfect circle.”
  - Under C-arm imaging, place a scalpel over the skin to precisely determine the location of the incision. Make every attempt to keep this incision just lateral to the biceps tendon. This will decrease the risk to brachial artery, median nerve, and musculocutaneous nerve.
- Carefully make the incision though the skin and use a blunt hemostat to spread under the brachialis muscle down to the bone.
- Insert a short drill bit through a soft tissue protector.
  - Center the drill bit in the locking hole and then position it perpendicular to the nail.
  - Ideally, place the drill bit distally in the oval hole to allow axial compression to occur postoperatively.
- Attach the drill and penetrate the near cortex.
  - The distal screws usually are 24 mm in length.
  - Use C-arm image intensification to confirm screw position through the nail as well as screw length.
  - Avoid articular penetration into the glenohumeral joint.
- Lateral-to-medial directed distal locking screws
  - Either in combination with or as an alternative to anterior-to-posterior screws, insert lateral-to-medial screws.
- Make the initial entry portal in one of two ways:
  - Traditional metaphyseal entry portal: created by reaming in the midline of the distal metaphyseal triangle 2.5 cm proximal to the olecranon fossa.
  - Olecranon fossa entry portal: established by reaming the proximal slope of the olecranon at the superior border of the olecranon fossa.
- The more distal location of the nontraditional olecranon fossa entry portal increases the effective working length of the distal segment and provides a straighter alignment with the medullary canal.
- However, biomechanical investigation has found that the olecranon fossa entry portal provides greater reduction in torque resistance and load to failure, which may increase the probability of an iatrogenic or postoperative fracture.16
- When making either entry portal, pay careful attention to the relation between the olecranon fossa and the longitudinal axis of the humerus in order to place the entry portal in line with the humeral shaft. The axis of the humerus usually is colinear with the lateral aspect of the olecranon fossa.
- Make the initial entry portal in one of two ways:
  - Open the near cortex with a 4.5-mm drill bit. Continue drilling while progressively lowering the drill toward the arm until the drill bit is in line with the medullary canal on the lateral C-arm images.
  - Drill three small pilot holes in a triangular configuration perpendicular to the cortical surface. Connect these holes with a large drill bit and small rongeur or enlarge the triangular site with a small curved awl to create a long, oval hole 1 cm wide × 2 cm long that leads directly into the medullary canal.
- Undercut the internal aspect of the posterior cortex in addition to the medial and lateral walls of the entry portal to create a distal bevel along the path of nail insertion.
- This will facilitate easy passage of the guidewire, optional reamer, and final implant.

**Retrograde Intramedullary Nailing**

**Approach**
- Make a limited posterior approach centered over the distal humerus, starting at the olecranon tip to a point 6 cm proximal.
- Longitudinally split the triceps in line with its fibers to the cortical surface of the humerus and identify the olecranon fossa.
- Make every attempt to avoid entering the elbow joint, to decrease the possibility of periarticular scarring.

**Starting or Entry Portals**
- As previously discussed in the Approach section, the coronal deviation of the distal humerus is variable, and, therefore, two potential starting portals exist:
  - Traditional metaphyseal entry portal: created by reaming in the midline of the distal metaphyseal triangle 2.5 cm proximal to the olecranon fossa.
  - Olecranon fossa entry portal: established by reaming the proximal slope of the olecranon at the superior border of the olecranon fossa.
- The more distal location of the nontraditional olecranon fossa entry portal increases the effective working length of the distal segment and provides a straighter alignment with the medullary canal.
- However, biomechanical investigation has found that the olecranon fossa entry portal provides greater reduction in torque resistance and load to failure, which may increase the probability of an iatrogenic or postoperative fracture.16
- When making either entry portal, pay careful attention to the relation between the olecranon fossa and the longitudinal axis of the humerus in order to place the entry portal in line with the humeral shaft. The axis of the humerus usually is colinear with the lateral aspect of the olecranon fossa.
- Make a generous 5 cm incision to decrease the risk to the radial nerve.
- Use the same technique employed when placing AP-directed screws: blunt dissection, a protecting drill/screw insertion sleeve, and perfect circle free-hand technique.
- Finally, confirm the IMN position, fracture reduction, and interlocking screw(s) placement with multiple orthogonal C-arm images.
- After orthogonal C-arm images demonstrate satisfactory reduction and hardware implantation, remove the proximal targeting device and place an end cap (this last step is optional, depending on surgeon preference).
- Carefully select the length of the end cap to avoid impingement.

**Wound Closure**
- Copiously irrigate all wounds before they are closed.
- During closure of the proximal insertion site, formally repair the surgically incised rotator cuff and deltoid raphe; side-to-side nonabsorbable sutures commonly are recommended.

**Provisional Reduction and Guidewire Passage**
- Now follow the same steps outlined in the antegrade IMN technique section to pass the guidewire, reduce the fracture, ream (optional), measure the desired nail length and diameter, and insert the chosen implant.
- Reduction of the fracture usually involves gentle longitudinal traction on the distal humerus and correction of the varus–valgus displacement.
Reaming (Optional)

- If it is necessary to ream, carefully select the reamer size to avoid damage to the posterior cortex. In addition, slowly advance the reamer under C-arm image guidance to avoid excessive reaming of the anterior humeral cortex.
- Both of these steps decrease the risk of possible iatrogenically induced fractures.

Distal Locking Screws

- Next, distally lock the nail to prevent backing out, that is, blocked elbow extension.
- Place the distal locking screws from posterior to anterior using a guide.
- Make an indentation with the guide, incise the cutaneous layer, and then use a blunt hemostat to spread down to the bone.
- Follow the remaining steps unique to the chosen implant.

- After distal interlocking, gently tap the insertion bolt with a mallet to compress the fracture site. Assess the reduction with C-arm images.

Proximal Locking Screws

- Next, place a proximal interlocking screw, either anterior to posterior, posterior to anterior, or lateral to medial.
- Incise the skin and use a blunt hemostat to spread down to bone to protect the biceps tendon (anterior-to-posterior directed screws) or axillary nerve (posterior-to-anterior and lateral-to-medial directed screws).
- Use C-arm image intensification to confirm screw position through the nail as well as screw length.

Wound Closure

- Copiously irrigate each wound before closing it. Close triceps split with interrupted nonabsorbable sutures.

PEARLS AND PITFALLS

<table>

<th>Nail length</th>
<th>Always err on the side of a shorter nail: do not distract the fracture site or cause iatrogenic fractures by trying to impact a nail that is excessively long.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>The retrograde IMN must be long enough to engage the cancellous part of the humeral head; the wide medullary flare of the proximal one third of the shaft does not provide sufficient stability to the inserted nail.</td>
</tr>
</tbody>
</table>

| Open fractures: reaming | After a thorough irrigation and débridement is performed and the guidewire is successfully passed across the fracture site, close the deep muscle layer around the fracture site to keep the osteogenic reaming debris from washing away. |

POSTOPERATIVE CARE

- Tailor the postoperative rehabilitation regimen to the method of nailing (antegrade versus retrograde), stability of the fracture, overall patient health, and preinjury level of activity/workplace demands.
- Antegrade IMN
  - Place the affected arm in a sling or shoulder immobilizer at the end of surgery.

- Postoperative day 2: remove the dressing and begin gentle shoulder pendulum and elbow ROM exercises.
- Postoperative days 10 to 14: remove the sutures. Institute a structured, supervised physical therapy program. Close patient monitoring and formal therapy are key components to achieving maximum postoperative function.
- Subsequently, schedule follow-up visits at 4- to 6-week intervals, depending on the patient’s clinical and radiographic progression. Healing often takes 12 weeks or longer.
As union progresses, the therapist may begin supervised exercises to recover upper extremity strength. Caution the therapist against instituting programs or exercises that create large rotational stresses to the arm until radiographic healing becomes evident.

Retrograde IMN
- Initial postoperative management is identical to treatment following antegrade nailing, unless weight bearing is necessary for wheelchair transfers, walkers, or crutch ambulation. Use a posterior splint and platform attachment if clutches are necessary.
- It is important to institute early elbow active ROM or gentle passive ROM by the patient to prevent elbow stiffness.
- Avoid
  - Aggressive PROM or stretching to decrease the risk of myositis ossificans formation
  - Resisted elbow extension for the first 6 weeks after surgery to protect the repair of the triceps split.

OUTCOMES
- Randomized clinical trials comparing IMN to compression plating show a higher reoperation rate and greater shoulder morbidity with the use of nails.\(^1\)
- Locked antegrade IMN has resulted in loss of shoulder motion in 6% to 37% of cases.\(^13\)
- Recent antegrade nails designed to eliminate insertion site shoulder morbidity though an extra-articular start point have been introduced, and prospective randomized trials are pending.
- Retrograde IMN union rates range from 91% to 98%, and the mean healing time is 13.7 weeks.\(^15\)
- Retrospective reviews of retrograde IMN have found shoulder function to be excellent in 92.3% of patients and elbow function excellent in 87.2% of patients after fracture consolidation.\(^15\)
- Functional end results were excellent in 84.6% of patients, moderate in 10.3% of patients, and bad in 5.1% of patients.
- Biomechanical studies have shown that, for midshaft fractures, both antegrade and retrograde nailing showed similar initial stability and bending and torsional stiffness—20% to 30% of normal humeral shafts.\(^8\)
- In proximal fractures (ie, 10 cm distal to the greater tuberosity tip), antegrade nails demonstrated significantly more initial stability and higher bending and torsional stiffness, as was true for distal fractures with retrograde nailing.

COMPLICATIONS
- Nonunion\(^3\)
  - Antegrade IMN: 11.6%
  - Retrograde IMN: 4.5%
- Infection: 1% to 2%
- Insertion site morbidity
  - Antegrade IMN: shoulder pain, impingement, stiffness, and weakness
  - Retrograde IMN: elbow pain, stiffness, and triceps weakness
- Iatrogenic fractures\(^3\)
- Antegrade IMN: 5.1%
- Retrograde IMN: 7.1%
- Iatrogenic comminution and distraction at the fracture site
- Neurovascular risk
  - Risk to the radial nerve in the spiral groove from canal preparation and nail insertion
  - Risk to the axillary nerve from proximal interlocking
  - Risk to the radial, musculocutaneous, and median nerves or brachial artery from distal interlocking
- Heat-induced segmental avascularity after reaming

REFERENCES
3. Court-Brown C. Paper presented at the Orthopaedic Trauma Association Specialty Day Meeting; February 26, 2005; Washington, DC.
DEFINITION
- Nonarticular scapular fractures include fractures of the glenoid neck, scapular spine and body, acromial process, and coracoid process. They account for 90% of scapular fractures.6
- Most nonarticular scapular fractures can be treated nonoperatively, including all isolated scapular body–spine fractures.
- Significant displacement at one or more of these sites, alone or in conjunction with ligamentous disruptions of the superior shoulder suspensory complex, require evaluation for surgical intervention.1,10

ANATOMY
- The scapula is a flat triangular bone with three processes laterally: the glenoid process, the acromial process, and the coracoid process.
- The glenoid process consists of the glenoid fossa, the glenoid rim, and the glenoid neck.
- The superior shoulder suspensory complex is a bone and soft tissue ring at the end of a superior and an inferior bony strut (FIG 1). This ring is composed of the glenoid process, the coracoid process, the coracoclavicular ligament, the distal clavicle, the acromioclavicular joint, and the acromial process. The superior strut is the middle third of the clavicle, whereas the inferior strut is the junction of the most lateral portion of the scapular body and the most medial portion of the glenoid neck.1

PATHOGENESIS
- Scapular fractures usually are the result of high-energy trauma and have a high rate of associated musculoskeletal and underlying thoracic injuries.3
- Fractures of the acromion process may be the result of direct trauma due to its subdermal location, whereas coracoid process fractures may be due to a sudden muscular contraction.4

NATURAL HISTORY
- The results of nonoperative treatment of nonarticular scapular fractures generally are good. Nonunion is rare because the area has a rich blood supply. Angular deformities often are well compensated for by the wide range of motion of the glenohumeral joint and scapulothoracic articulation.

PATIENT HISTORY AND PHYSICAL FINDINGS
- In addition to the specifics of the injury, it is helpful to obtain an understanding of the functional demands on the extremity. Hand dominance, occupation, and sports participation are all relevant.
- A thorough neurovascular examination must be performed and deficits evaluated with angiography and electromyography, as necessary.
- A thorough soft tissue examination also is warranted, as wounds may represent an open fracture and warrant exploration. Blisters or swelling may delay surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Nonarticular scapular fractures usually are identified on routine shoulder trauma series radiographs: a true anteroposterior (AP) view of the shoulder with the arm in neutral rotation, a true axillary view of the glenohumeral joint, and a true lateral scapular view. An AP weight-bearing view may be indicated.
- CT scans and three-dimensional reconstructions can be helpful for identification and classification of fractures owing to the complex bony anatomy in this region. In addition, the bony relationships should be evaluated for evidence of any ligamentous disruption.

DIFFERENTIAL DIAGNOSIS
- Nonarticular scapular fractures
- Intra-articular scapular fractures
- Double disruptions of the superior shoulder suspensory complex including a floating shoulder (ie, glenoid neck fracture with ipsilateral middle third clavicle fracture)
- Scapulothoracic dissociation
NONOPERATIVE MANAGEMENT

- Most (over 90%) scapular fractures can be treated nonoperatively.
- Glenoid fossa and rim fractures may require operative management and are discussed in Chapter SE-23.
- Glenoid neck fractures with more than 40 degrees of angulation in the coronal or sagittal plane or translational displacement of 1 cm or more require surgical management. Anatomic neck fractures (lateral to the coracoid process) are inherently unstable and should also be considered for operative intervention.²
- Isolated acromial and coracoid process fractures usually are minimally displaced and can be managed nonoperatively. Significant displacement or fractures in conjunction with other bony and soft tissue injuries to the shoulder girdle may require surgical stabilization.⁴

SURGICAL MANAGEMENT

Preoperative Planning

- Imaging studies should be reviewed and available for reference in the operating room. A draped fluoroscopy unit and competent technician should be available during the surgery.

Positioning

- Open reduction with internal fixation (ORIF) of scapular fractures requires wide access to the entire shoulder girdle. The patient may be placed in either the lateral decubitus position (FIG 2A) or in the beach chair position (FIG 2B), but care must be taken to allow adequate exposure of the entire scapula and clavicle.
- The shoulder girdle is prepped and draped widely, and the entire upper extremity is prepped and draped “free.”
- Alternatively, a staged procedure can be performed using separate positions, sterile preparations, and separate exposures.⁹

Approach

- Glenoid neck fractures are approached posteriorly.
- A superior approach can added for control and positioning of a difficult-to-control glenoid fragment.
- An anterior approach is used for coracoid process fractures.
- A superior approach is used for access to acromial process fractures.

POSTERIOR APPROACH TO GLENOID NECK

- Bony landmarks are outlined with marking pen (TECH FIG 1A).
- An incision is made along the scapular spine and acromion and down the lateral aspect of the shoulder, as needed.
- The origins of the posterior and middle heads of the deltoid muscle are sharply detached from the scapular spine–acromial process and retracted distally (TECH FIG 1B).
- The interval between infraspinatus and teres minor is developed.
- If access to the glenoid fossa is necessary, the infraspinatus tendon and underlying posterior gleno-humeral joint capsule are incised 2 cm lateral to their insertion on the greater tuberosity and reflected laterally (TECH FIG 1C,D).
- Mobilization of the teres minor muscle allows access to the lateral scapular border.

FIG 2 • A. The lateral decubitus position is used for posterior and posterosuperior approaches to the glenoid process. B. The beach chair position.
Reduction of the fracture is performed with lateral traction on the draped arm and manipulation of the fracture site.

Temporary fixation may be obtained with K-wires.

Rigid fixation may be obtained with a contoured reconstruction plate and 3.5-mm cortical screws (TECH FIG 1D).

Care must be taken to avoid violating the glenoid fossa with the screws in the glenoid fragment.

Meticulous repair of the deltoid origin to the scapular spine–acromion should be performed with permanent sutures through drill holes.

SUPERIOR APPROACH TO GLENOID NECK

The superior approach to the glenoid neck is made in an extensile fashion by extending the posterior incision superiorly.

The trapezius and underlying supraspinatus muscles are split in the line of their fibers (TECH FIG 2).

ORIF OF ACROMIAL PROCESS FRACTURE

Incision directly over the acromial process

Subperiosteal dissection to expose the superior surface of the acromion

Anatomic fracture reduction under direct visualization

Proximal fractures: fixation with a contoured 3.5-mm reconstruction plate (TECH FIG 3A)

Distal fractures: fixation with a tension band construct (TECH FIG 3B)
TECH FIG 3 • Fixation techniques for acromion process fractures. A. Plate-and-screw construct for a fracture of the base of the acromion. B. Tension band wire construct.

ORIF OF CORACOID PROCESS FRACTURE

- Vertical incision 1 cm lateral to coracoid process (TECH FIG 4A)
- Development of deltopectoral interval or split of the deltoid muscle in line with its fibers directly over the coracoid process
- Exposure of the fracture site (may need to open the rotator interval)
- If coracoid tip has sufficient stock, cannulated screw fixation can be performed (TECH FIG 4B).
- If not, fragment excision and suture fixation of conjoint tendon to remaining coracoid is performed (TECH FIG 4C).
- Coracoid base fractures are fixed with a single cannulated cortical screw (TECH FIG 4D).

TECH FIG 4 • A. Standard anterior incision extends from the superior to inferior margin of the humeral head, centered over the glenohumeral joint. B–D. Three repair techniques for coracoid fractures. B. Cannulated screw fixation of tip avulsion with sufficient bone to repair. (continued)
POSTOPERATIVE CARE

- How aggressive the rehabilitation program following ORIF of nonarticular scapular fractures must be is determined by the rigidity of the fixation construct and the adequacy of the soft tissue repair.5
- Patients are immobilized in a sling and swathe binder and started on gentle pendulum exercises during the first 2 weeks.
- Progressive passive and active-assisted range of motion exercises are emphasized during weeks 2 through 6 postoperatively.
- All protection is discontinued by 6 weeks postoperatively.
- Strengthening is begun after 6 weeks postoperatively and after range of motion is satisfactory.
- Return to sports or labor is restricted until 4 to 6 months postoperatively.

OUTCOMES

- Relatively few outcome studies detailing the results of scapular fractures treated operatively are available.
- While most nonarticular scapular fractures are treated nonoperatively, those that warrant surgical intervention appear to benefit from this treatment.7,8

COMPLICATIONS

- When neurologic complications occur, they most commonly are caused by overly aggressive retraction or misdirected dissection.
- The musculocutaneous and axillary nerves are vulnerable in the anterior approach, the suprascapular nerve in the superior approach, and the axillary and suprascapular nerves in the posterior approach.9
REFERENCES

DEFINITION

Intra-articular scapular fractures include fractures of the glenoid cavity, which includes the glenoid rim and the glenoid fossa. They account for 10% of scapular fractures. Most scapular fractures are extra-articular, and 50% involve the body and spine.

Over 90% of fractures of the glenoid cavity are insignificantly displaced and are managed nonoperatively. Significant displacement requires evaluation for surgical intervention to achieve the best possible outcome.

ANATOMY

The scapula is a flat triangular bone with three processes: the glenoid process, the acromial process, and the coracoid process.

The glenoid process consists of the glenoid cavity (the glenoid rim and glenoid fossa) and the glenoid neck.

The glenoid cavity provides a firm concave surface with which the convex humeral head articulates. The average depth of the articular cartilage is 5 mm.

Glenoid cavity fractures are classified according to whether they involve the glenoid rim or the glenoid fossa and the direction of the fracture line (FIG 1).

PATHOGENESIS

Scapular fractures usually are the result of high-energy trauma and have a high rate (90%) of associated bony and soft tissue injuries, both local and distant.

Fractures of the glenoid rim occur when the humeral head strikes the periphery of the glenoid cavity. They are true fractures, not avulsion injuries caused by indirect forces applied to the periarticular soft tissues by the humeral head.

Fractures of the glenoid fossa occur when the humeral head is driven into the center of the concavity. The fracture then promulgates in a number of different directions, depending on the characteristics of the humeral head force.

NATURAL HISTORY

The results of nonoperative treatment of intra-articular scapular fractures usually are good if the fracture displacement is minimal and the humeral head lies concentrically within the glenoid cavity.

Significant displacement can result in posttraumatic degenerative joint disease, glenohumeral instability, and even nonunion.

PATIENT HISTORY AND PHYSICAL FINDINGS

In addition to the specifics of the injury, it is helpful to obtain an understanding of the functional demands on the extremity. Hand dominance, occupation, and sports participation are all relevant.

A thorough neurovascular examination must be performed. Deficits are evaluated with angiography and electromyography, as necessary.

A thorough soft tissue examination also is warranted. Wounds may represent an open fracture and warrant exploration. Blisters or swelling may delay surgery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Intra-articular scapular fractures initially are evaluated with a routine scapula trauma radiographic series (a true anteroposterior view of the shoulder with the arm in neutral rotation, a true axillary view of the glenohumeral joint, and a true lateral scapular view; FIG 2A).

CT scans and three-dimensional studies with reconstructions can be helpful in evaluating articular congruity and fracture displacement (FIG 2B–D). In addition, the bony relationships should be evaluated for evidence of ligamentous disruption(s) or instability.

DIFFERENTIAL DIAGNOSIS

Intra-articular scapular fractures
Nonarticular scapular fractures
Scapulothoracic dissociation
Double disruptions of the superior shoulder suspensory complex, including a floating shoulder (a glenoid neck fracture with an ipsilateral middle third clavicle fracture)

NONOPERATIVE MANAGEMENT

Most (over 90%) intra-articular scapular fractures are insignificantly displaced and are managed nonoperatively.

Significantly displaced glenoid fossa and glenoid rim fractures require operative management.

SURGICAL MANAGEMENT

Surgical indications are as follows:

Rim fractures: 25% or more of the glenoid cavity anteriorly or 33% or more of the glenoid cavity posteriorly and displacement of the fragment 10 mm or more

Fossa fractures: an articular step-off of 5 mm or more, significant separation of the fracture fragments, or failure of the humeral head to lie in the center of the glenoid cavity

Preoperative Planning

Imaging studies should be reviewed before the surgery and should be available for reference in the operating room. A draped fluoroscopy unit and a competent technician should be available. An examination for instability can be performed while under anesthesia.

Positioning

Open reduction with internal fixation (ORIF) of intra-articular scapular fractures requires wide access to the entire Chapter 23 Open Reduction and Internal Fixation of Intra-articular Scapular Fractures Brett D. Owens, Joanna G. Branstetter, and Thomas P. Goss
FIG 1 • Goss-Ideberg classification of glenoid cavity fractures. Ia, anterior rim; Ib, posterior rim; II, inferior glenoid; III, superior glenoid; IV, transverse through the body; V, combination II-IV; VI, comminuted.

FIG 2 • A. The AP radiograph shows a type Vc glenoid cavity fracture. B. Axillary CT image shows a large anterosuperior glenoid cavity fragment including the coracoid process. (continued)
shoulder girdle. Depending on the particular fracture, the patient is placed in either the lateral decubitus position (FIG 3A) or the beach chair position (FIG 3B).
- Care must be taken to allow adequate exposure of the entire scapula and clavicle. The shoulder girdle is prepped and draped widely, and the entire upper extremity is prepped and draped “free.”
- In some cases, a staged procedure may be necessary using separate positions, sterile preparations, and exposures.10

**Approach**
- The posterior approach is used for fractures of the posterior glenoid rim and most fractures of the glenoid fossa.
- The superior approach is used, in conjunction with a posterior approach, for fractures of the glenoid fossa with a difficult-to-control superior fragment.
- The anterior approach is used for fractures of the anterior glenoid rim and some fractures involving the superior aspect of the glenoid fossa.

**POSTERIOR APPROACH TO THE GLENOID CAVITY**
- Bony landmarks are outlined with a marking pen.
- An incision is made along the scapular spine and acromion and down the midlateral aspect of the shoulder, as needed (TECH FIG 1A).
- Origins of the posterior and middle heads of the deltoid muscle are sharply detached from the scapular spine-acromial process, and the deltoid muscle is split in the line of its fibers for 2.5 cm in the midlateral line. It is then retracted distally (TECH FIG 1B).
- The interval between infraspinatus and teres minor is developed (TECH FIG 1C). To gain access to the glenoid fossa, the infraspinatus tendon and underlying posterior glenohumeral joint capsule are incised 2 cm lateral to their insertion on the greater tuberosity and reflected posteriorly (TECH FIG 1D).
- Subperiosteal mobilization of the teres minor muscle allows access to the lateral scapular border.
**SUPERIOR APPROACH TO THE GLENOID CAVITY**

- The superior approach to the glenoid cavity is made by extending the posterior incision superiorly.
- The trapezius and underlying supraspinatus muscles are split in the line of their fibers (TECH FIG 2).

**ANTERIOR APPROACH TO THE GLENOID CAVITY**

- The incision is made in Langer’s lines and centered over the glenohumeral joint from the superior to inferior level of the humeral head (TECH FIG 3A).
- The deltoid muscle is split in the line of its fibers over the palpable coracoid process and retracted medially and laterally.
- The conjoined tendon is retracted medially after division of the overlying fascia along its medial border (TECH FIG 3B).
- Care must be taken to protect all neurovascular structures from injury.
- Incise the subscapularis tendon vertically 2.5 cm medial to its insertion on the lesser tuberosity and along its superior and inferior borders.
- Dissect it off the underlying anterior glenohumeral capsule.
- Tag the corners of the subscapularis unit and turn it back medially (TECH FIG 3C).
- Incise the anterior glenohumeral capsule in the same fashion, tag its corners, and turn it back medially to gain access to the glenohumeral joint.
**TECH FIG 3** • A. Anterior approach using a skin incision made in Langer’s lines and centered over the glenohumeral joint. B. The conjoined tendon is retracted medially. C. Incise the subscapularis tendon 2 cm from its insertion on the lesser tuberosity, dissect it off the glenohumeral capsule, incise the capsule similarly, and turn both of them back medially to gain access to the glenohumeral joint. (From Goss TP. Open reduction and internal fixation of glenoid fractures. In: Craig EV, ed. Master Techniques in Orthopaedic Surgery: The Shoulder, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2004.)

**FIXATION TECHNIQUES**

- The fracture is reduced as anatomically as possible.
- Temporary fixation may be obtained with K-wires.
- Rigid fixation may be obtained with a contoured reconstruction plate and 3.5-mm cortical screws or with cannulated interfragmentary compression screws, depending on the characteristics of the fracture.
- Care must be taken to avoid violating the glenoid fossa with any screws placed in the glenoid fragment (TECH FIG 4A,B).
- If severe comminution is present, an iliac crest tricortical bone graft is an option (TECH FIG 4C).
- All soft tissues divided to gain access to the fracture site must be meticulously repaired. With posterior approaches, the deltoid must be securely reattached to the acromion and scapular spine with permanent sutures through drill holes.

**TECH FIG 4** • A. Postoperative AP image of the patient shown in Tech Fig 1. B. Axillary radiograph showing the glenoid cavity fragments secured together with cannulated screws and the glenoid unit secured to the scapular body with a malleable reconstruction plate (the acromial fracture was reduced and stabilized with a tension band construct). (continued)

PEARLS AND PITFALLS

Indications
- Rim fractures: 25% or more of the glenoid cavity anteriorly or 33% or more of the glenoid cavity posteriorly and displacement of the fragment 10 mm or more
- Fossa fractures: an articular step-off of 5 mm or more, significant separation of the fracture fragments, or failure of the humeral head to lie in the center of the glenoid cavity

Approach
- Incising the rotator interval and leaving the subscapularis unit intact may allow adequate exposure for injuries involving a displaced superior glenoid fragment.
- Some injuries require combined anteroposterior or posterosuperior approaches.
- Deltoid detachment and retraction provide maximal posterior exposure and access.
- During the posterior approach, develop the internervous plane between the infraspinatus (a bipennate muscle) superiorly and the teres minor inferiorly.

Reduction
- K-wires can be placed to serve as “joysticks” to assist with fracture reduction. They also can be driven across the fracture site to provide temporary or permanent fixation.

Fixation
- Bone stock capable of allowing internal fixation is at a premium in the scapula. The four satisfactory areas include the glenoid neck, the acromion–scapular spine, the lateral scapular border, and the coracoid process. Reconstruction plates may be pre-contoured using a scapula model and flash-sterilized. If severe comminution is present, an iliac crest tricortical bone graft is an option. Cannulated interfragmentary screws can be inserted using previously placed K-wires as guidewires.

Closure
- If the deltoid muscle is detached, meticulous repair to the scapular spine–acromial process is necessary using nonabsorbable sutures placed through drill holes.

POSTOPERATIVE CARE
- The aggressiveness of the rehabilitation program following ORIF of intra-articular scapular fractures is determined by the rigidity of the fixation construct and the adequacy of the soft tissue repair.  
- Patients are immobilized in a sling and swathe binder and started on gentle pendulum exercises during the first 2 weeks.
- Progressive passive and active-assisted range-of-motion exercises emphasizing forward flexion and internal–external rotation are prescribed during weeks 2 through 6 postoperatively.
Chapter 23 OPEN REDUCTION AND INTERNAL FIXATION OF INTRA-ARTICULAR SCAPULAR FRACTURES 3255

- All protection is discontinued at 6 weeks postoperatively.
- Strengthening is begun after 6 weeks postoperatively and when range of motion is satisfactory.
- Return to sports or physical labor is restricted until 3 to 6 months postoperatively.
- Close outpatient follow-up with radiographs, especially early in recovery, and a well-defined, closely monitored physical therapy program are extremely important.

OUTCOMES
- Good results have been reported for the operative management of glenoid rim fractures.⁹,¹²
- Bauer et al¹ reviewed six patients treated surgically for glenoid cavity fractures. Four patients with an anatomic reduction had good results; two patients with nonanatomic reductions developed arthritic changes.
- Kavanaugh and colleagues⁷ presented their experience at the Mayo Clinic in which 10 displaced intra-articular fractures of the glenoid cavity were treated with ORIF. They found ORIF to be “a useful and safe technique” that “can restore excellent function of the shoulder.” In their series, the major articular fragments were displaced 4 to 8 mm.
- Schandelmaier and coauthors¹¹ reported a series of 22 fractures of the glenoid fossa treated with ORIF with good results.
- Leung and colleagues⁸ reviewed 14 displaced intra-articular fractures of the glenoid treated with ORIF (30.5-year average follow-up) and reported 9 excellent and 5 good results.
- On the basis of these reports, it seems reasonable to conclude that there is a definite role for surgical management in the treatment of glenoid cavity fractures.

COMPLICATIONS
- Neurologic complications most commonly are caused by overly aggressive retraction or misdirected dissection.
- The musculocutaneous and axillary nerves are vulnerable in the anterior approach.
- The supraspinatus nerve is at risk in the superior approach, and the axillary and suprascapular nerves are vulnerable in the posterior approach.¹⁰
- A variety of other complications can occur as a result of poor surgical technique, inadequately directed or managed rehabilitation, and poor patient compliance.

REFERENCES
DEFINITION
- Despite significant advances in shoulder arthroplasty and other reconstructive procedures, glenohumeral arthrodesis remains an important treatment option in appropriately selected patients.
- The goal of glenohumeral arthrodesis is to provide a stable base for the upper extremity to optimize elbow and hand function.
- Given the tremendous normal range of motion of the glenohumeral joint and the relatively small amount of surface area available for fusion, particularly on the scapular side, successful arthrodesis is technically demanding and requires meticulous surgical technique.

ANATOMY
- The surface area of the glenoid is too small to allow for predictable fusion. Therefore, to increase the area available for fusion, the glenohumeral articular surface and the articulation between the humeral head and undersurface of the acromion are decorticated (FIG 1).
- The bone of the scapula is extremely thin, with only the glenoid fossa and base of the coracoid providing sufficient strength for fixation.
- The optimal position for glenohumeral arthrodesis has been controversial.1,4
  - We use a position of 30 degrees of abduction, 30 degrees of forward flexion, and 30 degrees of internal rotation.
  - This position brings the hand to the midline anteriorly, allowing the patient to reach his or her mouth with elbow flexion.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history and physical findings are specific to the underlying condition requiring arthrodesis.
- All patients will exhibit symptomatic dysfunction at the glenohumeral joint that prevents them from effectively using the involved extremity.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard radiographs, including an anteroposterior, lateral, and axillary view, are used to assess any deformities as well as the bone stock available for fusion.
- If there is concern regarding bone loss on the glenoid side, especially in the setting of failed arthroplasty, this is better evaluated with a CT scan.
- When the neurologic condition of the shoulder girdle muscles is unclear, an electromyelogram of the scapular muscles is indicated.

SURGICAL MANAGEMENT
Indications
- The presence of a flail shoulder is an indication for glenohumeral arthrodesis.
  - Paralysis in patients with a flail shoulder can be the result of anterior poliomyelitis, severe proximal root or irreparable upper trunk brachial plexus lesions, or isolated axillary nerve paralysis.
  - Many patients with flail shoulders develop a painful inferior subluxation that responds well to arthrodesis.
  - The need for fusion following isolated axillary nerve injury depends on the level of impairment. Many patients, especially those with partial paralysis, have reasonable function; however, complete injury often leads to significant limitation of shoulder function.
  - Glenohumeral arthrodesis is useful following en bloc resection of periarticular malignant tumors requiring resection of the deltoid, rotator cuff, or both.
  - Fusion is useful for the treatment of joint destruction following septic arthritis of the shoulder, particularly in young patients.
Arthrodesis is a salvage option for patients with multiple failed total shoulder arthroplasties who have insufficient bone stock or soft tissue for revision arthroplasty.

- Symptomatic, uncontrolled shoulder instability that is recalcitrant to soft tissue or bony reconstructive procedures can be managed with fusion.
- Rarely, arthrodesis is indicated in young laborers with severe osteoarthritis who are poor candidates for arthroplasty because of their young age and high activity levels.

**Contraindications**

- The primary contraindication to glenohumeral arthrodesis is weakness or paralysis of the periscapular muscles, especially the trapezius, levator scapula, and serratus anterior.
- Progressive neurologic disorders that are likely to lead to paralysis of these muscles also are a contraindication.
- Arthrodesis of the opposite shoulder is a contraindication to fusion.
- Shoulder fusion requires a significant effort by the patient to rehabilitate the shoulder and is contraindicated in patients unwilling or unable to participate in such a program.

**Preoperative Planning**

- Preoperative radiographs should be evaluated for any bone defects that may require bone grafting.

- The surgeon should make sure that the pelvic reconstruction plate and a set of handheld bending irons are available (FIG 2).

**Positioning**

- The patient is placed in the beach chair position with the back of the table elevated 30 to 45 degrees.
- A folded sheet is placed medial to the scapula to elevate it from the table.
- The drapes are applied as medial as possible, allowing access to the scapula and the anterior chest wall. The arm is draped free (FIG 3).
- We do not routinely use intraoperative fluoroscopy; however, early in their experience with this procedure, surgeons may find fluoroscopy useful to confirm the position of the hardware.

**Approach**

- We perform glenohumeral arthrodesis using a 10-hole, 4.5-mm pelvic reconstruction plate.
- Compression across the glenohumeral articular surface is achieved by placing the initial screws from the plate through the proximal humerus and into the glenoid fossa.
- The plate is then anchored to the spine of the scapula by a screw directed into the base of the coracoid.

**Exposure**

- An S-shaped skin incision begins over the scapular spine, transverses anteriorly over the acromion, and extends down the anterolateral aspect of the arm (TECH FIG 1A).
- The skin and subcutaneous tissue are incised down to the fascia along the entire length of the incision.
- The spine of the scapula and acromion are exposed first by electrocautery, and then by subperiosteal dissection (TECH FIG 1B).
- Anteriorly, the deltopectoral interval is developed, and the deltoid is subperiosteally elevated off the acromion, beginning at the medial aspect of the anterior head and progressing laterally and posteriorly to the posterolateral corner of the acromion.
- Alternatively, if the deltoid is de-innervated, as may occur following brachial plexus injury, it can be split between the anterior and lateral heads. The anterior head is then elevated medially and the lateral head laterally to provide wide exposure of the proximal humerus.
- Distally, the biceps tendon is identified and tenodesed to the upper border of the pectoralis major tendon.
The rotator cuff is resected from the proximal humerus, beginning at the inferior border of the subscapularis and proceeding superiorly and then posteriorly and inferiorly to the level of the teres minor.

A ring or Hohmann retractor is placed on the posterior lip of the glenoid, and the humeral head is retracted posteriorly to expose the glenoid.

The glenoid cartilage is removed using a \( \frac{3}{8} \)-inch curved osteotome or burr (TECH FIG 2A). The glenoid labrum also is removed.

The retractors are then removed, and the arm is extended, adducted, and externally rotated to expose the humeral head.

A \( \frac{1}{2} \)-inch curved osteotome or burr is used to remove the articular surface of the humerus in its entirety.

The undersurface of the acromion is decorticated with a \( \frac{3}{4} \)-inch curved osteotome or burr.

The arm is placed in 30 degrees of flexion, 30 degrees of abduction, and 30 degrees of internal rotation, and the humerus is brought proximally to appose the decorticated surface of the acromion (TECH FIG 2B).

The arm is maintained in this position by placing folded sheets between the thorax and the extremity and having an assistant stand on the opposite side of the table to support the forearm and hand.

The 4.5-mm, 10-hole pelvic reconstruction plate is contoured to run along the spine of the scapula, over the acromion and down the shaft of the humerus (TECH FIG 2C).

The plate is bent 60 degrees between the third and fourth holes and then twisted 20 to 25 degrees just distal to the bend so it apposes the shaft of the humerus.

With the arm supported in the appropriate position and the plate held against the scapula and humerus, a hole is drilled through the plate, through the humerus, and into the glenoid using a 3.2-mm drill bit.

The screw length is measured; usually it is between 65 and 75 mm.

The humeral cortex is tapped with a 6.5-mm tap.

A short-thread 6.5-mm cancellous screw is inserted as a lag screw into the glenoid.

Depending on glenoid bone stock, one or two more screws are placed in a similar manner.

The plate is then anchored to the scapula by placing one or two fully threaded cancellous screws from the plate through the spine of the scapula and into the base of the coracoid.

Another cancellous screw is placed across the acromiohumeral fusion site.

Distally, the remaining holes are filled with cortical screws (TECH FIG 2D).

The wound is closed in standard fashion over two \( \frac{1}{8} \)-inch suction drains. Care is taken to reattach the deltoid to the acromion in an effort to cover as much of the plate as possible.
We do not routinely use bone graft when performing glenohumeral arthrodesis.

Bone grafting is indicated to fill large defects in patients who are undergoing arthrodesis for complex and revision problems as well as following tumor resection.

Nonstructural autogenous bone graft can be obtained from the ipsilateral iliac crest and is combined with revision of the internal fixation for the treatment of nonunited fusions.

Tricortical iliac crest graft can be placed between the humerus and glenoid when structural bone graft is needed (TECH FIG 3A).

- This type of graft commonly is needed to treat bone deficiency following failed shoulder arthroplasty.
- The graft is placed underneath the plate so that the compression screws pass first through the plate and any remaining proximal humerus and then through the graft and into the glenoid.

When an intercalary defect larger than 6 cm is present, the surgeon should consider a vascularized fibular bone graft (TECH FIG 3B).

- The vascularized graft should be fixed at each end with minimal internal fixation.
- The entire defect is then spanned with a very long plate.
- The vascular anastomosis is performed between the peroneal artery and its vena comitantes and a branch of either the axillary or brachial artery.
- Nonstructural autogenous graft is placed at each end of the vascularized graft to maximize the likelihood of fusion occurring.
POSTOPERATIVE CARE

- In the operating room, after the procedure, a pillow is placed between the patient’s arm and chest, and the arm is then wrapped to the chest with a swathe.
- A radiograph is obtained in the recovery room to verify position of the internal fixation.
- A thermoplastic orthosis is applied on the day after surgery and adjusted as needed.
- Patients usually are discharged from the hospital on the second postoperative day and maintained in the orthosis for 6 weeks.
- If, at 6 weeks, there are no radiographic signs of loosening of the hardware, the patient may progress to a sling.
- Another radiograph is obtained at 3 months. If there are no signs of loosening, thoracoscapular strengthening and mobilization exercises are initiated.
- Glenohumeral arthrodesis places significant stress on the periscapular musculature. The rehabilitation process is slow, and a recovery period of 6 to 12 months should be expected.

OUTCOMES

- After successful arthrodesis, the patient usually can reach the mouth, opposite axilla, belt buckle, and side pocket. The patient cannot work or reach overhead, and cannot reach the back pocket or a bra strap, and perineal care often is very difficult using the fused shoulder.
- Richards et al.3 assessed the ability to perform specific activities of daily living in 33 patients following glenohumeral arthrodesis.
- Patient satisfaction was highest in those patients undergoing the procedure for a brachial plexus injury, osteoarthritis, and failed total shoulder arthroplasty.
- Cofield and Briggs4 reported their results for glenohumeral fusion with internal fixation in 71 patients. Eighty-two percent of the patients felt that they benefited from the procedure, and 75% were able to perform activities that involved reaching their trunk.
- Scalise and Iannotti5 analyzed the results of arthrodesis in seven patients following failed prosthetic arthroplasty. Five of the seven patients eventually achieved fusion. Four patients required additional bone-grafting procedures in an attempt to achieve union, and two of these patients ultimately had a persistent nonunion despite the additional procedures.

COMPLICATIONS

- Nonunion
- Prominent hardware
- Malposition
- Infection
- Humeral shaft fracture

REFERENCES

DEFINITION

- Glenohumeral arthritis is characterized by loss of articular cartilage and varying degrees of soft tissue contracture, rotator cuff dysfunction, and bone erosion, depending on the underlying arthritic condition.
- The results of surgical treatment are largely dependent on the integrity of the rotator cuff; therefore, glenohumeral arthritides are often subdivided on this basis.
- Common arthritic and related conditions that generally involve an intact or reparable rotator cuff include osteoarthritis, posttraumatic arthritis, and avascular necrosis.
- Although some patients with inflammatory arthritides such as rheumatoid arthritis have intact or reparable rotator cuffs, the rotator cuff is torn or dysfunctional in many patients. When reference is made to patients with inflammatory arthritides in this section, it pertains to the subset of patients in whom the cuff is intact or reparable.

ANATOMY

- The pertinent surgical anatomy can be divided into bone, ligaments, muscles, and neurovascular structures.
- Normal osseous relationships include humeral head center, thickness, and radius of curvature, humeral neck–shaft angle, humeral head offset, glenohumeral offset, greater tuberosity-to-acromion distance, greater tuberosity-to-humeral-head distance, glenoid radius of curvature, glenoid size, glenoid version, and glenoid offset (FIG 1).14,22
- Humeral head radius and thickness are variable and correlate with patient size. Mean humeral head radius is about 24 mm, with a range of 19 to 28 mm. Mean humeral head thickness is about 19 mm, with a range of 15 to 24 mm.14,22
- The ratio of humeral head thickness to humeral head radius of curvature is remarkably constant at about 0.7 to 0.9, regardless of patient height or humeral shaft size.14,22
- The center of the humeral head does not coincide with the projected center of the humeral shaft. The distance between the center of the humeral head and the central axis of the intramedullary canal is defined as the humeral head offset and is about 7 to 9 mm medial and 2 to 4 mm posterior (FIG 2).2,22
- Humeral retroversion averages 20 to 30 degrees, with a wide range of about 20 to 55 degrees.2,14,22 The vertical distance between the highest point of the humeral articular surface and the highest point of the greater tuberosity (ie, head to greater tuberosity height) is about 8 mm and shows a relatively small range of interspecimen variability.14
- Humeral neck–shaft angle is defined as the angle subtended by the central intramedullary axis of the humeral shaft and the base of the articular segment and shows substantial individual variation. The average neck–shaft angle is 40 to 45 degrees (130–135) degrees, with a range of 30 to 55 (120–145) degrees.2,14,22
- Pertinent musculotendinous anatomy includes the deltoid, pectoralis major, conjointed tendon of the coracobrachialis and short head of the biceps, rotator cuff, and long head of the biceps.

FIG 2 • The humeral head center, on average, lies 2 to 4 mm posterior and 7 to 9 mm medial to the projected center of the intramedullary canal. (Adapted from Boileau P, Walch G. The three-dimensional geometry of the proximal humerus: implications for surgical technique and prosthetic design. J Bone Joint Surg Br 1997;79B:857–865.)
Ligamentous structures that are potentially important in the surgical management of glenohumeral arthritis include the coracohumeral ligament and the glenohumeral capsular ligaments. In many cases of glenohumeral arthritis with an intact cuff, the anterior and inferior capsular ligaments are contracted, resulting in restriction of external rotation and posterior humeral head subluxation.

Neurovascular structures are abundant and subject to potential injury during shoulder arthroplasty. The axillary artery and all of its branches, especially the anterior humeral circumflex, posterior humeral circumflex, and the subscapular arteries, are particularly vulnerable.

The entire brachial plexus traverses the anterior aspect of the shoulder and is subject to traction and other injuries. The two most pertinent nerves are the axillary nerve and the musculocutaneous nerve.

The axillary nerve is a terminal branch of the posterior cord of the brachial plexus and is composed primarily of motor fibers from the fifth and sixth cervical roots. It descends the anterior surface of the subscapularis to the inferior aspect of the joint capsule, where it courses through the quadrilateral space to enter the posterior aspect of the shoulder.

The musculocutaneous nerve is one of the terminal branches of the lateral cord of the brachial plexus that is anterior and lateral to the axillary nerve. It typically pierces the conjoined tendon of the coracobrachialis and short head of the biceps about 5 cm distal to the tip of the coracoid. However, this course is variable and the entry point into the conjoined tendon can be as proximal as 2 cm.

**PATHOGENESIS**

The biologic basis for glenohumeral arthritis is not known. However, the loss of articular cartilage associated with primary osteoarthritis, posttraumatic arthritis, avascular necrosis, and other arthritides is, in some way, the result of imbalance in the normal cycle of cartilage damage and repair.

In some cases of posttraumatic arthritis, catastrophic cartilage damage associated with single-event or repetitive trauma overwhelms the shoulder’s cartilage repair mechanisms and arthritis ensues.

Primary osteoarthritis may be associated with mechanical factors such as glenoid hypoplasia and increased retroversion. However, in many cases, no cause is evident. The final common pathway involves a release of degradative enzymes such as collagenase, gelatinase, and stromelysin, and a variety of inflammatory mediators, which further damage the cartilage and eventually the underlying bone.

A detailed discussion of the pathogenesis of avascular necrosis is beyond the scope of this chapter. However, the development of glenohumeral arthritis in this condition is likely the result of advanced cartilage damage following collapse of the humeral head. Involvement of glenoid articular cartilage does not occur until the later stages of the disease, when the irregular humeral head has been articulating with the previously normal glenoid surface.

Rheumatoid arthritis is characterized by activation of the immune system that leads to an influx of lymphocytes into the joint and synovial tissue, with subsequent release of a variety of cytokines, destructive enzymes, and mediators of inflammation such as interleukins and tumor necrosis factor. This autoimmune response is thought to be important in perpetuating joint destruction.\(^{25}\)

**NATURAL HISTORY**

- Glenohumeral arthritis of any type is characterized by progressive stiffness, pain, and loss of function.
- Patients with primary osteoarthritis and many types of posttraumatic arthritis develop progressive loss of external rotation, posterior subluxation, and posterior glenoid bone loss. Large osteophyte formation, especially on the inferior humeral neck, is common. Full-thickness rotator cuff tears are distinctly uncommon and occur in 5% to 10% of patients.
- Rheumatoid arthritis results in progressive regional osteopenia, central glenoid bone erosion, and rotator cuff tears. The prevalence of full-thickness rotator cuff tears in patients with rheumatoid arthritis of the shoulder is 25% to 40%.\(^{27}\)
- However, rotator cuff dysfunction and substantial partial tearing are extremely common.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Patients with glenohumeral arthritis will give a history of chronic (years) shoulder pain and restricted motion, often with a recent (months) exacerbation. Posttraumatic arthritis is typically associated with a history of prior injury, such as fracture or dislocation, or surgery.
- Pain is often worse with activity and usually interferes with sleep. Neck pain, distal radiation below the elbow, and numbness and paresthesias in the fingers and hand are uncommon and should suggest other potential causes of shoulder pain, such as cervical stenosis or cervical radiculopathy.
- Bilateral involvement is common in primary osteoarthritis. Contralateral symptoms are often present, but to a lesser extent.
- Physical findings in patients with glenohumeral arthritis and an intact rotator cuff include:
  - Posterior joint line tenderness, especially in osteoarthritis associated with posterior subluxation\(^{20}\)
  - Generalized atrophy or flattening of the shoulder from long-term lack of function
  - Posterior prominence of the humeral head in cases of posterior subluxation
  - Symmetrical loss of active and passive range of motion (FIG 3)
  - Disproportionate loss of external rotation in comparison to other motions, especially in osteoarthritis or after capsulorraphy arthropathy\(^{20}\)
  - Increased pain with passive stretch of the capsule at the end range of motion, especially external rotation
  - Intact neurologic function, except in rare patients with prior neurologic injury from trauma or surgery

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Glenohumeral arthritis is a radiographic diagnosis. Routine radiographs should include anteroposterior (AP) views in internal and external rotation and an axillary view.

Radiographic findings in primary osteoarthritis include subchondral sclerosis and cyst formation, osteophyte formation, and asymmetrical posterior joint space narrowing (FIG 4A,B).\(^{20}\)

In cases of posttraumatic arthritis, radiographs may reveal retained hardware.
The hallmark of gleno-humeral osteoarthritis is symmetrical loss of both active and passive range of motion (A), especially external rotation (B).

Radiographic findings in osteoarthritis include osteophyte formation, especially on the inferior humerus as seen on the AP view (A), and asymmetrical posterior glenoid wear with posterior subluxation, as seen on the axillary view (B). C. CT scan reveals a large inferior humeral osteophyte and a type C glenoid, with increased glenoid retroversion. D. Coronal MR image in a patient with rheumatoid arthritis reveals an intact but very thin rotator cuff with erosion of the humeral attachment site, and evidence of rotator cuff dysfunction (ie, proximal humeral migration).
Glenoid deformity in osteoarthritis has been classified by Walch\(^\text{26}\) according to the presence of posterior subluxation and posterior bone deformity:

- **Type A**: centered
- **Type B**: posteriorly subluxated (B1) and posteriorly subluxated with posterior erosion (B2)
- **Type C**: posteriorly subluxated with increased retroversion (hypoplasia)

Computed tomographic (CT) scans are helpful in quantifying bone loss in patients with posterior subluxation (FIG 4C).

MRI is useful in patients with rheumatoid arthritis to determine rotator cuff integrity (FIG 4D).

Electromyography may be used in patients suspected of having posttraumatic or postsurgical nerve injuries.

Medical consultation is warranted in patients with substantial comorbidities.

**DIFFERENTIAL DIAGNOSIS**

- Frozen shoulder
- Posttraumatic or postsurgical infection
- Cervical stenosis
- Cervical radiculopathy
- Neoplasm

**NONOPERATIVE MANAGEMENT**

- Avoiding activities that are painful or place an undue strain on the shoulder, such as weight lifting, is important.
- Nonsteroidal anti-inflammatory medications may be helpful in reducing pain and inflammation.
- In patients with rheumatoid arthritis, rheumatologic consultation for maximizing medical treatment is helpful.
- Glucosamine chondroitin and other nutritional supplements may reduce the pain associated with arthritis, despite the relative lack of standardized data.
- Intra-articular corticosteroid injections are almost always helpful, but the relief is often only temporary.
- Hyaluronic acid derivatives are not yet approved by the U.S. Food and Drug Administration for use in the shoulder but may be of benefit in the future.
- Therapeutic exercises should be used judiciously. Stretching to maintain flexibility may be helpful, but vigorous exercises may increase pain.

**SURGICAL MANAGEMENT**

- Surgical options are considered when pain and dysfunction justify surgical intervention, nonoperative management has failed, medical comorbidities do not preclude surgery, and the patient is willing to accept the risks of surgery and the responsibility of postoperative rehabilitation and activity limitations.
- Nonprosthetic options such as arthroscopic or open debridement are indicated in patients who are too young and active for any type of prosthetic replacement.
- Prosthetic options include hemiarthroplasty, hemiarthroplasty plus biologic resurfacing, and total shoulder replacement.
- Total shoulder replacement with a polyethylene glenoid component provides the most predictable pain relief but has the disadvantage of progressive polyethylene wear and eventual component loosening.\(^{26}\)
- Hemiarthroplasty can be successful in providing pain relief, especially with minimal glenoid involvement or concentric glenoid wear. However, progressive glenoid erosion is likely and may require revision to total shoulder replacement.
- Hemiarthroplasty with resurfacing of the glenoid with biologic materials such as meniscal allograft, capsular or fascia lata autograft, fascia lata allograft, dermal allograft, Achilles tendon allograft, or xenograft materials has been performed, particularly in patients too young or active for a polyethylene glenoid component.\(^{3,21,30}\)
- The additional benefit of biologic resurfacing of the glenoid over hemiarthroplasty alone has not been clearly demonstrated, nor has its durability been confirmed.\(^{10}\)
- Hemiarthroplasty may be accomplished by replacement or resurfacing of the humeral head.
- Replacement of the humeral head is most commonly accomplished with a prosthetic head that is anchored to the shaft with a stem. However, more recently, humeral head replacements have been developed that are fixed to the metaphysis without violation of the diaphyseal canal.
- The relative indications for hemiarthroplasty, hemiarthroplasty with biologic resurfacing, and total shoulder arthroplasty are controversial, vary among surgeons, and must be individualized according to patient age, activity level, and bone deformity, among other factors.
- Similarly, the type of implant can be individualized according to patient factors and surgeon preference.
- Concentricity of the joint, without subluxation, likely improves prosthetic performance in all circumstances. Therefore, fixed subluxation should be corrected when possible. Options include contracture release and correction of bone deformity with some combination of asymmetric reaming, bone grafting, and specialized components.
- General principles that summarize procedural and implant indications in patients with glenohumeral arthritis and an intact or reparable cuff include the following:
  - Total shoulder arthroplasty is preferred with adequate glenoid bone, age greater than 50, and sedentary or moderate activity levels.
  - Hemiarthroplasty is favored in patients with normal or minimally involved glenoids, inadequate glenoid bone, age of 50 or under, and activity levels that include weight lifting or other strenuous activity.
  - Biologic resurfacing of the glenoid may be added to hemiarthroplasty but may also fail in patients who participate in heavy weight lifting or other strenuous activity.
- When substantial reaming or resurfacing of the glenoid is planned, the procedure is facilitated by removing the humeral head rather than resurfacing it. Currently stemmed implants are most popular, but implants with metaphyseal fixation may be useful in patients with adequate bone quality.
- Humeral resurfacing is useful when hemiarthroplasty is indicated in the absence of substantial glenoid deformity. Resurfacing preserves humeral bone and obviates the need to address humeral head–humeral canal offset.
- These principles are merely guidelines and should be individualized.
- The following sections will cover the technical aspects of humeral resurfacing, humeral replacement, humeral replacement combined with biologic glenoid resurfacing with allograft lateral meniscus, and total shoulder arthroplasty. Glenoid bone grafting is beyond the scope of this chapter and will not be covered.
Preoperative Planning

- Preoperative radiographs and CT scans should be reviewed to quantify humeral subluxation (especially posterior in osteoarthritis) and glenoid bone loss. This will identify the need for asymmetric glenoid reaming.
- If the goals of asymmetric reaming are to correct glenoid deformity and to contain all fixation appendages of the glenoid component within the glenoid vault, the extent of reaming should be limited to about 5 mm or 15 degrees. If greater correction is desired, arrangements for glenoid bone grafting should be made.
- Preoperative radiographs should be templated to gain an appreciation of the humeral head size, canal diameter, and neck–shaft angle. In patients with highly varus (115–120 degrees) or valgus (145–150 degrees) neck–shaft angles in whom cementless fixation of a stemmed implant is planned, alterations in the level of the humeral cut or the use of a prosthesis with neck–shaft angle variability will be required.
- MRI scans should be read for substantial rotator cuff abnormalities in rheumatoid patients and others suspected of having rotator cuff tears.
- All other relevant preoperative data should be reviewed, including consultations from medical colleagues. The presence of all surgical implants and instruments should be verified.
- Passive range of motion should be measured intraoperatively, before positioning, to determine the need for contracture release. In particular, the degree of passive external rotation loss may dictate the method of subscapularis reflection and repair.
- Subscapularis shortening is typically not a substantial factor in passive external rotation loss, unless the patient has had a prior subscapularis shortening or tightening procedure (eg, Putti-Platt or Magnuson-Stack) or the contracture is particularly severe (eg, external rotation of –30 degrees or more) and longstanding.
- Methods of managing the subscapularis include intratendinous incision and anatomic repair, lesser tuberosity osteotomy and anatomic repair, lateral tendinous release with medial advancement, and Z-lengthening.
- Recent evidence suggests that lesser tuberosity osteotomy is associated with better subscapularis function than soft tissue reflection and repair.12,23 However, randomized comparison data are not currently available. In addition, a recent study documents good postoperative subscapularis function with tenotomy and soft tissue repair.4
- My current preference for subscapularis management in primary shoulder arthroplasty is lesser tuberosity osteotomy and anatomic repair, with the following exceptions:
  - Rheumatoid arthritis with substantial erosion of the subscapularis attachment site on MRI
  - History of a subscapularis shortening or tightening procedure (eg, Putti-Platt or Magnuson-Stack procedure)
  - Passive external rotation of less than –30 degrees
  - If lesser tuberosity osteotomy is not performed, lateral detachment with medial reattachment is most often adequate. Subscapularis Z-lengthening is rarely required.

Positioning

- Shoulder arthroplasty is performed with the patient in the semirecumbent position (FIG 5A). The hips should be flexed about 30 degrees to prevent the patient from sliding down the table; the knees should be flexed about 30 degrees to relax tension on the sciatic nerves; the back should be elevated 35 to 40 degrees.
- The entire shoulder should be lateral to the edge of the table to allow adduction and extension of the arm (FIG 5B). This is
required for safe access to the humeral canal and can be accomplished by positioning the patient as far toward the operative side of the table as possible or by using a specialized table with removable cutouts behind the shoulders.

- A specialized padded, horseshoe-shaped headrest may be helpful in facilitating access to the superior aspect of the shoulder.
- An adjustable mechanical arm holder (McConnell Orthopedic Mfg. Co., Greenville, TX, or Tenet Medical Engineering, Inc., Calgary, Alberta, CA) is helpful for positioning the arm. Alternatively, a padded Mayo stand can also be used (FIG 5C).

**Approach**

- The most common approach for shoulder arthroplasty is the deltopectoral approach popularized by Neer. The advantages are preservation of the deltoid origin and insertion, extensibility, and excellent humeral exposure. The need for posterior deltoid retraction, especially in muscular men, can make posterior glenoid exposure difficult and can lead to injury of the cephalic vein, the deltoid itself, or the brachial plexus.
- The superior or anterosuperior approach was popularized by MacKenzie and involves access to the shoulder by reflecting the anterior deltoid from the acromion. Advantages include excellent anterior and posterior glenoid exposure and a lower incidence of axillary nerve traction injuries than the traditional deltopectoral approach. Disadvantages include nonextensibility, difficult medial and inferior humeral exposure, and potential deltoid dehiscence.
- Modifications of these exposures include the addition of a clavicular osteotomy and extensive takedown of the deltoid origin to aid in exposure for difficult cases.
- The deltopectoral approach is the most commonly used approach for primary arthroplasty with an intact or reparable cuff and will be used in all subsequent sections of this chapter.

### HUMERAL RESURFACING

**Superficial Dissection**

- A deltopectoral incision is made from the tip of the coracoid toward the deltoid insertion.
- The cephalic vein is taken laterally with the deltoid and the pectoralis major is taken medially.
- The upper 1 cm of the pectoralis major may be released to improve visualization of the inferior aspect of the joint, but this is not always needed.

**Deep Dissection**

- The clavipectoral fascia is incised lateral to the conjoined tendon of the short head of the biceps and coracobrachialis and is carried superiorly to the coracoacromial ligament, which does not require excision or release to attain adequate exposure.
- Digital palpation is used to verify the position of the axillary nerve, which is protected throughout the procedure. The musculocutaneous nerve is usually not easily palpable within the surgical field but can be palpated when its entrance is close to the tip of the coracoid. This should be noted so that excessive retraction of the conjoined tendon can be avoided.
- With the conjoined tendon retracted medially and the deltoid laterally, the arm is placed in slight external rotation to expose the anterior humeral circumflex artery and veins. These are clamped and coagulated or ligated to avoid inadvertent injury and bleeding during the case.
- The arm is placed in slight internal rotation and the long head of the biceps is exposed from the superior border of the pectoralis major to the supraglenoid tubercle by incising its investing soft tissue envelope and the rotator interval capsule. The long head of the biceps is tenodesed to the upper border of the pectoralis major using two nonabsorbable sutures and is then released proximal to this tenodesis site and excised from the supraglenoid tubercle.

### Lesser Tuberosity Osteotomy

- A large (2 inch) curved osteotome is used to perform a lesser tuberosity osteotomy (TECH FIG 1A). The goal is to obtain a 0.5- to 1-cm-thick, noncommitted fragment with which to reflect the subscapularis.
- This is most easily accomplished by placing the blade of the osteotome at the base of the bicapital groove with one hand, palpating the most anterior extent of the tuberosity with the index finger of the other hand, and allowing an assistant to strike the osteotome while the surgeon directs it.
- Once the osteotomy is completed, a large straight osteotome is placed in the osteotomy and is rotated about its long axis to free the osteotomy fragment from any adjacent soft tissue attachments.
- A large Cobb elevator is then placed in the osteotomy to lever the fragment anteriorly. This further frees the fragment from the underlying capsule and allows sectioning of the superior glenohumeral ligament attachment.
- The fragment should now be freely mobile. Three 1-mm nonabsorbable sutures are passed around the lesser tuberosity fragment through the bone–subscapularis tendon junction for traction and later reattachment (TECH FIG 1B,C).
- The arm is externally rotated to expose the most inferior portion of the subscapularis muscle. This may require a right-angle retractor for the pectoralis major. The muscle belly is incised superficially, in line with its fibers, about 1 cm superior to its most inferior border.
- A blunt elevator is used to dissect the interval between the subscapularis and the underlying capsule. Once this interval is adequately developed, a scalpel is placed between the subscapularis and capsule. With the lesser tuberosity pulled anteriorly, the scalpel is passed laterally so that is exits inferior to the fragment. This is continued from inferior to superior to release the subscapularis and

---

**REFERENCE**

3. Achilles tendon retraction, especially in muscular men, can make posterior glenoid exposure difficult and can lead to injury of the cephalic vein, the deltoid itself, or the brachial plexus.
4. The superior or anterosuperior approach was popularized by MacKenzie and involves access to the shoulder by reflecting the anterior deltoid from the acromion. Advantages include excellent anterior and posterior glenoid exposure and a lower incidence of axillary nerve traction injuries than the traditional deltopectoral approach. Disadvantages include nonextensibility, difficult medial and inferior humeral exposure, and potential deltoid dehiscence.
5. Modifications of these exposures include the addition of a clavicular osteotomy and extensive takedown of the deltoid origin to aid in exposure for difficult cases.
6. The deltopectoral approach is the most commonly used approach for primary arthroplasty with an intact or reparable cuff and will be used in all subsequent sections of this chapter.
lesser tuberosity from the underlying anterior and inferior capsule.

**Capsular Release and Osteophyte Excision**

- Once released, the subscapularis and attached lesser tuberosity are retracted medially to expose the anterior capsule. A blunt elevator is passed between the remaining inferior 1 cm of subscapularis and the inferior capsule to create a space for a blunt Hohmann retractor. This is used to retract and protect the axillary nerve during inferior capsular release and excision.
- The anterior capsule is released from the anatomic neck of the humerus, starting superiorly and extending inferiorly, well past the 6 o’clock position. This is facilitated by gradually flexing and externally rotating the adducted humerus.
- The humerus is then delivered into the wound with simultaneous adduction, extension, and external rotation (**TECH FIG 2A**). All humeral osteophytes are removed using a combination of rongeurs and osteotomes (**TECH FIG 2B**). This allows identification of the anatomic neck and the peripheral extent of the native articular surface.

**Humeral Preparation**

- Accurate placement of the central guide pin is the most important portion of the resurfacing procedure. This guide pin fixes the center and inclination of the articular surface in all planes. Once the guide pin is anatomically positioned, the remainder of the procedure is only a matter of choosing the appropriately sized head and placing it at the appropriate depth.

**TECH FIG 1** • A. A lesser tuberosity osteotomy is performed using a large curved osteotome placed in the base of the bicipital groove and driven medially to produce a lesser tuberosity fragment about 0.5 to 1.0 cm thick. B,C. A lesser tuberosity osteotomy has been performed in this right shoulder. B. After the fragment has been mobilized from the surrounding soft tissues, three heavy nonabsorbable sutures are placed around the fragment at the bone-tendon junction. C. The fragment is then reflected medially and the subscapularis and the accompanying lesser tuberosity are separated from the underlying capsule and retracted medially. (A: Adapted from Gerber C, Pennington SD, Yian EH, et al. Lesser tuberosity osteotomy for total shoulder arthroplasty: surgical technique. J Bone Joint Surg Am 2006; 88A[Suppl 1]:170–177.)

**TECH FIG 2** • A. The humerus is delivered into the wound with simultaneous adduction, extension, and external rotation in this right shoulder. Retractors include a Brown deltoid retractor superiorly, a large Darrach retractor medially, and a blunt Hohmann retractor anteroinferiorly on the calcar. B. All humeral osteophytes are removed at this stage to identify the anatomic neck.
In some systems, there are guides that can assist in accurate pin placement. The guides usually are hemispherical and cannulated centrally so that the edge of the guide is positioned parallel to the articular margin in the visual center of the head.

Once the surgeon is satisfied with pin placement, shaping of the humeral head to fit the deep surface of the resurfacing implant can commence.

Reamers are selected based on the anticipated size of the prosthetic humeral head, which is, in turn, decided through a combination of preoperative templating and intraoperative measurements.

Proper selection of humeral head radius and thickness (ie, neck length) is critical and there is a tendency to choose a head that is too large.

The appropriate reamer is selected and the humerus is reamed until the reamer bottoms out on the humerus (TECH FIG 3). There is a tendency to underream. Reaming can continue to within 2 to 3 mm of the rotator cuff reflection superiorly.

Trial implants are placed over the guide pin onto the reamed humeral surface. Circumferential contact is verified.

The central punch is placed over the guide pin and driven into the humeral metaphysis to prepare it for the central peg of the prosthetic head.

Substantial glenoid reaming should not be required, as these patients are treated with humeral head resection and a stemmed implant in my practice.

**Humeral Component Placement and Lesser Tuberosity Repair**

The humerus is redelivered into the wound and the appropriate humeral resurfacing implant is placed and impacted into position (TECH FIG 4). Care should be taken to ensure that the implant is completely seated. This requires removal of excess bone from around the periphery of the projected seating point of the implant.

Two small bone anchors are placed in the humerus medial to the osteotomy but lateral to the humeral prosthetic edge. The sutures on the anchors are passed in a mattress configuration through the subscapularis tendon from deep to superficial at the bone–tendon junction. The sutures are clamped but not tied yet.

With the humerus reduced and the arm in neutral rotation, the deep limbs of the three sutures previously passed around the lesser tuberosity are passed through the cancellous bone of the osteotomy bed as far laterally as possible.

**Glenoid Inspection, Capsular Excision, and Release**

The guide pin is removed and the glenoid is exposed by placing a humeral head retractor within the joint and retracting the humeral head posteriorly. Care should be taken not to damage the reamed surface of the humerus.

The axillary nerve is protected and the anteroinferior capsule is excised. If the labrum is present, it is left in place. The posterior capsule is released.
as possible, deep to the bicipital groove and out the lateral cortex of the humerus using a large, cutting free needle. A new needle is used for each pass and the sutures are clamped but not tied.

- The clamps on these three sutures are pulled laterally to hold the lesser tuberosity in a reduced position. The rotator interval is then closed laterally with a 1-mm non-absorbable suture.

- After the rotator interval suture is tied, the three interfragmentary sutures are tied, followed by the sutures from the anchors. This provides a secure lesser tuberosity and subscapularis repair.

- Passive motion achievable without undue tension on the subscapularis repair is noted for guidance of postoperative rehabilitation.

**Wound Closure**

- A drain is placed deep to the deltoid and is brought out through a separate stab wound, distal to the axillary nerve.

- The wound is closed in layers with interrupted absorbable sutures in the subcutaneous tissues and a running subcuticular monofilament suture.

### HEMIARTHROPLASTY

- Hemiarthroplasty with head resection is performed when concentric glenoid reaming is required.

- The techniques of superficial and deep dissection, lesser tuberosity osteotomy, capsular release, and osteophyte excision are the same as described previously.

### Humeral Head Resection

- The humeral head is removed with a saw at or near the anatomic neck (TECH FIG 5A). This can be accomplished freehand or with intramedullary or extramedullary guides.

- Retroversion of the cut in my practice is prescribed by the plane of the periphery of the native articular surface (ie, native retroversion). A small amount of bone (2 to 3 mm) can be left medial to the supraspinatus insertion (TECH FIG 5B).

- The neck-shaft angle of the humeral cut is determined by the type of implant used.

- With fixed neck-shaft angle devices, the cut should precisely fit the neck-shaft angle of the selected device.

- With variable neck-shaft angle implants there is more flexibility in osteotomy angle, especially if the variability of the implant neck-shaft angle is infinite within a range.

- Preoperative templating should identify the patient with an extreme varus (less than 125) or valgus (greater than 145 degrees) neck-shaft angle.

- In cases of extreme varus, use of a fixed-angle cementless stem will require a humeral cut that is more valgus than the native neck-shaft angle.

- The cut exits superiorly 2 to 3 mm medial to the cuff reflection and inferiorly through the native head. This will leave a small portion of the native head in place, even after the inferior osteophyte is removed.

- In cases of extreme valgus, use of a fixed-angle cementless stem will require a humeral cut that is more varus than the native neck-shaft angle.

- The cut exits inferiorly at the native articular margin and superiorly through the native head. This will leave a small portion of the native head medial to the cuff reflection.

- Alternatively, the cut can be made along the native neck-shaft angle and a variable neck-shaft angle device can be used to fit the native neck-shaft angle.

- The size of the humeral head is estimated by placing trial humeral heads on the cut surface of the osteotomy.

### Glenoid Exposure, Capsular Excision, and Surface Preparation

- With the humeral head resected, a Fukuda ring retractor is placed within the joint and the humerus is retracted posteriorly.

- A reverse, double-pronged Bankart retractor is placed on the scapular neck anteriorly, between the anterior capsule and the subscapularis.

- A blunt Hohmann retractor is placed along the anteroinferior portion of the scapular neck to retract and protect the axillary nerve, and the anterior and inferior capsule is excised.

**TECH FIG 5**

- **A.** After removal of all osteophytes, the location of the anatomic neck is marked with an electrocautery. This can be done freehand or using an external guide.

- **B.** The humerus is cut in native retroversion, leaving 2 to 3 mm of bone medial to the supraspinatus insertion.
The posterior capsule is released unless preoperative posterior humeral subluxation of greater than 25% was present, in which case the posterior capsule is preserved. The labrum is excised circumferentially to expose the entire periphery of the glenoid. If greater than 25% posterior humeral subluxation was present preoperatively, care is taken to preserve the posterior capsular attachment to the glenoid. The glenoid is sized with a sizing disk. The previously estimated humeral head size may give some idea of the glenoid size. The center of the glenoid is marked and a centering drill hole for the glenoid reamer is drilled. The orientation of this drill hole should be perpendicular to the estimated reamed surface. This can be estimated using preoperative CT measurements of the amount of posterior glenoid bone loss. The glenoid is reamed until a concentric surface is obtained.

Humeral Preparation and Component Placement

The humerus is redelivered into the wound and the humeral canal is reamed with sequentially larger reamers until light purchase is obtained within the intramedullary canal. A box osteotome that corresponds to the final reamer size is passed into the humerus to cut the footprint of the humeral implant. A broach that corresponds to the size of the box osteotome and final canal reamer is placed to the appropriate depth. The system I use allows either a fixed 135-degree neck–shaft angle or an infinitely variable neck–shaft angle within 120 to 150 degrees (Global AP, Depuy, Warsaw, IN). Therefore, a collar is screwed into the broach that creates a 135-degree neck–shaft angle. A calcar reamer is placed over the collar and, if the reamer is nearly parallel to the osteotomy surface, it is used to plane the surface to 135 degrees so that an implant with a fixed neck–shaft angle of 135 degrees can be used. A trial humeral head is placed over the collar, it is rotated into the offset position that provides the most symmetrical coverage of the humeral metaphysis, and the collar is locked to the broach. If the planes of the calcar reamer and the osteotomy surface are not nearly parallel, a variable neck–shaft angle implant will be used. The 135-degree collar is removed and a trial ball taper fitted with a humeral head trial is inserted into the broach. The trial head and ball taper are placed into the position that provides symmetrical coverage of the humeral metaphysis, and the taper is locked to the broach. With the trial humeral head locked into position, the remaining humeral osteophytes are removed so that the humeral bone is flush with the humerus around the entire periphery. Assuming the humerus has been reduced and adequate soft tissue tension and stability have been verified, the trial broach is removed and the real implant is assembled with either a fixed 135-degree taper or a variable ball taper in the same position as the trial. A nonabsorbable suture is passed around the neck of the prosthesis and the prosthesis is impacted into the humerus with the two ends of the suture protruding anteriorly. The humerus is then reduced.

Lesser Tuberosity Repair

The technique for lesser tuberosity repair is the same as described for humeral resurfacing, except that the suture that was placed around the prosthetic neck before impaction into the humerus takes the place of the suture anchors that were placed in the anterior humerus between the osteotomy bed and the lateral extent of the resurfacing prosthesis (TECH FIG 6A). Therefore, the osteotomy is stabilized with three suture groups: The three interfragmentary sutures from the lesser tuberosity to the osteotomy bed The rotator interval closure suture at the superior aspect of the osteotomy The suture from the prosthetic through the bone–tendon junction (TECH FIG 6B) The technique for wound closure is identical to that described for humeral resurfacing.

Tech FIG 6 • A. The final implant is seated and any remaining bone prominences are removed. The three interfragmentary sutures around the lesser tuberosity are visible posterior to the prosthesis. The strands from the suture that was placed around the neck of the prosthesis can be seen exiting the space between the prosthetic humeral head and the anterior humeral metaphysis. B. The lesser tuberosity has been repaired with a superior side-to-side suture in the lateral rotator interval, the three interfragmentary sutures tied over the bicipital groove, and the medial suture passed from the prosthetic neck through the bone–tendon junction.
HEMIARTHROPLASTY WITH BIOLOGIC RESURFACING  
(LATERAL MENISCAL ALLOGRAFT)

- All techniques are the same as described earlier for humeral resurfacing and hemiarthroplasty, except that placement of the allograft requires maximum glenoid exposure.
- The allograft can be grossly sized using glenoid sizing disks. It is prepared by suturing the anterior and posterior horns together.
- The glenoid surface should be concentric in order for biologic resurfacing with meniscal allograft to be successful. Therefore, reaming to correct glenoid bone deficiency (eg, posterior wear) should be performed before placing the allograft.
- If the labrum can be preserved, it can be used to anchor the allograft to the glenoid.
- Often, the labrum is absent or too degenerative to dependably hold sutures. Under these circumstances, absorbable suture anchors are used to attach the allograft around the periphery of the glenoid. Four to six anchoring points should be used, depending on the size of the glenoid (TECH FIG 7A).
- The sutures are passed into the periphery of the ring-shaped allograft above the wound at appropriate positions (TECH FIG 7B). The allograft is then shuttled down the sutures onto the glenoid surface and the sutures are tied (TECH FIG 7C).  
- If there is no bleeding bone exposed from reaming, drilling a few holes through the subchondral surface into the glenoid vault may assist in decompressing the glenoid vault and providing progenitor cells that can assist in healing.

TECH FIG 7 • A. The glenoid in this right shoulder is exposed with a Fukuda retractor posteriorly, a large Darrach retractor anteriorly on the neck of the scapula, and a single-prong Bankart retractor posterosuperiorly. Anchors have been placed in the four quadrants of this small glenoid. B. The meniscal allograft has been sutured into a ring and sutures from the previously placed anchors are passed through the meniscal allograft above the joint. C. The allograft is then transported down the sutures onto the glenoid surface and the sutures are tied. (From Williams G. Hemiarthroplasty and biological resurfacing of the glenoid. In: Zuckerman JD, ed. Advanced Reconstruction: Shoulder. Rosemont, IL: AAOS, 2007:545–556.)

TOTAL SHOULDER ARTHROPLASTY

- All techniques are the same as described earlier for humeral resurfacing and hemiarthroplasty except for placement of the glenoid component.
- Concentric glenoid reaming is an important step in glenoid resurfacing that improves initial seating and stability. This is accomplished by drilling a pilot hole in the center of the glenoid (TECH FIG 8A). Special glenoid reamers are used to ream concentrically around the center pilot hole (TECH FIG 8B).
- After the surface of the glenoid has been reamed concentrically, the anchoring holes for the glenoid component are created. Both pegged and keeled components are available. The technique described is for an off-axis pegged system (anchor peg glenoid, Depuy, Warsaw, IN).
- The center hole for the larger fluted central peg is drilled, followed by the holes for the three peripheral pegs (TECH FIG 8C). Penetration of any of the peripheral holes is uncommon but should be noted so that a bone plug from the humeral head can be placed before filling the hole with cement.
- A trial glenoid component is placed and complete seating and stability are verified.
- The holes are irrigated and dried.
- Bone cement is placed into the three peripheral holes using a syringe to pressurize the cement column. Any holes that required bone grafting from drill perforation should not receive pressurized cement.
- The glenoid component is impacted into position and can be held with digital pressure until the cement hardens (TECH FIG 8D).
Postoperative Care

- Early rehabilitation (6 weeks)
  - The goals of rehabilitation during the first 6 weeks after surgery are to maximize passive range of motion and to allow healing of the subscapularis or lesser tuberosity.
  - The safe range of glenohumeral motion that prevents excessive tension on the subscapularis is identified intraoperatively.
  - This range of passive motion is performed starting the first postoperative day.
  - In general, uncomplicated shoulder arthroplasty will allow passive elevation to 140 degrees and passive external rotation to 40 degrees. If there is concern for the subscapularis repair, elevation and external rotation can be dropped to 130 and 30 degrees, respectively. If the tissue is poor quality, one may even drop the limits to 90 degrees of elevation and 0 degrees of external rotation.
  - These exercises are performed for 6 weeks postoperatively, in combination with pendulum exercises.
  - The sling may be discontinued at home after the first week or 10 days, when the hand can be used as a helping hand for daily activities.
- Active elevation above 90 degrees is delayed until 6 weeks postoperatively.
- Midterm rehabilitation (6 to 12 weeks)
  - During midterm rehabilitation, active range of motion is encouraged, passive stretching is instituted, and strengthening exercises for the rotator cuff, deltoid, and scapular stabilizers are pursued.
  - Active assisted range of motion within the limits of pain is accomplished with an overhead pulley and 3-foot stick.
  - This is progressed to active range of motion as tolerated.
  - End-range stretching in all planes is begun and progressed.
  - Strengthening exercises with the Theraband commence when active range of motion is maximized.
- Late rehabilitation (12 to 24 weeks)
  - Strengthening exercises for the rotator cuff, deltoid, and scapular stabilizers continue throughout the late stage of rehabilitation.
  - Patients will be functional with most daily activities, except at the extremes of motion.
  - Total arm strengthening and gradual return to activities are encouraged.

Pearls and Pitfalls

- Imaging
  - Radiographic evaluation must include a quantification of glenoid version, asymmetrical wear, and available bone stock. This requires either a perfect axillary lateral or cross-sectional study, preferably a CT scan.
- Patient selection
  - Glenoid components should be used cautiously if at all in young (ie, under 50) or active patients. The use of biologic resurfacing is controversial and may not offer any advantage over hemiarthroplasty alone.
- Patient positioning
  - Safe access to the humerus during humeral preparation and component placement requires maximum humeral adduction. Therefore, patient positioning must prevent interference from the edge of the operating table.
- Glenoid exposure
  - Adequate glenoid exposure requires accurate humeral resection, humeral osteophyte excision, and adequate capsular excision and releases.
- Humeral preparation
  - Do not over-externally rotate or overream. This may lead to periprosthetic fracture.
- Nerve management
  - Know the position of the axillary nerve and protect it throughout the procedure. Avoid excessive traction on the conjoined tendon, especially if the musculocutaneous nerve is close to the tip of the coracoid. Take the arm out of extreme positions whenever possible.
Although improvement in function will continue for about 1 year, the vast majority of improvement from formal rehabilitation will be seen in the first 24 weeks (6 months).

OUTCOMES

Resurfacing

Reports of resurfacing arthroplasty are relatively sparse. Most data come out of a single institution.

In general, the results parallel the results of hemiarthroplasty. In one series of 103 patients with 5 to 10 years of follow-up, constant scores for patients with osteoarthritis undergoing total shoulder arthroplasty and hemiarthroplasty were 93.7% and 73.5% respectively. Lucency around the humeral component was 30.7%, and 1.9% required revision.17

In another series of patients with osteoarthritis undergoing resurfacing, hemiarthroplasty was found to be similar to total shoulder replacement.16

Hemiarthroplasty

Neer’s original article on replacement for osteoarthritis in 1974 included primarily hemiarthroplasties. Over 90% of patients had good or excellent results.20

The addition of concentric glenoid reaming to encourage the formation of a biologic membrane to resurface the glenoid has been reported by Matsen et al.8,18 The authors note that similar pain relief and function are possible with this procedure but that patients may take longer than total shoulder replacement patients to reach maximum improvement. In addition, in one of their series, 3 of 37 patients were no better or worse after the surgery.18

Additional studies have stressed the importance of concentricity of the glenoid in attaining a successful result as well as the relative difficulty in converting a painful hemiarthroplasty to total shoulder replacement.5

In addition, progressive, painful glenoid erosion can be associated with hemiarthroplasty.

Survivorship of hemiarthroplasty in one series decreased substantially with increasing follow-up, with 92%, 83%, and 73% survival at 5, 10, and 15 years, respectively.26

Hemiarthroplasty with biologic resurfacing

Although descriptions of this procedure exist before 1993, Burkhead popularized the concept of combining hemiarthroplasty with biologic glenoid resurfacing.3

A more recent report from Krishnan et al15 with long-term follow-up revealed only 5 of 39 patients with unsatisfactory results. Moreover, the patient population was relatively young and active.

Elhassan et al10 reported poor results in 13 patients undergoing hemiarthroplasty with biologic glenoid resurfacing. Ten of 13 patients required revision to total shoulder arthroplasty at a mean of 14 months after hemiarthroplasty.

Two additional studies,21,30 one with a minimum 2-year follow-up,30 confirm good early pain relief and return of function in young active patients undergoing hemiarthroplasty and glenoid resurfacing with lateral meniscal allograft. Both emphasize the importance of articular concentricity and offer data that may be interpreted to question the durability of the allograft.

Total shoulder arthroplasty

Many studies document consistent improvement in pain and function with total shoulder arthroplasty.

Several studies document better pain relief and, in some cases, better function with total shoulder arthroplasty in comparison to hemiarthroplasty. Survivorship of total shoulder arthroplasty in patients with an intact or reparable cuff is 84% to 88% at 15 years.5,26

COMPICATIONS

The reported complication rate after shoulder arthroplasty is 12% to 14.7%.1,6,31 One series reports a decrease in the complication rate with time, which may be explained by glenoid and humeral component loosening in only one shoulder.6

Complications include:

- Instability
- Rotator cuff tear
- Ectopic ossification
- Glenoid component loosening
- Intraoperative fracture
- Nerve injury
- Infection
- Humeral component loosening

REFERENCES

**DEFINITION**
- Glenohumeral arthritis is defined as loss of the normal articular cartilage covering of the humeral head and glenoid fossa.
- An irreparable rotator cuff defect is one in which a durable attachment of detached cuff tendons to the tuberosity cannot be re-established.
- The association of glenohumeral arthritis and irreparable rotator cuff defects occurs in several distinct clinical situations, each of which has unique features and specific treatment options.
- The key points in managing these conditions are to define the following:
  - The pathology
  - The deficits in comfort and function experienced by the patient
  - The options for reconstruction
  - The benefits and risks of each of the treatment options

**ANATOMY**
- The glenohumeral articulation normally is covered with hyaline articular cartilage. The glenoid fossa is a spherical concavity that is deepened because the cartilage is thicker at the periphery and the glenoid rim is surrounded by a fibrocartilaginous labrum. The humeral head is a convexity that fits into this concavity.
- The rotator cuff is a synthesis of the tendons of the subscapularis, supraspinatus, infraspinatus, and teres minor with the subjacent glenohumeral capsule.
- The rotator cuff tendons insert into the humerus just lateral to the articular cartilage and at the base of the tuberosities.
  - The spherical proximal humeral convexity is formed by the smooth blending of the cuff tendons with the tuberosities.
  - The radius of the proximal humeral convexity is the radius of the humeral head plus the thickness of the rotator cuff tendons.
- The coracoacromial arch is a spherical concavity consisting of the undersurface of the acromion and the coracoacromial ligament. The proximal humeral convexity fits into this concavity.
- The glenohumeral joint is normally stabilized by the concavity compression mechanism:
  - The rotator cuff muscles compress the humeral head into the glenoid fossa.
  - The deltoid compresses the proximal humeral convexity into the coracoacromial arch.

**PATHOGENESIS**
- Loss of glenohumeral articular cartilage can be caused by osteoarthritis, rheumatoid arthritis, neurotrophic arthritis, septic arthritis, traumatic arthritis, avascular necrosis, and iatrogenic arthritis.
- It also can arise from abrasion of the unprotected humeral head on the undersurface of the coracoacromial arch in chronic rotator cuff deficiency, a situation that often is referred to as rotator cuff tear arthropathy.
- Defects in the rotator cuff tendons arise when loads are applied to the tendon insertion that are greater than the strength of the tendon attachment to the tuberosity.
- These defects typically begin at the anterior undersurface of the supraspinatus tendon.
- Age, systemic disease, corticosteroid injections, and smoking are among the factors that weaken the insertional strength of the rotator cuff tendons, making them more susceptible to tearing and wear.
- When the superior rotator cuff is deficient, the radius of the proximal humeral convexity is decreased by the thickness of the cuff tendon.
- The loss of the spacer effect of the cuff tendon allows the humeral head to translate superiorly under the active pull of the deltoid until the uncovered head contacts the coracoacromial arch.
- The intact coracoacromial arch can provide secondary superior stability to the uncovered humeral head.
- The upward translation of the humeral head necessary to contact the arch slackens the deltoid, however, reducing its effectiveness in elevation of the arm.
- The coracoacromial arch can be compromised by progressive abrasion with the uncovered humeral head. It also can be compromised by acromioplasty and section of the coracoacromial ligament.
- Compromise of the coracoacromial arch coupled with a substantial rotator cuff defect permits anterosuperior escape of the humeral head on deltoid contraction.
- This anterosuperior escape eliminates the fulcrum needed for the deltoid to elevate the arm.
- The inability of a functioning deltoid to elevate the arm because of slackening and lack of a fulcrum is known as pseudoparalysis.

**NATURAL HISTORY**
- Rotator cuff deficiency and arthritis can occur individually or together.
  - In most cases of osteoarthritis, the rotator cuff is functionally intact.
  - In most cases of rheumatoid arthritis, the rotator cuff may be thinned but usually is functionally intact.
- In rotator cuff tear arthropathy, the integrity of the cuff, the articular cartilage, and the coracoacromial arch all characteristically degenerate in a progressive manner.
Some surgeons attempt to improve the comfort and functions of individuals with rotator cuff problems by performing an acromioplasty and coracoacromial ligament section.

- Unless cuff function is durably restored, this sacrifice of the coracoacromial arch predisposes the shoulder to anterosuperior escape.
- The rotator cuff mechanism can be damaged in the process of humeral head resection during shoulder arthroplasty.
- Individuals who have had a shoulder arthroplasty may tear their rotator cuff in a fall or while lifting.
- When a prosthesis is used to reconstruct a complex proximal humeral fracture, the tuberosities may fail to unite, resulting in the functional equivalent of rotator cuff deficiency.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Rotator cuff tendons fail by some combination of applied load and degeneration (“tear” and “wear”).
  - There need be no history of a traumatic episode, especially in older individuals who give a history of progressive loss of comfort, strength, and ability to perform functions of their daily living. These are the persons whose condition may progress to cuff tear arthropathy.
  - By contrast, individuals with acute traumatic rotator cuff tears from the application of substantial load do not typically progress to cuff tear arthropathy.
  - In patients with massive atraumatic cuff deficiency, it is important to seek historical evidence of factors that may weaken the cuff, such as systemic disease, cortisone injections, antimitabolic medications, and smoking.
  - Osteoarthritis often presents without a history of injury. Instead, it presents as progressive stiffness, pain, and loss of function.

- Rheumatoid arthritis of the shoulder presents in the context of this systemic condition.
- Important elements of the history are the patient’s self-assessment of shoulder comfort and function (such as the simple shoulder test) and an assessment of the patient’s goals for treatment.
- The integrity of the principal rotator cuff tendons is determined by the isometric strength of each of the three primary muscles in defined positions.
  - Supraspinatus integrity: weakness (ie, strength grade 3 or less) indicates a full-thickness supraspinatus tear.
  - Infraspinatus integrity: weakness (ie, strength grade 3 or less) indicates a large, full-thickness rotator cuff tear, extending into the infraspinatus.
  - Subscapularis integrity: weakness (ie, strength grade 3 or less) indicates a full-thickness subscapularis tear.
  - Defects in the rotator cuff often can be palpated just anterior to the acromion while the shoulder is passively rotated.
  - Chronic cuff defects usually are accompanied by atrophy of the muscles attached to the deficient tendons.
  - Cuff degeneration often is associated with subacromial crepitus on passive rotation of the humerus beneath the coracoacromial arch.
  - Cuff tear arthropathy often is associated with a substantial subacromial effusion.
  - Superior instability is demonstrated by having the patient relax the shoulder, hanging it at the side, and then actively contracting the deltoid while the examiner notes superior translation of the humeral head until it contacts the coracoacromial arch (FIG 1A,B).
  - Anterosuperior escape is the exaggerated form of superior instability that results when the coracoacromial arch is compromised (FIG 1C,D).

![FIG 1 • A,B. Characteristic findings of cuff tear arthropathy, including superior displacement of the humeral head, “femoralization” of the proximal humerus, and “acetabularization” of the coracoacromial arch. In such a case, a conventional hemiarthroplasty, possibly using a special cuff tear arthropathy (CTA) head, may be considered.](image)

![FIG 1 • C,D. Anterosuperior escape of the humeral head resulting from surgical compromise of the coracoacromial arch. In such a case, a conventional arthroplasty will not provide stability, and a Delta (DePuy, Warsaw, IN) or reverse prosthesis may be considered.](image)
IMAGING AND OTHER DIAGNOSTIC STUDIES

- An anteroposterior plain radiograph in the plane of the scapula may reveal:
  - Decreased acromio–humeral distance, signaling the absence of the normally interposed supraspinatus tendon
  - “Femoralization” of the proximal humerus (ie, rounding off of the tuberosities so that the proximal humerus is spherical) as well as other changes in humeral anatomy (FIG 2A,B)
  - “Acetabularization” of the acromion-coracoid-glenoid socket (ie, sculpting of a concavity matching the femoralized proximal humerus)
  - The amount of superior and medial erosion of the acromion and upper glenoid

- A true axillary view (FIG 2C,D) may reveal:
  - The degree of medial glenoid erosion, ie, the amount of glenoid bone stock available for reconstruction
  - The presence of anterior or posterior glenoid erosion and humeral subluxation, indicating a more complex pattern of instability

- An anteroposterior (AP) view of the proximal humerus with the arm in 30 degrees of external rotation with respect to the x-ray beam may reveal:
  - The approximate size of the humeral medullary cavity that may be used in prosthetic reconstruction
  - Any humeral deformities that may affect prosthetic reconstruction
  - We do not routinely use either CT or MRI scans, but they may be useful in clarifying the pathology.
    - CT scans may help with:
      - Defining glenoid bone volume and deformities
      - Defining the glenohumeral relationships
    - MRI scans may help with:
      - Determining the condition of the different rotator cuff tendons
      - Determining the condition of the different rotator cuff muscles
      - The volume and location of fluid in the joint
      - Other pathology, such as tumor or avascular necrosis

- Factors suggesting that the cuff defect is likely to be irreparable include:
  - Insidious, atraumatic onset of cuff deficiency
  - Advanced age of the patient
  - History of repeated corticosteroid injections
  - Systemic illness
  - History of smoking
  - Previous unsuccessful attempts at rotator cuff repair
  - Muscle atrophy
  - Superior displacement or superior instability of the gleno-humeral joint
  - Anterosuperior escape
  - Pseudoparalysis

FIG 2 • A. Normal glenoid and normal head–glenoid relationship are seen on this AP radiograph in the plane of the scapula. B. Superior glenoid erosion and upward displacement of the head are seen on this AP radiograph in the plane of the scapula. This demonstrates “femoralization” of the proximal humerus and “acetabularization” of the coracoacromial arch. C,D. A proper axillary view will reveal anterior, posterior, or medial glenoid erosion. (Copyright Steven B. Lippitt, MD.)
DIFFERENTIAL DIAGNOSIS

- Milwaukee shoulder
- Neurotrophic (Charcot) arthropathy
- Septic arthritis
- Nonseptic inflammatory arthropathy

NONOPERATIVE MANAGEMENT

An acute rotator cuff tear is a matter of relative urgency, but a chronic cuff defect coupled with glenohumeral arthritis provides the opportunity for nonoperative management, including:

- Range-of-motion exercises in an attempt to resolve the stiffness that may accompany this condition (eg, the four-quadrant stretching program)
- Gentle progressive strengthening exercises for the deltoid and the rotator cuff musculotendinous units that remain intact (eg, the two-hand progressive supine press)
- Mild nonnarcotic analgesics may be useful in symptom control.
- However, injections of corticosteroids into the shoulder may compromise the integrity of the remaining tendons and increase the risk of infection.

SURGICAL MANAGEMENT

Preoperative Planning

- Consideration of surgical management is based on the type of involvement (Table 1), the patient’s overall health and wellbeing, and the risk–benefit ratio in trying to meet the patient’s goals for treatment.
- With each of the procedures, the patient must be well-informed and give informed consent to the risk of infection, neurovascular injury, pain, stiffness, weakness, fracture, instability, loosening of components, anesthetic complications, and the possible need for revision surgery.

Conventional Hemiarthroplasty, Total Shoulder Arthroplasty, and Special Hemiarthroplasty

- Use AP radiograph in the plane of the scapula and axillary view to identify medial, superior, anterior, posterior, or inferior glenoid erosion.
- Use AP humeral radiograph to estimate the size and fit of the humeral component (FIG 3).
- Give prophylactic antibiotics.

Delta or Reverse Arthroplasty:

- Use AP radiograph in the plane of the scapula and transparent glenoid template to estimate the most inferior position of the glenoid that will result in the inferior screw being contained in the thick bone of the scapular axillary border.
- Use AP humeral radiograph to estimate the size and fit of the diaphyseal and metaphyseal humeral components.

Positioning

- All procedures can be performed in the beach chair position. This position is comfortable and safe for the patient, and allows good access for the anesthesiologist and the surgeon.
- The patient is positioned and secured with the glenohumeral joint at the edge of the operating table.
- The forequarter is doubly prepped, and the arm is draped so it can be moved freely.

Approach

- Although some surgeons advocate a deltoid-incising lateral approach, we prefer the deltopectoral approach, because it is effective, familiar, versatile, safe, and extensile.
- Each procedure strives to completely preserve and protect the deltoid and the axillary nerve.
- Each procedure includes a complete mobilization of the humeroscapular motion interface with resection of all scar,
suture, and suture anchors from previous surgical procedures, and hypertrophic bursa.

- This débridement permits complete assessment of the surgical anatomy.
- The integrity of the acromion and coracoacromial ligament is assessed and preserved.
- The subscapularis and subjacent capsule are incised from their attachment to the humerus at the lesser tuberosity.
- A 360-degree subscapularis release is carried out while the axillary nerve is protected.

One of two types of reconstruction is selected:

- Anatomic arthroplasty, with one of the following:
  - Hemiarthoplasty using a conventional prosthesis
  - Total glenohumeral arthroplasty
  - Hemiarthoplasty with a special head (eg, Delta CTA [cuff tear arthropathy; DePuy, Inc., Warsaw, IN])
  - Delta or reverse arthroplasty

At the conclusion of the arthroplasty, the subscapularis is repaired to the bone of the cut humeral surface adjacent to the lesser tuberosity using six sutures of no. 2 nonabsorbable suture passed through drill holes.

A suction drain is placed just anterior to the subscapularis and led out through a long subcutaneous track to exit the skin of the lateral arm.

Dry sterile dressings are applied.

Continuous passive motion is used for 36 hours for all reconstructions except for the Delta or reverse arthroplasty.

After the Delta arthroplasty, the arm is immobilized for 36 hours.

**CONVENTIONAL HEMIARTHROPLASTY, TOTAL SHOULDER ARTHROPLASTY, AND SPECIAL HEMIARTHROPLASTY**

**Incision and Approach**

- Create a deltopectoral incision.
- Lyse adhesions and remove bursa from the humeroscapular motion interface.
- Verify irreparability of the rotator cuff tear and resect useless tendon tissue. If useful cuff elements remain, tag for later reattachment.
- Incise subscapularis and capsule from insertion to lesser tuberosity, preserving maximal length of tendon.
- Release inferior capsule from humerus.
- Identify axillary nerve.
- Perform a 360-degree subscapularis release.

**Humeral Preparation and Implant Sizing**

- Insert progressively larger reamers into the canal, stopping at the first endocortical bite (**TECH FIG 1A**).
- Resect the humeral head in 30 degrees of retroversion and 45 degrees with the long axis of the shaft (**TECH FIG 1B**).
- Measure height and diameter of the curvature of the resected head (**TECH FIG 1C**).
- Mince bone of the humeral head to make autogenous graft.
- If the glenoid is rough or eroded medially, but not superiorly, and if the infraspinatus and subscapularis are intact or robustly reconstructable, and if the patient has soft glenoid bone (as in rheumatoid arthritis), consider inserting a prosthetic glenoid component.
- Using minced autogenous bone from the humeral head, perform impaction autografting of the humeral canal so that the prosthetic stem will achieve a snug press-fit (**TECH FIG 1D**).
- If a partial rotator cuff repair can be carried out, perform that before definitive sizing of component, because repair may diminish the room available for the prosthesis (**TECH FIG 1E**).
- If glenoid arthroplasty has been performed, select the humeral head prosthesis with the appropriate diameter of curvature for the glenoid.
- If glenoid arthroplasty has not been performed, select the humeral head prosthesis with the diameter equal to that of the resected head.

**Component Placement**

- With the trial component in position, resect any prominent tuberosity that may abut against the coracoacromial arch on elevation of the arm (**TECH FIG 2A,B**).
- Consider a special humeral head (eg, CTA head) to cover the area of the greater tuberosity (**TECH FIG 2C**).
Part 7 SHOULDER AND ELBOW • Section VI GLENOHUMERAL ARTHRITIS

TECH FIG 1 • A. Reaming the humerus until the first endocortical bite is achieved. B. Marking the humeral osteotomy at 45 degrees with the reamed axis of the shaft and in 30 degrees of retroversion. Care must be taken to protect the rotator cuff in making the osteotomy. C. Measuring the resected head to determine the diameter of curvature and the height. D. Impaction grafting of the medullary canal to achieve a secure press-fit without jeopardizing the strength of the diaphyseal cortex. E. Partial repair of the rotator cuff to the edge of the resected humerus. (Copyright Steven B. Lippitt, MD.)

- Select the humeral head height that, on trial reduction, allows 40 degrees of external rotation with the subscapularis approximated, 50% posterior translation on the posterior drawer test, and 60 degrees of internal rotation when the arm is abducted to 90 degrees (TECH FIG 2D–G).
- Place six no. 2 nonabsorbable sutures in the anterior humeral neck cut for reattachment of the subscapularis (TECH FIG 2H).
- Assemble the definitive humeral prosthesis.
- Insert the prosthesis in the impaction-grafted medullary canal.

Final Contouring and Wound Closure
- Ensure smooth passage of the proximal humerus beneath the coracoacromial arch. If abutment occurs, perform smoothing on the humeral side, preserving the integrity of the arch.
- Repair the subscapularis.
- Insert drain.
- Close the deltopectoral interval.
- Perform subcutaneous and skin closure.
- Apply sterile dressings.
TECH FIG 2 • A,B. Smoothing of the greater tuberosity lateral to the articular surface of the prosthetic humeral head. C. Cuff tear arthropathy (CTA) head prosthesis, providing a smooth lateral articulation for the shoulder with irreparable cuff deficiency. D–G. Balancing the soft tissue tension: 40 degrees of external rotation (D), 50% posterior translation (E,F), and 60 degrees of internal rotation in 90 degrees of abduction (G). H. Preparing for subscapularis reattachment to the cut edge of the humerus. (Copyright Steven B. Lippitt, MD.)
Incision and Approach
- Make a deltopectoral incision.
- Lyse adhesions and remove bursa from the humeroscapular motion interface, protecting deltoid, acromion, and residual cuff tissue.
- Verify irreparability of the rotator cuff tear and resect useless tendon tissue.
- Tag any potentially reparable elements of the cuff that are identified, for later use.
- Incise the subscapularis and capsule from insertion to lesser tuberosity, preserving maximal length of the tendon.
- Release the inferior capsule from the humerus.
- Identify the axillary nerve.
- Perform a 360-degree subscapularis release.

Humeral Preparation
- Insert humeral resection guide stem into medullary canal (TECH FIG 3A).
- Resect humeral head in zero degrees of retroversion (TECH FIG 3B).
- When the arm is pulled distally, the plane of the humeral cut should pass just below the inferior glenoid.

Glenoid Preparation
- Dissect the capsule from the anterior glenoid down to and around the inferior pole so that the upper axillary border of the scapula can be palpated and seen, releasing the origin of the long head of the triceps as necessary.
- Check radiographs and exposed glenoid to identify abnormal glenoid anatomy (eg, superior, inferior, anterior, posterior, inferior or medial erosion, as well as defects from previous surgery [such as earlier arthroplasty]).
  - Note the relation of the inferior glenoid lip to the axillary border of the scapula.
- Remove the labrum and cartilage from the glenoid.
- Mark a point 13 mm anterior to the posterior rim of the glenoid and 19 mm superior to the inferior glenoid rim.
  - Drill the guidewire into the glenoid at this point (TECH FIG 4A).
  - Place the metaglene of the Delta prosthesis (TECH FIG 4B) over this guidewire, with the peg laterally, to verify the appropriateness of this center point.
  - The inferior aspect of the metaglene should align with a line extended from the axillary border of the scapula.
  - When the rim of the metaglene is flush with the extrapolated axillary border, remove the metaglene and drill a central hole with the step drill (TECH FIG 4C).
  - Ream the glenoid conservatively, removing only enough bone to make the surface relatively flat and making sure the reamer handle remains perpendicular to the face of the glenoid (TECH FIG 4D).

Metaglene Placement
- Insert the metaglene peg into the central hole (TECH FIG 5A).
- Palpate the anterior and posterior aspects of the axillary border of the scapula and rotate the metaglene so the inferior screw hole is centered over the axillary border.
  - Recall that the inferior locking screw makes a 16-degree angle with the central peg.
  - Using a drill guide, drill a hole for the inferior locking screw, checking frequently to ensure that the drill is in bone by pushing on the drill while it is not rotating.
  - Use a 2-mm drill bit unless the bone is hard (TECH FIG 5B).
  - At least 36 mm of intraosseous drilling should be achieved.
  - If not, re-examine rotation of the metaglene with respect to the axillary border (TECH FIG 5C).

Screw Fixation
- Insert the inferior locking screw (TECH FIG 6A).
- Drill and insert the superior locking screw using similar technique (TECH FIG 6B,C).
**TECH FIG 4** • A. The glenoid guidewire is inserted 19 mm up from the inferior edge of the glenoid and 13 mm anterior to the posterior glenoid border. B. The Delta prosthesis. From left to right: humeral stem, polyethylene cup, glenosphere, and metaglene. C. A step drill is inserted over the guidewire. D. Glenoid reaming is performed conservatively to preserve bone stock. (Copyright Frederick A. Matsen, MD.)

**TECH FIG 5** • A. Inserting the metaglene, noting its flush position with the inferior glenoid. B. Drill guide aligned with the axillary border of the scapula. C. Verifying the intraosseous position of the inferior drill hole by direct palpation. (Copyright Frederick A. Matsen, MD.)

**TECH FIG 6** • A. Desired location of the inferior screw in the axillary border of the scapula. B. Drilling the superior hole using a fixed-angle guide. C. Inserting the superior screw. D. Drilling the anterior hole using a variable-angle guide. E. Inserting anterior screw. (continued)
Drill and insert the anterior nonlocking screw, guiding orientation by palpating the anterior glenoid neck (TECH FIG 6D–F). Drill and insert the posterior nonlocking screw (TECH FIG 6G). Once screws have been placed, check the security of metaglene fixation. Insert a trial glenosphere onto the metaglene. Inspect the inferior aspect of the glenoid, removing any bone that may abut against the humeral polyethylene component. Adequacy of bone resection can be verified by placing a trial polyethylene humeral component over the glenosphere and making sure it can be adducted fully, recalling that the humeral cup makes a 65-degree angle with the humeral shaft.

**Humeral Preparation**

Prepare the humeral canal in a manner that preserves bone stock by insertion of progressively larger reamers until cortical contact is just achieved (TECH FIG 7A,B).

Insert a trial stem with a metaphyseal reamer guide in 0 degrees of rotation (TECH FIG 7C). Ream the metaphysis until bone purchase is achieved (TECH FIG 7D).

**Trial Placement**

Perform trial reduction of the prepared humerus (without trial components) to see if the reamed metaphysis can be reduced to the glenosphere, indicating that the humeral resection is adequate (TECH FIG 8A). Assemble and insert the trial humeral component in 0 degrees of retroversion with a 3-mm trial plastic component (TECH FIG 8B). Reduce the joint (TECH FIG 8C,D) and check for:

- Medial abutment of plastic against the axillary border of the glenoid
- Stability
- Range of motion
- Minimal (<2 mm) distraction on distal traction
- If the joint cannot be reduced, consider lowering the humeral component position by sequentially resecting small amounts of humeral bone.
Final Component Placement

- Insert the glenosphere into the metaglene, making sure it is aligned to avoid cross-threading and making sure it is fully seated.
- Securely assemble the definitive humeral component with a strong crescent wrench.
- Brush and irrigate the humeral medullary canal.
- Insert a cement restrictor 13 cm distal to the lateral aspect of the humeral cut.
- Place six drill holes and no. 2 nonabsorbable sutures in the anterior neck cut for later reattachment of the subscapularis.
- Repair the posterior cuff, if possible.
- Cement the assembled humeral component in 0 degrees of retroversion without a polyethylene insert.
- Trial different heights of polyethylene liners, starting with 3 mm, reducing shoulder to discover the height that allows for reduction but less than 2 mm of distraction, checking again for abutment of adducted plastic against the lateral glenoid bone inferiorly.
- Insert the definitive polyethylene component, making sure it seats fully.
- Irrigate the wound completely.
- Reduce the joint.

Wound Closure

- Repair the subscapularis to sutures previously placed at the anterior neck cut.
- Place a suction drain.
- Close the deltopectoral interval, close the subcutaneous layer, and close the skin with staples.
- Apply dry sterile dressings and an axillary pad.

PEARLS AND PITFALLS

- Glenohumeral arthritis is a chronic condition, so there is no rush to surgical judgment.
- Try gentle range-of-motion and deltoid-strengthening exercises.
- Perform a thorough preoperative assessment and minimize surgical risk factors before surgery.
- Obtain multiple intraoperative cultures for these organisms and hold cultures for 2 weeks.
- At surgery, seek subscapularis and infraspinatus elements that are reparable.
- Treat deltoid, acromion, glenoid, and humeral bone gently.
- Drain the surgical site and rehabilitate slowly.
POSTOPERATIVE CARE

- Hemiarthroplasty with a conventional prosthesis, total glenohumeral arthroplasty, or hemiarthroplasty with a special head (eg, CTA).
- Institute a continuous passive motion (FIG 4) and early active assisted motion protocol as soon as possible postoperatively (unless major partial cuff repair has been carried out).
- Elevation of the arm to 140 degrees is achieved before the patient leaves the medical center.
- For 6 weeks, external rotation is limited to what was easily achievable on the operating table.
- Gentle progressive strengthening exercises, including the supine press, usually are started at 6 weeks.
- Delta or reverse arthroplasty
- Institute hand-gripping and active elbow flexion postoperatively.
- Motion is withheld for 36 hours to minimize the risk of hematoma formation.
- Gentle activities, such as eating, are started at 36 hours, followed by the slow, progressive addition of other activities, reminding the patient of the need for the shoulder bones and muscles to have time to remodel to their new loading patterns.
- Avoid lifting anything heavier than 1 pound for 3 months.

OUTCOMES

- The highly variable patient characteristics, shoulder pathology, and surgical techniques make general statements about functional and prosthetic survival difficult.
- For this reason, a conservative approach to surgery is advised.

COMPLICATIONS

- Atelectasis
- Cardiac events
- Local perioperative
- Intraoperative fracture of humerus, glenoid, acromion
- Axillary nerve or plexus injury
- Deltoid injury
- Postoperative
- Hematoma
- Infection
- Dislocation
- Failure of tissue repair
- Fracture of humerus, glenoid, acromion
- Prosthetic loosening
- Pain
- Weakness
- Failure to regain function

REFERENCES

DEFINITION
- Pectoralis major ruptures are injuries to the one of the largest and strongest muscles of the shoulder region.
- Injuries can be divided into complete and partial tears.
  - Complete tears typically occur at the tendon-to-bone junction and involve both heads.
  - Partial tears can occur to either the sternocostal or the clavicular head.
  - Both types may also occur at the musculotendinous junction or the muscle itself.

ANATOMY
- The pectoralis major is a broad triangular muscle that originates from the medial clavicle, anterior sternum, costal cartilages to the sixth rib, and external obliques.
- It inserts into the proximal humerus on the lateral edge of the bicipital groove. It has two distinct heads: the smaller clavicular head and the larger sternocostal head.
- The pectoralis major tendon is about 5 cm long. The insertion site has two distinct laminae. The clavicular head is anterior and distal and is about 1 cm long, and the sternocostal head inserts posterior and is 2.5 cm long.3
- The sternocostal head spirals 180 degrees on itself, inserting posterior to the clavicular head, creating a rolled inferior surface that is the axillary fold (FIG 1).
- The function of the pectoralis major varies depending on the division. Its primary function is to adduct the humerus and its secondary role is to forward flex and internally rotate. The clavicular head primarily forward flexes and horizontally adducts. The sternocostal head internally rotates and adducts.

PATHOGENESIS
- Pectoralis major ruptures typically occur when a powerful eccentric or concentric forward flexion or adduction load to the humerus (such as heavy bench pressing) occurs. The final 30 degrees of humeral extension disproportionally stretches the inferior fibers of the sternocostal head, putting it at a mechanical disadvantage and predisposing it to injury. The inferior fibers fail first, followed by progression toward the clavicular head.
- Ruptures may also occur when a traction injury such as rapid extension, abduction, or external rotation force is applied to the extremity (such as catching oneself during a fall).
- Injuries to the muscle belly can also be caused by a direct blow, which can result in hematoma formation.
- Patients often hear or feel a rip or tear in the shoulder region, feel a burning pain, and occasionally hear a pop.
- Younger patients (under 30 years) tear at the tendon–bone insertion, whereas patients over 30 tend to tear at the musculotendinous junction.
- Swelling and ecchymosis occur from several hours to days after the injury in the lateral chest wall, upper arm, or axilla.
- Medial muscle retraction along with loss of the axillary fold may not be evident for several days until the swelling subsides.
- Anabolic steroids weaken the muscle–tendon unit, making patients more susceptible to tears.1

NATURAL HISTORY
- Weakness of the affected shoulder in adduction, forward flexion, and internal rotation can be expected with nonoperative treatment of full-thickness tears of both heads or of partial tears of the sternocostal head.
- Isokinetic strength testing has demonstrated 25% to 50% deficits of strength in adduction and internal rotation in preoperative patients and people treated nonoperatively.3,4,9
- Cosmetic deformity occurs secondary to the loss of the tendon in the axillary fold as well as from the medial retraction that occurs during contraction of the muscle.
- Partial tears will elicit a variable degree of weakness and deformity, depending on the amount and location of tendon torn.
The initial pain and cramping that occurs during contraction of the pectoralis major usually subsides in 2 to 3 months. Patients treated nonoperatively for full-thickness tears will complain of weakness and fatigue with recreational and occupational activities as well as the cosmetic deformity.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- A previous history of pain is not typical.
- The patient’s occupation and involvement in sports and weight-lifting activities are important in decision making regarding treatment.
- Physical examination initially will yield painful range of motion of the shoulder and arm. When the swelling subsides, patients typically have full range of motion of the glenohumeral joint.
- Swelling and ecchymosis are variable depending on the chronicity and the degree of the tear.
- Isometric or resisted adduction and forward flexion will show the loss of the tendon in the axillary fold and medial retraction of the pectoralis muscle.
- The examiner should instruct the patient to hold the arm at 90 degrees of abduction, and the anterior head of the deltoid will be accentuated. If the arm is held in forward flexion, the clavicular head will be accentuated (FIG 2A).
- Having patients press their hands together in front of their body for isometric adduction allows inspection of both sides at the same time and simultaneous palpation (FIG 2B).
- Manual strength testing will demonstrate weakness in adduction and forward flexion.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A standard shoulder radiographic series is obtained to rule out fractures, avulsions, or signs of instability.
- An MRI of the chest, with attention to the pectoralis major tendon, may be obtained to evaluate the location of the tear or assist in making the diagnosis.\(^6,11\) It has been shown to be beneficial in differentiating musculotendinous junction ruptures from tendinous avulsions and may change the treatment strategy.\(^11\) It is difficult, however, to distinguish between complete and partial ruptures (FIG 3).
- Ultrasound may be used to identify the location and severity of the tear. Results, however, are user-dependent.

**DIFFERENTIAL DIAGNOSIS**

- Rotator cuff tears
- Proximal biceps tear
- Anterior shoulder instability
- Deltoid rupture
- Latissimus dorsi tear
- Brachial plexus injury

**NONOPERATIVE MANAGEMENT**

- Nonoperative treatment is indicated for medial tears, intramuscular tears, or tears at the musculotendinous junction in some people. Also, nonoperative treatment should be considered in low-demand patients with complete or partial distal tendon ruptures.
- Nonoperative treatment begins with a sling for the first 7 to 10 days. Ice should be applied intermittently for the first 72 hours.
- Gentle active assisted range of motion is then begun, avoiding aggressive external rotation, abduction, or extension stretching in the initial phases.
- Strength training is typically initiated at 6 to 8 weeks. Depending on the level of occupational or sporting demands, patients may return between 8 and 12 weeks.
Strength deficits of 25% and 50% can be expected with nonoperative treatment.5

**SURGICAL MANAGEMENT**

- Pectoralis major repair is recommended for all complete distal tears, partial distal tears in high-demand patients, and musculotendinous junction tears in high-demand patients with large defects.
- A direct tendon-to-bone repair with heavy, nonabsorbable sutures is performed for complete distal tears and sternocostal tears.
- A side-to-side repair is used for musculotendinous junction tears.

**Preoperative Planning**

- A standard examination under anesthesia of the glenohumeral joint is performed to evaluate for instability.

**Positioning**

- The patient is placed in the 30-degree modified beach chair position. The shoulder and arm are prepared free. A shoulder positioning device is helpful, but not necessary, to position the arm during surgery (FIG 4).

**Approach**

- An anterior approach to the shoulder and proximal humerus is used—the internervous plane between the axillary nerve of the deltoid and the superior and inferior pectoral nerves of the pectoralis major.

---

**PECTORALIS MAJOR REPAIR USING DRILL HOLES**

- Our preferred technique for direct primary repair of the pectoralis major tendon is to attach the tendon directly to the humeral cortex using drill holes.
- A limited 4- to 5-cm deltopectoral incision is made (TECH FIG 1A). The cephalic vein is identified and retracted laterally with the deltoid.
- The biceps tendon is identified, gaining access to the insertion of the pectoralis major just lateral to the biceps tendon in the proximal humerus. In cases of musculotendinous junction tears or partial tears, the entire tendon or a portion of it will be intact.
- Medial dissection is then performed to identify the retracted tendon. The sternocostal and clavicular heads are identified as well as the location of the tendon or musculotendinous junction tear.
- In cases of complete tears, the tendon is typically retracted medially and folded upon itself, identifiable by palpation.
- A traction suture is placed in the tendon, and stepwise gentle blunt mobilization of the muscle and tendon is performed.
- The excursion of the tendon is then tested. Even in cases of chronic tears, the tendon can typically be mobilized to reach the humerus without difficulty.
- The tendon edge is freshened with a scalpel. A no. 5 braided, nonabsorbable suture is used in a Bunnell or modified Mason-Allen locking stitch in the end of the tendon (TECH FIG 1B). Two or three sutures are used, spaced about 1 cm apart, depending on the width of the tendon.
Chapter 27 PECTORALIS MAJOR REPAIR

The insertion site lateral to the biceps tendon is decorticated with a burr.

A commercially available drill can be used to drill the proximal and distal sets of holes. A bridge of 8 to 10 mm is adequate secondary to the thickness of the humerus. The holes usually need to be overdrilled with a 2-mm drill bit, as the humeral cortex is extremely strong and thick.

A needle with a matching radius of curvature is then used to pass a 2-0 looped Vicryl passing suture (TECH FIG 1C). Each corresponding suture is passed using the 2-0 Vicryl passing suture.

The central drill holes are shared by the upper and lower respective sutures in a horizontal mattress configuration for the Bunnell technique (TECH FIG 1D).

If a modified Mason-Allen stitch was used, the deep suture is passed through the drill hole and the knot tied on the upper surface of the tendon (TECH FIG 1E).

The sutures are then tied with the arm in adduction and internal rotation to ensure apposition of the tendon to the humerus (TECH FIG 1F).

Alternatively, the drill holes may be made freehand and the sutures passed with either a free needle or a loop of 24-gauge wire.

PECTORALIS MAJOR REPAIR USING SUTURE ANCHORS

The musculotendinous unit is mobilized in the same way as described for drill hole repair. The humeral cortex is decorticated with a burr.

Two or three suture anchors are then placed in the humeral insertion, spaced 1 cm apart. The sutures are passed in a Kessler mattress stitch through the distal pectoralis tendon (TECH FIG 2).

One limb is passed in a simple fashion. This is used as the post during tying so the knot slides and apposes the tendon to the humerus without the knot lying in the repair site.

Metallic anchors loaded with braided, nonabsorbable no. 5 sutures are used, as the humeral cortex in this region may be too thick to accept an absorbable anchor.

MUSCULOTENDINOUS JUNCTION REPAIRS

Multiple figure 8 or modified Kessler sutures of a no. 2 braided, nonabsorbable suture are used on both the superficial and deep layers.

The quality of the repair depends on the strength and the amount of tendon left on the muscular side.
PEARLS AND PITFALLS

<table>

<td>Chronic tears</td>
<td>Repair of pectoralis major ruptures is feasible up to 5 years after the injury. The outcome of chronic repairs is not as good as that of acute repairs, with residual weakness as the most common complaint.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- The arm is kept in a sling for 6 weeks postoperatively. It is removed from the sling one or two times daily for gentle, progressive passive and active assisted range of motion of the shoulder, elbow, wrist, and hand.
- The extremes of abduction and external rotation are avoided for the first 6 weeks. At this time, the sling is removed and unrestricted movement is allowed. In addition, strengthening is begun.
- Return to full activities is generally achieved between 3 and 5 months.

OUTCOMES

- There are no large prospective or randomized studies in the literature comparing operative and nonoperative treatment. Results are universally good with acute repairs (within 8 weeks).
- Park and Espinilla7 in 1970 evaluated 30 patients with pectoralis major ruptures. The results were 90% good to excellent results with operative repair versus 75% with nonoperative treatment.
- McEntire and colleagues5 in 1972 compared operative and nonoperative treatment in 11 patients. Again, operative repair had a more favorable outcome at 88% versus 83%, with a higher ratio of excellent to good results.
- Zenman and coworkers10 in 1979 reviewed nine athletes with pectoralis major ruptures. Four patients were treated with surgical repair and had excellent results. All five of the patients treated nonoperatively had residual weakness, and two were dissatisfied with their outcome.
- Kretzler and Richardson3 in 1989 reported on their results after repair of 16 distal tendon tears. Eighty-one percent regained full motion and strength. Two repairs that occurred 5 years after repair of 16 distal tendon tears. Eighty-one percent regained full motion and strength. Two repairs that occurred 5 years after the injury had persistent weakness.
- Wolfe and colleagues9 in 1992 evaluated 14 patients with pectoralis major ruptures, half of whom were treated with operative repair. Cybex strength testing demonstrated normal strength in the repaired patients, with persistent weakness in the unrepair group.
- Jones and Matthews2 in 1988 reviewed the literature and concluded that acute repair within 7 days has 57% excellent and 30% good results. Repair in the setting of a chronic tear yielded 0% excellent and 60% good results. They concluded that although chronic repair is possible even up to 5 years after the injury, the outcome is not as good as an acute repair, with a high likelihood of persistent weakness and cosmetic deformity.
- Schepsis and colleagues8 in 2000 found that operatively repaired patients (both acute and chronic) had significantly better outcomes than conservatively treated patients.
- There are no studies to date documenting rerupture after repair.

COMPLICATIONS

- Complications are relatively infrequent after pectoralis major repair. One patient experienced loss of abduction.3 Another patient had ulnar-sided hand paresthesias of unknown etiology that spontaneously resolved.8
- There have been several reports of complications in the elderly after rupture and nonsurgical management. One patient needed a blood transfusion. Two died of sepsis from an infected hematoma. Myositis ossificans developed in one patient 4 months after rupture.

REFERENCES

DEFINITION
- The snapping scapula syndrome first was described by Boinet in 1867.14
- It is characterized by painful scapular motion with associated crepitus during scapulothoracic motion, with or without a clear history of injury or trauma.
- It has also been referred to as scapulothoracic bursitis, retroscapular creaking, superior scapular syndrome, and retroscapular pain.3,7,11,14
- The associated audible crepitus, which can be tactile in most instances, has been described by Milch and Burman11 as a tactile-acoustic phenomenon, possibly generated secondary to an abnormality in the scapulothoracic interval.
- This crepitus is divided into three classes, based on the volume of the sound produced.10
  - The first group is considered physiologic, with what is described as a “gentle friction” sound.
  - The second group, which includes most patients with the snapping scapular syndrome, features a louder grating sound.
  - The third group is defined by a loud snapping noise that is considered pathologic in most cases.

ANATOMY
- The scapulothoracic articulation consists of the interface between the anterior aspect of the scapula and the ribs in the posterior aspect of the convex thoracic chest wall (FIG 1).
- This articulation is cushioned by several muscles, specifically the subscapularis and the serratus anterior.
- In addition, two major and four minor bursae have been described in the scapulothoracic articulation6,7,23 (Fig 1).
  - The two major bursae are the infraserratus bursa, located between the serratus anterior muscle and the chest wall, and the supraserratus bursa, located between the serratus anterior and the subscapularis muscles.
  - The four minor bursae are distributed as follows: two at the superomedial angle of the scapula, one at the inferior angle of the scapula, and one at the medial base of spine of the scapula, underlying the trapezius muscle.
- While the major bursae have been found consistently in cadaveric and clinical studies, those of the minor bursae were not.3,19,20

PATHOGENESIS
- Incongruence of the scapulothoracic articulation has been postulated to be the main cause of the snapping scapular syndrome, which may or may not be associated with bony anomalies of this region.13,17
- Maltracking or dynamic compression of the scapulothoracic articulation has been postulated as a main etiology of this syndrome, because it leads to irritation of the bursa secondary to pathologic contact between the ribs and the superior angle of the scapula.4,22
  - This maltracking is considered to be a soft tissue cause of snapping scapula syndrome, which has been reported in cases of subscapularis atrophy secondary to glenohumeral fusion and long thoracic nerve palsy.11,24
- Clinical studies and histologic findings of muscle infrasacular fibrosis, bursitis, edema, and shoulder girdle muscle atrophy support this hypothesis.7,17
- Bony or skeletal causes of snapping scapula syndrome are rare. These include scapular osteochondromas and exostoses (FIG 2), anterior angulation of the scapula, scapula fracture, scapular tubercle of Luschka, skeletal abnormalities of the vertebrae (omovertebral bone), and abnormal angulations and tumors of the ribs.10,11,21

NATURAL HISTORY
- Patients with snapping scapula syndrome usually complain of pain around the shoulder girdle.
- This pain most often is secondary to bursitis in the scapulothoracic articulation. Constant motion irritates the soft tissues, leading to inflammation and a cycle of chronic bursitis and scarring.
The chronic inflammation of the bursae will lead to fibrotic, scarred, and tough bursal tissues that can lead to mechanical impingement and pain with motion, resulting in further inflammation.

Once the patient reaches this level of chronic bursal inflammation, the symptoms rarely subside by themselves without trial of rest and physical therapy.

In many cases, especially when the cause of snapping is skeletal, surgical intervention becomes essential to manage this problem.

PATIENT HISTORY AND PHYSICAL FINDINGS

Patients with scapulothoracic bursitis report a history of pain in the shoulder or neck with overhead activities for months or years and often have a history of repetitive overuse in work or recreation or a history of trauma.

A history of neck injury, shoulder injury or fracture, or previous shoulder surgery should be ruled out.

Audible or palpable crepitus may accompany the symptoms with scapulothoracic motion; this is another indication for the location of the symptomatic inflamed bursa.

Some patients report a family history of the disorder and have bilateral symptoms.

Localized tenderness is an indication for the site of scapulothoracic bursitis.

Improvement of symptoms by lifting the scapula off the chest wall helps localize the source of pathology to the scapulothoracic articulation.

Diagnosis is confirmed if significant relief or even elimination of the pain occurs when local anesthetic and corticosteroids are injected in the scapulothoracic bursa under the superomedial border of the scapula.

The examiner also must assess soft tissue tightness, muscle strength, and flexibility around the involved shoulder.

Special attention should be directed to rule out tight trapezius, pectoralis minor, or levator scapula muscles, as well as weakness of any of the scapular muscles, specifically the serratus anterior and the trapezius.

In patients with winging of the scapula, a careful neuromuscular examination should be performed to differentiate true winging from compensatory pseudo-winging that might originate from a painful scapulothoracic articulation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiologic studies should include an anterior-posterior (AP) and tangential (Y) views of the shoulder, to identify bony abnormalities in the scapula and ribs (FIG 3A).
- A CT scan may be needed for more bony definition. Its role, with or without three-dimensional reconstruction, is still debated, but in patients with suspected bony skeletal abnormality, the CT scan might be helpful (FIG 3B).
- Fluoroscopy could be used to visualize the snapping during simulated shoulder motion.
- MRI can identify the location and size of the inflamed bursa, but its usefulness is debated. The senior author does not believe that the MRI is necessary and has never ordered it in any of his cases.
- Nerve conduction and electromyography studies are useful if a neurologic injury is suspected as the reason for scapula winging.

DIFFERENTIAL DIAGNOSIS

- Soft tissue lesions, such as atrophied muscle
- Fibrotic muscle
- Anomalous muscle insertion
- Subscapular elastofibroma. This tumor is nonneoplastic and appears to form in response to repetitive injury or microtrauma. Most patients who have this tumor complain of a palpable mass rather than pain.
- Cervical spondylosis and radiculopathy
- Periscapular muscle strain
- Glenohumeral pathology

NONOPERATIVE MANAGEMENT

- The initial management of snapping scapula syndrome, once the diagnosis has been made, is conservative.
- Rest, activity modification, and nonsteroidal anti-inflammatory medications should be started.
- Next, physical therapy should be initiated to restore the normal kinematics of the shoulder and prevent it from sloping.
- Weakness in the serratus anterior, even if subtle, may lead to tilting of the scapula forward, thus increasing the friction and rubbing of the upper medial pole of the scapula on the thoracic ribs. This will cause irritation and inflammation of the scapulothoracic bursae.
- Therapy should emphasize periscapular muscle strengthening, particularly the serratus anterior and subscapularis, which can elevate the scapula off the chest wall when they are hypertrophied.
- Taping, a figure-8 harness, scapulothoracic bracing, or postural training can serve to minimize shoulder sloping and thoracic kyphosis.
- Injection of corticosteroid and local anesthetic into the scapulothoracic bursa can be diagnostic and also may be therapeutic and helpful in the rehabilitation program.
- There is no consensus on how long the patient should be kept on trial of physical therapy. The underlying diagnosis is important. In general, a 3- to 6-month trial is a good estimate.
- If the diagnosis is certain, no structural anatomic lesion is present, and the patient has failed 3 to 6 months of appropriate conservative treatment, then surgical options should be considered.
- The threshold to proceed to surgical intervention also should be much lower if the patient has a real structural lesion such as a bony exostosis or an osteochondroma.
SURGICAL MANAGEMENT

Preoperative Planning
- All radiographs are reviewed before surgery.
- The decision to operate is made based on relief of pain with anesthetic injection into the scapulothoracic region in patients who failed conservative management, or in patients who have symptomatic snapping scapula syndrome secondary to structural lesion.
- The different surgical approaches, as well as the technique that the surgeon decides to perform, are discussed with the patient before surgery.

Positioning
- The patient is positioned in the prone position for both arthroscopic and open techniques (FIG 4).
- The involved arm is placed in internal rotation against the patient’s lower back (chicken-wing position). This will cause the scapula to wing out from the thorax and make the superomedial angle more prominent.
- The surgeon stands on the side opposite the scapula to be operated to get the best access to the surgical field.

Approach
- Multiple surgical approaches are available that can decompress the impingement in the superomedial region of the scapula.

These include open surgical decompression, arthroscopic surgical decompression, or a combination of the two approaches.
- Each of these approaches may include bursectomy alone, bony resection of the superomedial aspect of the scapula alone, or a combination.
OPEN DECOMPRESSION

- A longitudinal incision is made along the medial scapular edge (TECH FIG 1A).
- Subcutaneous undermining is performed to expose the superior portion of the scapula, from the level of the scapula spine to the superomedial angle of the scapula.
- Splitting and elevation of the trapezius in line with its fibers is performed at the level of the scapular spine, and the superomedial edge of the scapula is exposed (TECH FIG 1B).
- The levator scapulae and rhomboids are detached from the superior and medial edge of the scapula to expose the upper scapular border (TECH FIG 1C).
- Care is taken not to dissect into the rhomboids or fully detach them so as not to injure the dorsal scapular nerve.

TECH FIG 1 • A. Patient positioned prone with hand positioned behind back to lift the scapula off the chest wall. The surgical incision is placed over the medial border of the scapula, centered over the level of the scapula spine. B. The trapezius is split along its fibers, and the levator scapulae, the rhomboids, and the posterior surface of the scapula are exposed. C. The levator scapulae, rhomboid major, and rhomboid minor are detached from their insertion on the scapula and tagged with sutures. (continued)
which usually is located 2 cm medial to the medial scapular edge.

- The serratus anterior muscle is left intact.
- A retractor is placed underneath the scapula to lift it away from the thoracic ribs.
- The scapulothoracic bursa is identified against the ribs, underneath the serratus anterior muscle.
- A clamp is used to grasp the bursa, and sharp excision of it is performed from superior to inferior.
- Subperiosteal elevation of the muscles around the superomedial border of the scapula, including the supraspinatus, infraspinatus, subscapularis, and serratus anterior muscles, is performed with the use of electrocautery to expose 1 to 2 cm of bone (TECH FIG 1D).
- This exposed portion of the superomedial portion of the scapula is resected with use of an oscillating saw (TECH FIG 1E).
- Once the bony resection is accomplished, drill holes are placed into the upper-medial border of the scapula in order to reattach the muscles to their anatomic insertion (TECH FIG 1F) using a no. 2 nonabsorbable braided suture (TECH FIG 1G).
- The skin is closed with absorbable subcuticular suture.

TECH FIG 1 • (continued) D,E. Resection of the superomedial border of the scapula. F. The detached muscles are reattached to the scapula through drill holes. G. The final repair of the detached levator scapulae and rhomboids.
Positioning is the same as in open decompression.
Placement of the arm in the chicken-wing position results in scapula winging and protraction off the posterior thorax, which facilitates the entry of the arthroscopic instruments in the bursal space.
Standard arthroscopic portals are used.
The initial “safe” portal is placed at the level of the scapular spine, 2 cm medial to the scapular edge, to avoid injury to the dorsal scapular nerve and artery (TECH FIG 2A).
The scapulothoracic space is localized with a spinal needle and distended with approximately 30 mL of saline, and the portal is created.
A blunt obturator is inserted into the scapulothoracic (subserratus) bursa between the posterior thoracic wall and the serratus anterior muscle.
Care should be taken to avoid overpenetration through the serratus anterior into the subscapular space or through the chest wall.
A 30-degree arthroscope is inserted into the scapulothoracic space, which was distended with fluid infiltration.
Use of a fluid pump is optional. Our preference is to use an arthroscopy pump but keep the pressure low, at around 30 mm Hg, to minimize fluid extravasation.
A spinal needle is used to localize the second portal under direct visualization.
This portal is inserted, in most instances, in line with and approximately 4 cm distal to the first portal.
A bipolar radiofrequency device and a motorized shaver are introduced into a 6-mm cannula through the lower portal, and used to resect the bursal tissue. Because the inflamed scapulothoracic bursa is a potential source of bleeding during arthroscopic shaving, the radiofrequency device becomes particularly useful to minimize bleeding in these tissues (TECH FIG 2B).
A methodic approach to resection should be followed, because there are no real landmarks.
Ablation of tissues should be performed from medial to lateral and then from inferior to superior.
The surgeon should be ready to switch portals and should have a 70-degree arthroscope ready to facilitate visualization. A probe can be used to palpate the scapula and serratus muscle superiorly and the ribs and intercostal muscles inferiorly.
An additional superior portal may be placed as needed. We prefer not to use this portal, because it may place the accessory spinal nerve, transverse cervical artery, and dorsal scapular neurovascular structures at risk.
After complete bursectomy is performed, the arthroscopic instruments are withdrawn, and skin closure is performed with absorbable subcuticular sutures.

TECH FIG 2 • A. Locations of the arthroscopic portals. A proximal (safe) portal (black arrow) is placed 2 cm medial to the spine of the scapula. A distal portal (white arrow) is placed in line with and 4 cm distal to the proximal portal. B. Sites of portal placement. The shaver and the camera can be placed interchangeably in either portal for viewing and shaving.
**ARTHROSCOPIC BURSECTOMY AND PARTIAL SUPEROMEDIAL SCAPULECTOMY**

- First, all the steps for arthroscopic bursectomy are followed.
- After the bursa has been completely resected, the superomedial angle of the scapula is localized by palpation through the skin.
- Detachment of the conjoined insertion of the levator scapulae, supraspinatus, and rhomboids is performed with the use of the radiofrequency device.
- A motorized shaver and a burr are used to perform a partial scapulectomy. We do not attempt to repair the periosteal sleeve; it is allowed to heal through scarring.
- The rest of the steps are the same as those for arthroscopic bursectomy.

**ARTHROSCOPIC BURSECTOMY AND OPEN PARTIAL SUPEROMEDIAL SCAPULECTOMY**

- The decision to perform the superomedial scapular bony resection through a small skin incision rather than through the arthroscope may be made either before surgery or at the time of surgery.
- If full definition of the superomedial border of the scapula becomes difficult because of swelling from the arthroscopic fluid, then bony resection is performed through a small skin incision.
- A 4- to 6-cm incision is performed obliquely over the superomedial border of the scapula (see Tech Fig 1A).
- The trapezius muscle is split, and the levator scapulae and rhomboids are detached from the superomedial angle (see Tech Fig 1B-C).
- The superomedial angle of the scapula is resected. Then the levator scapulae and rhomboids are repaired to the superior scapula through drill holes (see Tech Fig 1D).
- Skin closure is performed with absorbable subcuticular sutures.

**PEARLS AND PITFALLS**

| Indications                                                                 | • Appropriate history, physical examination, and review of radiographs should be done. |
|                                                                             | • Diagnostic injection is very helpful to confirm the diagnosis and predict a good surgical outcome. |
| Contraindications to arthroscopic decompression                             | • Symptoms that originate from the trapezoid bursa. This bursa is superficial to the scapulothoracic space, and, therefore, removing it will not remove the pathologic tissue. |
| Positioning                                                                 | • Patient prone, with hand of the affected shoulder behind the back to elevate and protract the scapula. |
|                                                                             | • Surgeon should be standing by the opposite shoulder. |
| Open decompression                                                          | • Avoid suprascapular notch during bony resection. |
|                                                                             | • It is essential to reattach the detached muscles to the scapula through bony drill holes. |
| Arthroscopic decompression                                                   | • Use a spinal needle for localization of the scapulothoracic space. |
|                                                                             | • Care should be taken to avoid over-penetration through the serratus anterior into the subscapular space or through the chest wall. |
|                                                                             | • Use of a bipolar radiofrequency device is essential to avoid bleeding from the inflamed bursa. |
|                                                                             | • Complete bursectomy should be performed. |

**POSTOPERATIVE CARE**

- After open decompression and a combined arthroscopic and open approach:
  - The patient is kept in a sling, and gentle, passive range of motion is started early after surgery and continued for 4 weeks.
  - After 4 weeks, active range of motion is started.
  - Strengthening is allowed at 8 to 12 weeks.
  - After arthroscopic decompression:
    - The patient is kept in a sling and allowed passive and active assisted range-of-motion exercises immediately after surgery.
    - After 4 weeks, isometric exercises are started.
    - Strengthening of the periscapular muscles begins by 8 weeks.

**OUTCOMES**

- No published reports have compared the outcomes of different surgical techniques of scapulothoracic decompression.
The outcome of open decompression, as reported in the literature, has been good.\(^7,12,17,18\)

No large series have been published reporting the outcome of arthroscopic scapulothoracic decompression for symptomatic snapping scapular syndrome.

Early results from small series of patients who underwent arthroscopic decompression seem promising, with minimal morbidity and early return to work.\(^2,3,8,15,16\)

**COMPLICATIONS**

- Recurrence of symptoms secondary to incomplete resection
- Pneumothora
- Iatrogenic injury to the neurovascular structures around the superomedial border of the scapula
- Aggressive bony resection risking injury to the suprascapular nerve through the notch
- Insufficiency of the scapular muscles due to detachment after surgery

**REFERENCES**

DEFINITION
- Trapezius palsy results from a disruption of cranial nerve (CN) XI, also known as the spinal accessory nerve.
- Because the trapezius is innervated exclusively by CN XI, any disruption causes trapezius palsy.
- Spinal accessory nerve palsy is a rare but well-described complication of cervical lymph node biopsy.15,17
- The trapezius plays an integral part in stabilization of the scapula, and dysfunction leads to painful shoulder disability.
- Nonoperative treatment, including strengthening of the functioning thoracoscapular muscles, does not provide satisfactory clinical results.2,4
- Transfer of the levator scapulae, rhomboid major, and rhomboid minor (Eden-Lange procedure, or triple transfer) is an accepted technique for this difficult problem.16
- The procedure was first described by Eden5 in 1924 and then corroborated by Lange6 in 1951 and Francillon7 in 1955, all reporting satisfactory short-term results. Further modifications have improved on the initial procedure.1
- Lateral transfer of the insertions of the three muscles allows the scapula to be stabilized in a position of abduction and anterior flexion.15

ANATOMY
- The trapezius muscle is broad and superficial, taking its origin from the C7–T12 spinous processes and inserting on the acromion, clavicle, and spine of the scapula (FIG 1A).
- Its function is to elevate and rotate the scapula; absence of the trapezius leads to lateral winging of the scapula.
- In the posterior cervical triangle, CN XI is located in the subcutaneous tissue; this superficial location renders it susceptible to damage during procedures such as cervical lymph node biopsy.
- Functionally, the trapezius can be divided into three separate parts: upper, middle, and lower.
- The upper portion consists of descending fibers and functions as an aid to suspension of the shoulder girdle, allowing shrugging of the shoulder. The middle portion consists of transverse fibers and contributes to abduction and rotation of the inferior angle of the scapula. The ascending fibers of the lower portion (along with the serratus anterior) anchor the scapula to the chest wall.
- Scapular winging occurs in both spinal accessory and serratus anterior palsy. In serratus palsy, the inferior angle of the scapula is noted to rotate medially (FIG 1B), whereas in trapezius palsy, the scapula rotates laterally (FIG 1C, D).

PATHOGENESIS
- Paralysis of the trapezius most often results from injury to the spinal accessory nerve during cervical lymph node biopsy.13
- Other causes include trauma (including traction injuries) or injuries from other surgical procedures, such as radical neck dissection.1
- In one instance, a CN XI palsy was reported to have occurred after a viral infection.13
- Idiopathic CN XI paralysis also has been reported.6
- Patterson11 reported trapezius palsy after acromioclavicular and sternoclavicular dissociation.
- Even rarer causes include post-carotid endarterectomy and post-catheterization of the internal jugular vein.3
- In most cases, patients report pain and present with visible deformity and dysfunction of the shoulder girdle.

NATURAL HISTORY
- Trapezius palsy most often results from iatrogenic causes, as noted earlier, and, if left untreated, will lead to progressively worsening altered biomechanics and pain of the shoulder girdle.
- Radiating arm pain is thought to be the result of traction on the brachial plexus caused by drooping of the shoulder girdle.13

FIG 1 • A. Schematic of the three parts of the normal trapezius muscle: upper, middle, and lower. (continued)
Although nonoperative management can provide reduction of pain, it does not lead to return of function, and patients treated without surgery usually go on to progressive shoulder dysfunction.

Typically, the initial presentation is acute shoulder pain without palsy, with weakness of anterior elevation and abduction appearing after a few days (with slow diminution of pain). Atrophy of the trapezius becomes clinically apparent after a few weeks.16

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Altered mechanics of the entire shoulder girdle are possible with trapezius palsy.
- The classic winging of the scapula seen in CN XI palsy is characterized by downward and lateral translation of the scapula.
- The patient should be observed from behind so comparison can be made with the contralateral side.
- Signs unique to CN XI palsy include lateral winging of the scapula (FIG 2A), an asymmetric neckline, pain, weakness of shoulder abduction, and forward elevation.14 Visible atrophy of the trapezius muscle should be noted16 (FIG 2B).
- Symptoms include weakness made worse by prolonged use of the arm, a feeling of a heavy arm, and a dull pain radiating from the scapula to the forearm (and occasionally with radiation to the hand). The radiation of pain is described as mimicking thoracic outlet syndrome (medial aspect of the upper limb). Pain typically is made worse by abduction of the shoulder as well as forward elevation.16 Some patients also reported paresthesias in the distribution of the auricular nerve (posterolateral side of the neck).16
- Patients also often state that the arm feels difficult to control.13
- It should be noted, however, that occasionally patients are pain free and present only with winging and drooping of the scapula.
- Range of motion is decreased in elevation as well as abduction, and typically is limited to 90 degrees.13 Teboul et al16 report average active abduction of 78 degrees (range 30 to 140 degrees), and active forward flexion of 110 degrees (range 50 to 180 degrees). As a result, overhead activities are not possible, nor is shrugging of the shoulder.

![FIG 1](continued)

**FIG 1**

**B.** Schematic of trapezius palsy, demonstrating lateral scapular winging and shoulder drooping.

**C.** Schematic of serratus anterior palsy, demonstrating medial scapular winging.

**FIG 2**

**A.** Patient with a trapezius palsy demonstrating characteristic scapular winging.

**B.** Anterior sternocleidomastoid muscle wasting due to the spinal accessory nerve palsy.
- External rotation of the shoulder and elbow flexion are not affected by CN XI lesions.\textsuperscript{16}
- Reports of stiffness and passive range of motion are somewhat contradictory in the literature. Romero and Gerber\textsuperscript{13} state that patients did not always present with a stiff shoulder but passive range of motion typically was decreased. On the other hand, Teboul et al\textsuperscript{16} report that patients often presented with stiffness but with no deficit in passive range of motion.
- Often, the diagnosis of CN XI dysfunction is one of exclusion, and it is not until an unsuccessful trial of physical therapy that a patient is referred for an electrodiagnostic study and spinal accessory nerve palsy is confirmed.
- The necessity for electrodiagnostic testing is an issue of debate in the literature. Romero and Gerber\textsuperscript{13} state that this testing is not necessary to establish the diagnosis of CN XI palsy, but that it can be a valuable tool if other nerve lesions are suspected. Setter et al\textsuperscript{14} advocate electrodiagnostic testing as part of the initial workup.
- Evaluate the scapula for signs of lateral translation by asking patient to perform a wall push-up.
- Spinal accessory nerve (CN XI) palsy also affects the sternocleidomastoid muscle.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- A standard five-view shoulder series (including true AP views of the glenohumeral joint in neutral, external, and internal rotation; as well as a scapular Y and axillary view) is required for every patient, although osseous pathology typically is not associated with CN XI palsy.
- MRI is not necessary, although it could be useful to assess the degree of fatty atrophy of the trapezius muscle as well as to help rule out any associated pathology such as rotator cuff injury.
- Electrodiagnostic testing is recommended in every case, according to Setter et al.\textsuperscript{14} Not only will an EMG help confirm the diagnosis of spinal accessory nerve palsy, but it also will serve as confirmation that the muscles to be used in the transfer procedure are functioning normally.

**DIFFERENTIAL DIAGNOSIS**
- Missed diagnosis of spinal accessory nerve palsy is the rule,\textsuperscript{13} most likely owing to the rare nature of the condition.
- Other possible types of shoulder dysfunction that may confuse the issue include serratus palsy and rotator cuff pathology.
- It is crucial to be able to differentiate between spinal accessory nerve (trapezius) palsy and long thoracic nerve (serratus) palsy. In serratus palsy, the inferior angle of the scapula rotates medially, whereas in trapezius palsy, the inferior angle of the scapula rotates laterally.

**NONOPERATIVE MANAGEMENT**
- Typically, if the injury is not detected within 6 months (after which point nerve repair usually is not recommended), a 12-month trial of nonoperative treatment is recommended.\textsuperscript{14}
- Due to possible compensation by the levator scapulae, the impact of injury to the spinal accessory nerve must be determined individually for each patient.\textsuperscript{9}
- Maxillofacial surgeons have reported that 30\% to 49\% of patients do not exhibit any clinical symptoms after radical neck dissection where the spinal accessory nerve is sacrificed.\textsuperscript{10}
- If the CN XI palsy is symptomatic, pain sometimes can be relieved after a course of nonoperative treatment, but satisfactory return to function cannot be achieved.
- Strengthening of the remaining scapulothoracic muscles does not compensate for the trapezius deficit, and, in one study, patients who elected nonoperative management could not elevate their arms above the horizontal.\textsuperscript{13}
- One study has reported favorable results with nonoperative management in sedentary or elderly persons because discomfort was alleviated.\textsuperscript{12}

**SURGICAL MANAGEMENT**
- If trapezius palsy is detected early, microsurgical repair or reconstruction of the nerve can be considered. Timing of the repair attempt is controversial; some authors believe that repair should only be attempted if diagnosis is confirmed within 6 months of injury,\textsuperscript{14} whereas other surgeons advocate repair up to 20 months from the time of the nerve insult.\textsuperscript{16}
- In patients with spontaneous spinal accessory palsy for whom conservative treatment has not been helpful, some authors advocate proceeding directly to muscle transfer reconstruction, because nerve procedures have produced poor results.\textsuperscript{15}
- Patients who have failed nerve repair attempt or conservative therapy should be considered surgical candidates for the Eden-Lange procedure, the current procedure of choice for stabilization of the scapula after CN XI palsy.
- Timing of the Eden-Lange procedure also is controversial. Typically, however, reconstructive surgery is recommended if more than 12 months has elapsed since the injury.\textsuperscript{17}
- The goal of the Eden-Lange procedure is to reconstruct the three parts of the trapezius muscle. Because the rhomboid major and minor and levator scapulae have medial insertions, they are not capable of stabilizing the scapula unless they are transferred laterally.\textsuperscript{16}

**Preoperative Planning**
- It is imperative to have appropriate preoperative discussions with the patient so that he or she understands the procedure, the postoperative rehabilitation program, and the timeframe within which improvement should be expected.

**Positioning**
- The patient is placed in the lateral decubitus position with the entire extremity draped free (FIG 3).
EXPOSURE

- Teboul et al\textsuperscript{16} describe an incision starting from the spine of the scapula and progressing along its medial angle up to a point 2 cm above the inferior angle of the scapula (TECH FIG 1A).
- The trapezius is then divided and retracted, and the three muscles of interest (the levator scapulae, rhomboid major, and rhomboid minor) are identified and dissected and marked with vessel loops (TECH FIG 1B).
- The supraspinatus and infraspinatus must be elevated 3 to 5 cm to expose their respective fossae for transfer of the rhomboids\textsuperscript{16} (TECH FIG 1C).

Modification

- Bigliani et al\textsuperscript{1} proposed a modification of the procedure in which the rhomboid minor is transferred cephalad to the scapular spine, thereby closing the gap between the rhomboid minor and the levator scapulae (TECH FIG 3).
- In this modification, the new position of the rhomboid minor more efficiently substitutes for the middle part of the trapezius.

RHOMBOID TRANSFER

- A series of transosseous mattress sutures are placed in anticipation of transferring the rhomboids. At least four mattress sutures are used in the infraspinous fossa (TECH FIG 2A) and two in the supraspinous fossa.
- The rhomboids are advanced about 3 cm laterally and attached to the scapula with heavy, nonabsorbable transosseous sutures (TECH FIG 2B).

Modification

- Bigliani et al\textsuperscript{1} proposed a modification of the procedure in which the rhomboid minor is transferred cephalad to the scapular spine, thereby closing the gap between the rhomboid minor and the levator scapulae (TECH FIG 3).
- In this modification, the new position of the rhomboid minor more efficiently substitutes for the middle part of the trapezius.
A second incision is made about 5 to 7 cm from the posterolateral corner of the acromion for transfer of the levator scapulae (TECH FIG 4A).

Care must be taken to ensure that the levator has been dissected laterally enough to allow tension-free excursion to the scapular spine (TECH FIG 4B). The levator is then transferred subcutaneously and affixed with a series of heavy nonabsorbable sutures.

The infraspinatus muscle is then sutured over the new rhomboid muscle insertions and, finally, the wounds are closed in layers.

**LEVATOR TRANSFER AND WOUND CLOSURE**

- A second incision is made about 5 to 7 cm from the posterolateral corner of the acromion for transfer of the levator scapulae (TECH FIG 4A).
- Care must be taken to ensure that the levator has been dissected laterally enough to allow tension-free excursion to the scapular spine (TECH FIG 4B). The levator is then transferred subcutaneously and affixed with a series of heavy nonabsorbable sutures.

The infraspinatus muscle is then sutured over the new rhomboid muscle insertions and, finally, the wounds are closed in layers.

**TECH FIG 3** • A. Normal position of the levator scapula, rhomboid minor, and rhomboid major on the medial border of the scapula. B. Lateral transfer of the levator scapula, rhomboid minor, and rhomboid major. This modification includes transfer of the rhomboid minor to the supraspinatus fossa.

**TECH FIG 4** • A. The second incision is made 5 to 7 cm medial to the posterolateral corner of the acromion for transfer of the levator scapula muscle. B. Excursion of the levator is confirmed before the muscle is subcutaneously tunnelled to the planned transfer site.
### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Rhomboid transfer</th>
<th>Levator transfer</th>
</tr>
</thead>
<tbody>
<tr>
<td>Separate the rhomboid minor from the rhomboid major so they can be transferred separately.</td>
<td>Dissect the levator scapula far enough laterally to allow tension-free transfer to the scapular spine.</td>
</tr>
<tr>
<td>The infraspinatus and supraspinatus are elevated from their respective fossae for approximately 5 cm. This modification of the original procedure permits the rhomboid minor to be transferred to a position that better substitutes for the action of the middle trapezius.</td>
<td>Avoid iatrogenic injury to the transverse cervical artery and the dorsal scapular nerve, which run superficial and deep, respectively, to the levator scapulae and then terminate into the deep surface of the rhomboids near their insertion onto the scapula.</td>
</tr>
<tr>
<td>Care should be taken to prevent injury to the suprascapular nerve, which lies on the deep surface of the supraspinatus muscle.</td>
<td>A tunnel is created through the atrophied trapezius, in line with its upper fibers, for passage of the tagged levator scapulae.</td>
</tr>
<tr>
<td>The infraspinatus and supraspinatus are elevated from their respective fossae for approximately 6 weeks after surgery is important to avoid pull-out of the transferred muscles, especially the rhomboids, which, unlike the levator scapulae, are not attached to their new scapular insertion with the tendo-osseous interface intact.</td>
<td></td>
</tr>
<tr>
<td>The levator should not be transferred too far laterally, because this can cause a web-like deformity in the neck. A good position is 5 to 7 cm from the posterior lateral corner of the acromion.</td>
<td></td>
</tr>
</tbody>
</table>

### POSTOPERATIVE CARE
- Most authors advocate immobilization for 6 weeks postoperatively, followed by initiation of physical therapy (passive and active).  
  13,14,16
- Romero and Gerber13 prefer an abduction splint, whereas Teboul et al16 suggest securing the arm to the chest with an elastic bandage.
- Our routine postoperative protocol is to use a foam wedge or orthosis for the first 4 weeks, keeping the arm in 60 to 70 degrees of abduction. We encourage early passive range of motion above the wedge or orthosis to prevent stiffness (forward elevation to 130 degrees and external rotation to 40 degrees in the first 4 weeks).
- At 4 weeks, the wedge is discontinued, and gentle strengthening exercises are added. We have designed a progressive strengthening program that uses rubber tubing, free weights, and medicine ball throws to achieve dynamic scapular stability. All of the exercises in the protocol are designed to strengthen the transferred levator scapula and rhomboids.

### OUTCOMES

- The Eden-Lange procedure produces satisfactory results for the difficult problem of trapezius palsy.
- In a study in which 16 patients were reviewed at a mean follow-up of 32 years, clinical outcomes were noted to be excellent in 9 patients, fair in 2 patients, and poor in 1 patient (as determined by Constant score).13 Some patients with outcomes that were less than satisfactory also had dorsal scapular and long thoracic lesions.
- Romero and Gerber13 describe a radiographic outcomes measure that uses an AP radiograph to measure the angle between a line drawn between the cranial and caudal ends of the glenoid with a vertical axial line. This measurement was compared to the contralateral side, and no statistical differences were found.
- Another recent study16 concluded that muscle transfer should be performed only after previous nerve repair surgery had failed or when more than 20 months has elapsed since the injury was incurred. In this series of 7 patients treated with the Eden-Lange procedure (the other 20 patients were treated with nerve surgery), results were excellent in 3 patients, good in 1 patient, and poor in 3 patients. Teboul et al16 state that two factors are most predictive of a poor result following reconstructive surgery: if the patient is older than 50 years or the lesion is caused by radical neck dissection, penetrating injury, or spontaneous palsy.

### COMPLICATIONS

- Complications associated with the Eden-Lange procedure, in addition to the usual surgical risks, include failed integration of the transferred muscles with resultant continued dysfunction. Such a complication is discussed rarely, and we were only able to find one report of a failure of muscle integration.16
- Patient compliance with strict immobilization for the first 6 weeks after surgery is important to avoid pull-out of the transferred muscles, especially the rhomboids, which, unlike the levator scapulae, are not attached to their new scapular insertion with the tendo-osseous interface intact.
- Initial complications do not seem to be the problem with the Eden-Lange procedure; rather, the primary complication appears to be later effects of functional outcome falling short of expectations.
- Iatrogenic dysfunction resulting from no longer having a physiologic levator scapula or rhomboids is not, to our knowledge, discussed in the literature. However, because the origin of these muscles is merely being transposed more laterally, it does not appear that the Eden-Lange procedure creates a new problem while fixing the old one.
- In cases of failure of the procedure, where pain and dysfunction continue, scapulothoracic arthrodesis can be performed as a salvage procedure.

### REFERENCES
DEFINITION
■ Long thoracic nerve palsy leads to classical scapular winging because of weakness of the serratus anterior muscle (FIG 1).
■ Other types of winging include trapezius winging and rhomboid winging.
■ Lesions of the long thoracic nerve can range from paresis to complete paralysis, leading to varying degrees of shoulder dysfunction.
■ The serratus anterior muscle functions to stabilize the scapula against the chest wall, thus providing a fulcrum for the humerus to push against while moving the arm in space.3,4
■ Without this fulcrum, shoulder elevation is weakened, which leads to inability to use the arm in forward activities.
■ Forward elevation of the shoulder is most severely affected, followed by shoulder abduction.

ANATOMY
■ The serratus anterior is a large broad muscle that covers the lateral aspect of the thorax. It has digitations that take origin from the upper nine ribs, pass deep to the scapula, and insert on the medial aspect of the scapula.15
■ The muscle has three divisions.5
■ The first division consists of one slip and takes origin from the first two ribs. This division runs slightly upward and inserts on the superior angle of the scapula.3,4
■ The second division is made up of three slips from the second, third, and fourth ribs, and inserts on the anterior surface of the medial border of the scapula.
■ The third division, which consists of the inferior five slips from ribs five through nine, inserts on the inferior angle of the scapula. Because this division has the longest course it has the longest lever-arm and the most power for scapular rotation.
■ The serratus anterior muscle stabilizes the scapula against the chest wall, creating a fulcrum for the proximal humerus to lever against while moving the arm in space.
■ The serratus anterior protracts and upwardly rotates the glenoid.
■ Its direction of pull brings the inferomedial border of the scapula anteriorly. The inferior border of the scapula is pulled forward with forward elevation of the arm. This causes the glenoid to tip posteriorly and allow full forward elevation without impingement.
■ With weakness of the serratus anterior muscle, the scapula translates superiorly and medially, and the inferior border rotates medially and dorsally (FIG 2A).
■ The serratus anterior muscle is innervated by the long thoracic nerve, which arises from the ventral rami of cervical roots C5–7.
■ The C5 and C6 roots pass through the scalenus medius muscle and merge before they receive a branch from C7.
■ The nerve enters the axillary sheath at the level of the first rib and travels posteriorly in the axilla.
■ It then passes over a prominence in the second rib and descends along the lateral chest wall, where it enters the serratus anterior fascia and then the muscle itself (FIG 2C).5,15
■ The total length of the nerve is about 24 cm, and there are several possible points of injury.
■ Proximally, as well as distally along the chest wall, the nerve is susceptible to injury because of its superficial location.
■ The nerve is tethered in the axillary sheath, which places it on stretch with forward elevation of the arm.

PATHOGENESIS
Scapular Winging
■ Scapular winging may be due to primary, secondary, or voluntary causes.8
■ Primary scapular winging can be divided into neurologic, bony, and soft tissue types.
■ Neurologic disorders, which are most common, include:
  - Long thoracic nerve palsy (serratus anterior weakness)
  - Spinal accessory nerve palsy (trapezius weakness)
  - Dorsal scapular nerve palsy (rhomboid weakness)
  - Trapezius weakness winging may be distinguished from serratus winging by the position and direction of scapular laxity (see Fig 2A, B).
■ Bony abnormalities include osteochondromas of the scapula or fracture malunion.
■ Soft tissue disorders include:
  - Soft tissue contractures, causing winging
  - Muscular disorders such as fascioscapulohumeral dystrophy

FIG 1 • Clinical photograph of serratus winging.
Congenital absence or traumatic rupture of the parascapular muscles
- Scapulothoracic bursitis
- Secondary winging may occur following disorders of the glenohumeral joint. The most common causes are multidirectional and posterior instability.
- The sequence of events leading to secondary scapular winging due to primary shoulder pathology is as follows:
  - Primary glenulohumeral or subacromial pathology, leading to
  - Limited glenulohumeral motion, leading to
  - Increased compensatory scapulothoracic motion, leading to
  - Increased demand on periscapular muscles, leading to
  - Fatigue of periscapular muscles—serratus, trapezius, and rhomboids—leading to
  - Secondary scapular winging
- Voluntary winging may occur in psychiatric patients or for secondary gain.

Long Thoracic Nerve Palsy
- Long thoracic nerve palsy is the most common cause of serratus dysfunction resulting in symptomatic scapular winging, especially in those patients who fail nonoperative management and are being considered for pectoralis tendon transfer.¹
- Long thoracic nerve palsy has been reported to result from idiopathic, iatrogenic, viral, compressive, or traumatic (blunt or penetrating) causes.¹³
- Most injuries are neurapraxic, due to blunt trauma.
- Lesions also may occur through entrapment of the fifth or sixth cervical roots at the level of the scalenus medius, during traction over the second rib, or with traction and compression at the inferior angle of the scapula with general anesthesia or prolonged abduction of the arm.
Iatrogenic injuries may occur during radical mastectomy, first rib resection, or transaxillary sympathectomy, or during surgical positioning.\(^6\)

Other less common causes include viral illnesses, Parsonage-Turner syndrome, isolated long thoracic neuritis, immunizations, or C7 nerve root lesions.\(^4\)

Often, the cause is idiopathic, with a questionable history of trauma or viral illness.

**Pathoanatomy**

A mechanical advantage is gained by stabilization of the scapula against the chest wall.

- With loss of this mechanical advantage, forward elevation against resistance is decreased owing to scapulothoracic motion.
- Additional types of shoulder pathology can result secondary to stabilization of the scapula:
  - Impingement due to relative anterior rotation of the acromion (FIG 3)
  - Weakness due to loss of mechanical advantage in forward elevation
  - Adhesive capsulitis from disuse
  - With complete paralysis of the serratus anterior, complete forward elevation and abduction greater than 110 degrees are not possible.\(^3,15\)

**Natural History**

- As mentioned previously, most injuries to the long thoracic nerve are neurapraxic from stretch of the nerve or blunt trauma.
- Most cases resolve spontaneously without operative intervention within 12 months, although maximal recovery may take up to 24 months.\(^2,7,9\)
- The exception to this rule is injury due to nerve laceration from penetrating trauma or iatrogenic injury.

**Patient History and Physical Findings**

A thorough history (including previous illnesses, procedures and interventions, hand dominance, and activity level) and complete examination of the shoulder and back are essential.

Treatment often is delayed, and diagnosis may become apparent only after failed treatment for other disorders.

Furthermore, patients may develop secondary stiffness from disuse, and this may be the primary complaint.

Patients often present with vague complaints of shoulder pain or weakness with overhead activities.

Because winging may be subtle, the patient must be undressed from the waist up, viewed from the back, and tested with provocative maneuvers such as resisted forward elevation and pushups against a wall.

Pain may come from several sources, making diagnosis of long thoracic nerve palsy based on pain distribution difficult.

Compensatory overuse of the remaining scapulothoracic musculature may cause pain localized posteriorly about the scapula.

Patients may present with impingement-type pain with forward elevation.

In secondary winging, pain may result from an underlying diagnosis such as glenohumeral instability.

With severe pain, long thoracic neuritis or Parsonage-Turner syndrome should be considered.

Physical examination usually reveals classic winging, with the scapula translated medially and the inferior border rotated toward the midline (see Fig 1).

Patients may present with varying degrees of weakness of forward elevation of the arm.

- Resisted testing may accentuate winging, as will having the patient do a pushup against a wall.
- Weakness of forward elevation may be decreased by manual scapular stabilization against the chest wall by an examiner, the so-called “scapular stabilization test.”\(^13\)

**Imaging and Other Diagnostic Studies**

- Plain radiographs of the shoulder, cervical spine, and chest should be part of the workup.
- Although radiographs rarely are diagnostic, bony abnormalities such as osteochondromas, cervical spondylosis, or scoliosis may be evident.
- CT or MRI scans may be helpful in these situations, but are often not necessary.
Electromyographic and nerve conduction velocity studies are useful in confirming the diagnosis as well as following patients clinically.

- Additionally, in idiopathic cases or where dystrophy is suspected, these tests may be helpful in ruling out other neuromuscular disorders (such as fascioscapulohumeral dystrophy) that may preclude muscle transfer as an option for scapular stabilization.
- Serial studies every 3 months are recommended.
- Studies should include cervical roots, brachial plexus, and the spinal accessory nerve.

DIFFERENTIAL DIAGNOSIS
- Rotator cuff tear
- Fracture malunion
- Glenohumeral instability
- Impingement
- Acromioclavicular joint disease
- Biceps tendinitis
- Neurologic disorders
- Suprascapular nerve entrapment
- Scoliosis
- Scapular osteochondroma

NONOPERATIVE MANAGEMENT
- Whether idiopathic, viral, or compressive, almost all cases of serratus winging from long thoracic palsy resolve spontaneously within 1 to 2 years.\(^2,7,9\)
  - Without a clear history of penetrating trauma, all patients initially should be treated conservatively (FIG 4).
  - Physical therapy should consist of range-of-motion exercises to avoid secondary glenohumeral stiffness.
  - Braces and orthotics that have been designed to stabilize the scapula to the chest wall may provide symptomatic relief. Their use is controversial, however, and many patients find them cumbersome.
  - Some authors have recommended bracing to decrease continued traction on the nerve.\(^14\)

SURGICAL MANAGEMENT
- Patients for whom nonoperative treatment has failed and who have persistent symptomatic scapular winging are candidates for surgical stabilization.
- Patients often are given up to 24 months to recover nerve and muscle function before surgical repair is considered.
- However, Fery\(^2\) has reported that up to 25% of patients with serratus anterior paralysis may fail nonoperative treatment.
- Patients who have penetrating trauma or iatrogenic injury, where a long thoracic nerve transection is suspected, may be indicated for acute nerve exploration and repair.
- Historically, three different procedures have been used to treat patients with symptomatic serratus anterior dysfunction: scapulothoracic fusion, static stabilization procedures, and dynamic muscle transfers.
  - Scapulothoracic fusion is mainly a salvage procedure, sometimes used in patients with previous failures or in patients with dystrophies, such as fascioscapulohumeral dystrophy, where multiple muscles may be affected.
  - Static stabilization uses fascial slings or tethers to help stabilize the scapula.
  - These procedures have fallen out of favor because the slings may gradually stretch out, with subsequent loss of scapular stability.
  - Dynamic muscle transfers, first described by Tubby\(^12\) in 1904, have been found to offer the optimal recovery and result in nearly normal scapulothoracic motion.

Numerous different transfers have been described, but most surgeons currently perform a transfer of the sternal head of the pectoralis major to the inferior angle of the scapula to reconstruct the function of the deficient serratus anterior.

- The sternal head of the pectoralis is preferred because it has good excursion and similar power to the serratus, and its fiber orientation is similar to that of the serratus.\(^1,2\)

Preoperative Planning

- Preoperative planning should include a discussion with the patient regarding allograft versus autograft augmentation of the pectoralis transfer.
  - Typical options include contralateral fascia lata or semitendinosus autograft, or semitendinosus allograft.
  - A tendon stripper is needed for autograft harvest if desired.
  - A 5-mm round trip burr or drill bit is needed to fashion a tunnel through the inferior angle of the scapula.
  - Heavy nonabsorbable suture (no. 2 or no. 5) is needed to attach the pectoralis transfer and prepare the graft augmentation.

Patient Positioning

- The patient is placed supine in the beach chair position, with care taken to leave access to the midline posteriorly and anteriorly.
  - A pad is placed behind the midline of the thorax to improve posterior exposure.
  - The forequarter is draped free with the entire scapula in the surgical field.
  - A pneumatic arm positioner (Spider Limb Positioner, Tenet Medical Engineering, distributed by Smith & Nephew Endoscopy, Andover, MA) is helpful during the procedure to maintain position of the extremity.
  - If fascia lata or semitendinosus autograft is to be harvested, the lower extremity must be prepped and draped free as well.

Approach

- The following section describes our preferred technique for transfer of the sternal head of the pectoralis major to the inferior angle of the scapula for serratus anterior dysfunction.

**EXPOSURE**

- A 10- to 15-cm incision is made in the axillary crease posterior to the lateral border of the scapula (**TECH FIG 1A**).
  - The deltopectoral interval is developed, and the cephalic vein is retracted laterally.
  - The pectoralis tendon is identified at its humeral insertion.
  - The sternal head, which lies deep to the clavicular head, is identified and isolated bluntly (**TECH FIG 1B, C**).
  - Often, abduction and external rotation of the extremity is helpful in exposing the sternal head.

- The sternal head insertion is released sharply from the humerus, taking care not to damage the underlying long head of the biceps tendon or the clavicular head of the pectoralis major (**TECH FIG 1D, E**).
  - Traction sutures are placed into the sternal head tendon, and the muscle belly is freed of adhesions medially.

**TECH FIG 1** • A. Axillary incision used for pectoralis major transfer. B.C. The sternal head, which lies deep to the clavicular head, is identified and isolated bluntly. (continued)
Chapter 30  PECTORALIS MAJOR TRANSFER FOR LONG THORACIC NERVE PALSY 3313

TECH FIG 1  (continued) D,E. The sternal head insertion is released sharply from the humerus, taking care not to damage the underlying long head of the biceps tendon or the clavicular head of the pectoralis major. (B–E: from Post M. Orthopaedic management of neuromuscular disorders. In: Post M, Flatow EL, Bigliani LU, Pollack RG, eds. The Shoulder: Operative Technique. Philadelphia: Lippincott Williams & Wilkins, 1998:201–234.)

GRAFT HARVESTING

- At this point, attention is turned to the fascia lata harvest, or preparation of the allograft tendon.
  - For fascia lata harvest, two small incisions (2 to 3 cm) are made on the lateral aspect of the thigh, about 20 cm apart.
  - After incision, the fascia lata is exposed and cleaned with an elevator between the two incisions.
  - Once the fascia lata is identified and isolated, a tendon stripper is used to harvest a graft approximately 6 cm × 20 cm.

- The graft is then folded over itself and tubularized using heavy, nonabsorbable suture.
- Once prepared, the graft is woven into the sternal head tendinous origin and secured with heavy, nonabsorbable suture (TECH FIG 2).

SCAPULAR EXPOSURE, PREPARATION, AND TENDON ATTACHMENT

- After the pectoralis tendon and graft are ready, the scapula is exposed.
- The inferior angle of the scapula is identified and exposed by blunt dissection along the chest wall.
- The latissimus dorsi and teres major tendons are retracted distally, and the lateral neurovascular structures are avoided by staying medial.
- Once the inferior angle of the scapula is identified, it is exposed subperiosteally, and a 6- to 8-mm burr hole is made 2 cm from the lateral and inferior border of the scapula.
- The graft is then passed through the bone hole from anterior to posterior, tensioning the graft while reducing the scapula on the chest wall, so that the native pectoralis tendon is flush with the bone tunnel.
- The graft is then looped through the hole in the inferior scapula and sutured to itself using heavy, nonabsorbable suture (TECH FIG 3).
  - It is necessary to ensure that native pectoralis tendon is brought to the scapula, because the tendon graft may stretch over time.

PEARLS AND PITFALLS

- Electromyography is helpful in identifying patients with dystrophy or other palsies, which may preclude the possibility of a sternal head transfer for serratus anterior dysfunction.
- Patients with blunt trauma or idiopathic etiologies initially should be managed nonoperatively, because most will recover serratus anterior function.
- The sternal head lies deep to the clavicular head, and positioning the arm in abduction and external rotation can help identify the insertion of the tendon.
- When approaching the inferior scapula, care is taken to stay medial while retracting the latissimus and teres major distally, because the neurovascular structures are lateral.
- The scapula should be reduced to the chest wall by an assistant before tensioning the pectoralis transfer.
- Avoid scapular fracture by keeping the osseous tunnel a minimum of 1 cm away from the scapular borders.
- The sternal head is lengthened by autograft or allograft, but it is critical to have native, living pectoralis tendon attached directly to the inferior scapula. The auto- or allograft is meant for augmentation.

POSTOPERATIVE CARE

- Patients are kept immobilized in the sling and orthosis for 6 weeks.
- After 6 weeks, range-of-motion exercises are begun, and the brace is discontinued.
- Strengthening exercises are begun as motion returns.
- Patients are restricted from heavy lifting or manual labor for 6 months.

OUTCOMES

- Most series of sternal head transfer for serratus anterior dysfunction and scapular winging report good to excellent results with improvement in function, relief of pain, and correction of winging.
- Post11 reported on eight patients treated with sternal head transfer with excellent results.
- Connor et al1 reported on 11 patients, 10 of whom (91%) had significant improvement in pain and function and relief of winging.
- Warner and Navarro13 reported that seven of eight patients had excellent results, with the only unsatisfactory outcome following a deep infection.
- Conversely, Noerdlinger et al10 reported that of 15 patients treated, only 7 (47%) had good to excellent results. They found that those patients who lacked external rotation at follow-up
had poorer results, and that more aggressive therapy regarding rotation may be needed.

**COMPLICATIONS**

- Seroma and infection\(^{13}\)
- Neurovascular injury
- Scapular fracture through bone tunnel
- Shoulder stiffness\(^{10}\)
- Graft loosening and loss of tension\(^{11}\)

**REFERENCES**

DEFINITION
- Refractory disorders of the scapulothoracic articulation have been reported to result in debilitating pain and dysfunction that may require surgical management.
- The most common clinical presentation, scapular winging, was first reported in the published literature in 1723, and several etiologies for scapular winging have been documented since then.
- Soft tissue operations (eg, pectoralis major tendon transfer) have had reported success in stabilizing the dyskinetic scapula in appropriate patients.
- Despite successful clinical outcomes, a population of patients experience recurrent symptomatic scapular winging even after pectoralis major transfer.
- Several authors report that arthrodesis is the treatment of choice for these failed muscle transfers. For failed pectoralis transfer or significant (ie, irreducible) fixed winging, scapulothoracic arthrodesis can be a successful salvage operation for these patients.

ANATOMY
- The scapula is positioned over the posterolateral aspect of the rib cage, overlying ribs 1 to 7. It is suspended from the sternum by the clavicle anteriorly and plays an important role in positioning the upper extremity for proper function.
- The lateral scapula includes the glenoid fossa for articulation with the humeral head.
- The scapula provides an attachment for 16 muscles, which help maintain it in functional positions. It articulates on the thoracic cavity, allowing rotation, protraction, and retraction.
- A thin bursal layer separates the scapula from the underlying ribs.

PATHOGENESIS
- Dysfunction of the scapulothoracic articulation has been well documented in the peer-reviewed literature.
- The most common manifestation of scapulothoracic dysfunction is symptomatic scapular winging (FIG 1).
- Traumatic injuries to the serratus anterior muscle or the long thoracic nerve have been reported to cause symptomatic winging.
- Atraumatic etiologies, such as neuralgic amyotrophy, polio, and the muscular dystrophies, also may produce disabling scapular winging.
- Intolerable winging also has been demonstrated in association with other bony abnormalities (eg, rib or scapular osteochondromas and malunited scapular fractures) or soft tissue lesions (eg, scapular-stabilizing muscle contractures, muscle avulsions, and scapulothoracic bursitis).
- Recent authors have reported a significant incidence of scapular winging secondary to glenohumeral joint lesions such as rotator cuff tears and glenohumeral instability (especially posterior and multidirectional instability).

The scapulothoracic articulation also is a potential source of debilitating pain in the shoulder girdle.
- Several authors have documented the incidence of painful scapulothoracic crepitus (“snapping scapula” syndrome) and scapulothoracic bursitis.
- Painful crepitus can be due to interposed muscle, fibrous and granulomatous lesions, or bony incongruity associated with osteochondromata, fractures, scoliosis, or kyphosis.

NATURAL HISTORY
- Most patients who present with symptomatic scapular winging, scapulothoracic pain, or crepitus respond to nonoperative measures.
- A subset of this patient population, however, experiences complex scapulothoracic dysfunction or pain refractory to conservative measures.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients presenting with scapulothoracic disorders typically complain of debilitating pain, shoulder dysfunction, or scapulothoracic crepitus.
- Physical findings commonly include scapular winging, crepitus, alterations in normal scapulohumeral rhythm, or neurologic deficits.
- Physical examination should focus on the resting posture of the scapula, as well as its dynamic position.
- Both scapulae should be observed and palpated while the arms are elevated or while the patient performs a wall push-up. These dynamic tests may make subtle winging more obvious.
- The pattern of winging distinguishes between serratus anterior dysfunction (long thoracic nerve) or trapezius palsy (spinal accessory nerve).

FIG 1 • A. Moderate dynamic scapular winging demonstrated with slow forward elevation of the arms in the frontal plane. B. The same patient demonstrating marked medial winging with the resisted elevation at 30 degrees.
• The more common medial winging is consistent with serratus anterior dysfunction, whereas lateral winging is observed in trapezius palsy.

• Further assessment includes the scapula stabilization test to assess for fixed or correctable winging. This test is crucial in determining fixed versus reducible winging. It demonstrates the amount of discomfort the patient has and indicates the extent to which reduction of the scapula will relieve that discomfort.

• Painful crepitus localized to the scapulothoracic region is verified by diagnostic injection, in which 1% lidocaine is injected beneath the medial border of the scapula into the scapulothoracic bursa. Improvement in pain may be noted in the examination room, further supporting the diagnosis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

• Standard plain radiographs of the shoulder, including anteroposterior views in internal and external rotation, axillary lateral views, and scapula Y views are obtained to evaluate the status of the clavicle, acromioclavicular joint, glenohumeral joint, and bony contour of the scapula.

• CT scans, including axial images and reformatted coronal and sagittal images, provide further detail, and may be required to assess scapula morphology and the presence of exostoses or deformity.

• Electromyography and nerve conduction velocity are important to verify neurologic dysfunction of the long thoracic or spinal accessory nerves.

DIFFERENTIAL DIAGNOSIS

• Long thoracic nerve palsy

• Spinal accessory nerve palsy

• Glenohumeral joint derangement with secondary scapular winging

• Scapulothoracic bursitis

• Snapping scapula

• Scapular exostosis or osteochondroma

NONOPERATIVE MANAGEMENT

• Nonoperative treatment is the cornerstone of management of scapulothoracic dysfunction.

• Therapeutic modalities involve supervised scapular–stabilizer and glenohumeral stretching and strengthening, the judicious use of oral anti-inflammatory medications, and selective cortisone injections.

SURGICAL MANAGEMENT

• Patients who have failed an extensive nonoperative course are candidates for surgical treatment.

• Surgical options for scapulothoracic dysfunction include:

  • Arthroscopic or open decompression and bursectomy or medial border scapulectomy for painful crepitus

  • Split pectoralis major tendon transfer for dynamic winging

  • Scapulothoracic arthrodesis

• Surgical indications for scapulothoracic arthrodesis include the following clinical situations:

  • For patients with disabling pain associated with fixed scapular winging or failed pectoralis transfer, indications for fusion include:

    • Significant winging

    • Difficulty in reducing the scapula with the “scapular stabilization test”

    • Significant pain relief (>75%) that substantially improved function during a scapular stabilization test

Preoperative Planning

• Preoperative anesthesia consultation is recommended. We use general anesthesia with a double-lumen endotracheal tube to allow for selective deflation of the ipsilateral lung during wire passage.

Positioning

• Patients are placed in the prone position.

• Care is taken to pad all bony prominences.

• The entire involved arm, scapula, and ipsilateral posterior iliac crest are prepped and draped to the midline of the spine (FIG 2).

• It is essential that the entire arm be prepped and draped in the surgical field to allow for appropriate manipulation of the scapula and accurate placement of the scapula on the rib cage for fusion.

Approach

• A direct approach to the scapulothoracic articulation along the medial border of the scapula is used. This approach allows excellent exposure of the underlying ribs and undersurface of the scapula. The superficial location of the scapula makes this approach relatively straightforward.
**EXPOSURE**

- The incision is placed along the medial border of the scapula from just superior to the scapular spine to the inferior angle.
- The superficial fascia is incised, and the trapezius muscle is identified and retracted medially (TECH FIG 1A). The rhomboid muscles are incised off the medial edge of the scapula and are tagged for reattachment before closure (TECH FIG 1B).
- With the rhomboid muscles elevated, a rake retractor can be placed on the anterior surface of the medial scapular border to retract the medial scapula away from the rib cage (TECH FIG 1C).
- About one third of the musculature of the serratus anterior and subscapularis is resected from medial to lateral off the anterior surface of the scapula to allow for a wide fusion surface (TECH FIG 1D).
- Care must be taken to avoid resecting the subscapularis beyond the midline of the scapula to prevent denervation.

**BONY PREPARATION**

- The anterior surface of the scapula is now roughened slightly with a burr (TECH FIG 2A). Care must be taken during this maneuver to avoid thinning the medial border excessively, because that could lead to fracture during hardware fixation.
- Next, the scapula is reduced to the rib cage in approximately 20 to 25 degrees of external rotation from the midline to maximize subsequent shoulder range of motion (most notably elevation and external rotation).
- If patients demonstrated concomitant multidirectional glenohumeral instability with a symptomatic inferior component, the scapula is rotated externally 35 to 40 degrees from the midline to use the inferior glenoid rim to buttress against inferior translation.
- The ribs corresponding to the decorticated anterior surface of the scapula are identified, and the scapula is again retracted to allow for rib preparation.
- Depending on the size and configuration of the scapula, three or four ribs typically will be used in the fusion (usually the third to sixth ribs).
- The periosteum is incised carefully in a longitudinal direction and stripped off each rib (TECH FIG 2B,C).
- The ribs are minimally roughened with a burr down to bleeding bone.
- It is essential to remove all areas of soft tissue between the scapula and rib cage to permit maximum bony contact between the anterior surface of the scapula and the ribs (TECH FIG 2D).
TECH FIG 2 • A. The anterior surface of the scapula is lightly decorticated with a motorized oval burr. B. The first rib has been prepared with the periosteum incised and stripped off of the rib, ready for light decortication. C. Rib preparation continues, exposing the bony surface of the ribs corresponding to the undersurface of the scapula. This typically involves three to four ribs. D. Appearance of the rib surface after light decortication to a bleeding bony surface. Note that in this case, three ribs were prepared for the fusion surface.

WIRE PASSAGE AND PLACEMENT OF SEMITUBULAR PLATE

- At this time, the involved lung is deflated before cerclage wires are passed around the ribs, to minimize trauma to the lung fields.
- Using rib and periosteal dissectors, a cerclage wire with a minimum diameter of 1.5 mm is passed carefully around each of the exposed ribs at the level where the medial border of the scapula will be placed on the rib cage (TECH FIG 3A,B).
- After passage of the cerclage wires, a one-third semitubular large fragment plate (usually with 5 or 6 holes, depending on the size of the scapula) is lined up on the posterior aspect of the medial border of the scapula (the thickest part of the scapula; TECH FIG 3C).
- A 3-mm burr is used to make holes through the scapula corresponding to the holes in the semitubular plate (TECH FIG 3D).

TECH FIG 3 • A. A 1.5-mm wire is passed around the rib using rib and periosteal elevators. The lung is deflated by the anesthesia team before the wire is passed to minimize damage to the underlying pleura. B. Wires are passed around each of the ribs to be involved in the fusion construct. C. A one-third semitubular plate (typically with 5 or 6 holes) is positioned over the medial border of the scapula. D. Holes are drilled in the scapula, corresponding to the plate, with a 3-mm motorized burr. A skin retractor is placed beneath the scapula to protect the underlying thoracic cavity.
Cancellous bone is now harvested from the posterior iliac crest in routine fashion through a separate incision paralleling the path of the cluneal nerves.

- If more bone graft is desired, either allograft cancellous chips or a synthetic bone graft substitute can be added.

- The wires are now passed through the scapula and semitubular plate (TECH FIG 4A), and the bone graft is placed between the scapula and ribs.

- The scapula is reduced to the underlying ribs (TECH FIG 4B), and the wires are sequentially tightened with the scapula held in 20 to 25 degrees of external rotation from the midline (TECH FIG 4C,D).

- The semitubular plate allows uniform stress distribution once the wires are tightened (TECH FIG 4E,F).

- The wires are cut, and attention is turned to closure of the wound (TECH FIG 4G).

**TECH FIG 4 • A.** The previously placed wires are then passed through the scapula and plate in the appropriate position. **B.** The scapula is reduced into the predetermined position overlying the ribs and held in place before wire tightening. **C,D.** The wires are tightened sequentially, applying uniform tension on the plate and compressing the scapula against the ribs. **E.** The final position of the scapula after fixation with the wires. Note the autologous bone graft seen along the medial border. **F.** Illustration of the final construct. **G.** The wires are then cut, and attention is turned to wound closure.
POSTOPERATIVE CARE

- The patient is placed in a “gunslinger” brace, immobilizing the arm in neutral rotation (FIG 3), and a postoperative chest radiograph is obtained to document any hemo- or pneumothorax.
- If a chest tube has been placed, it is removed 1 or 2 days postoperatively, depending on chest tube outputs and pulmonary status.
- Patients are immobilized in the brace for 12 weeks.
- Rehabilitation is commenced at 12 weeks with a gentle passive range-of-motion program that emphasizes forward elevation and external rotation.
- Three weeks later, the patient is progressed to an active range-of-motion program.
- A strengthening program involving resisted exercises is begun 6 weeks after the gunslinger brace is removed.

OUTCOMES

- Despite the significant complication rate (nearly 50%) that accompanies scapulothoracic arthrodesis, this operation has been documented to provide improvements in both pain and functional disability.
- A high level of patient satisfaction when patients are chosen appropriately and expert surgical technique is used can make this operation rewarding for both patient and surgeon.
- In one series of 23 patients undergoing scapulothoracic fusion, mean ASES scores improved from 35.8 to 40.1. Postoperative pain scores decreased from mean 5.5 to 4.7. Mean patient satisfaction was 9.5 out of 10 for the surgical procedure, and 91% of patients reported that they would undergo the procedure again.14

COMPLICATIONS

- Complications are not uncommon with this procedure and have been reported to be as high as 50% in some series.14
The most commonly cited complications associated with this procedure include:

- Pneumothorax
- Hemothorax
- Hardware complications, including wire breakage, nonunion, and pseudoarthrosis
- Neurologic complications, including intercostal neuralgia
- Wound complications, including infection or wound dehiscence

REFERENCES

DEFINITION

- Suprascapular nerve (SSN) entrapment is an uncommon cause for shoulder pain and weakness. It was initially described by Koppel and Thompson.\(^{11}\)
- SSN entrapment typically occurs at the suprascapular or spinoglenoid notch and presents with symptoms ranging from diffuse shoulder pain to weakness and atrophy of the supraspinatus and infraspinatus muscles.

ANATOMY

- The SSN arises from the upper trunk of the brachial plexus, with contributions from C5 and C6 (rarely also C4), and provides branches to the supraspinatus and infraspinatus muscles. It also carries afferent fibers from the glenohumeral joint and rarely also cutaneous fibers from the lateral aspect of the shoulder.
- The nerve traverses two potential compression points, at the suprascapular notch and spinoglenoid notch (FIG 1), and is accompanied by the suprascapular artery and vein.
- At the suprascapular notch, the nerve runs in a fibro-osseous canal formed by the scapular notch and the transverse scapular ligament. Generally, the nerve runs under the ligament, but it is occasionally accompanied by a branch of the main vessels, which course over the ligament.
- The suprascapular notch is approximately 4.5 cm medial to the posterolateral corner of the acromion and 3 cm medial to the glenoid rim (supraglenoid tubercle). The spinoglenoid notch is approximately 1.8 cm medial to the glenoid rim and 2.5 cm inferomedial to the supraglenoid tubercle.\(^{3}\)
- Several anatomic studies have described the presence of a spinoglenoid ligament (inferior transverse scapular ligament) at the spinoglenoid notch in 3% to 60% of specimens,\(^{5,6}\) but its role in nerve entrapment at this level is controversial.

PATHOGENESIS

- The most common site of entrapment is at the suprascapular notch, where it can be compressed by a thickened or ossified transverse scapular ligament.
- The relative confinement of the nerve at the suprascapular notch also places it at risk for injury due to traction, such as seen either in acute trauma or repetitive overhead activities such as volleyball, tennis, or weightlifting.
- Compression from labral ganglions can also occur, typically at the spinoglenoid notch.\(^{1}\) These cysts can develop as the result of labral tears that allow fluid extravasation but block backflow, similar to a one-way valve.
- More recently, traction injury to the nerve has been described as the result of massive, retracted tears of the posterosuperior cuff.\(^{2}\)
- Direct or indirect trauma leading to SSN neuropathy has been described as the result of shoulder dislocation, proximal humerus fracture, or scapular fracture.
- Iatrogenic injury to the SSN can occur during distal clavicle resection, positioning during spine surgery, transglenoid drilling for instability repair, shoulder arthrodesis, or the posterior approach to the glenohumeral joint.

NATURAL HISTORY

- The natural history depends on the presence or absence of a space-occupying lesion as the cause of SSN neuropathy.
- Without compression by a mass, most patients will improve with time and supervised physical therapy.\(^{8}\)
- Conversely, the presence of a mass, such as a cyst or ganglion, usually results in failure of conservative management and will require decompressive surgery.
- The natural history of periarticular ganglion cysts in the shoulder is controversial, but they are thought to persist and enlarge with time.\(^{9}\) In rare instances, spontaneous resolution of ganglion cysts has been documented.

PATIENT HISTORY AND PHYSICAL FINDINGS

- SSN neuropathy secondary to compression at the suprascapular notch typically presents as a dull pain in the posterior...
and lateral shoulder, but the pain can also be referred to the anterior chest wall, lateral arm, and ipsilateral neck. Compression at the spinoglenoid notch is often comparatively pain-free and presents with isolated infraspinatus atrophy (FIG 2).

- The patient often provides a history of acute or repetitive trauma to the shoulder, such as a fall on the outstretched hand, or activities such as volleyball, tennis, or weightlifting.
- There appears to be an increased incidence of isolated infraspinatus atrophy in asymptomatic volleyball players. This typically responds well to conservative measures.
- Depending on the chronicity and degree of compression, varying amounts of weakness in abduction and external rotation can be detected on physical examination.
- In longstanding compression, atrophy of the supraspinatus and infraspinatus can be observed.
- Atrophy, if present, may assist in differentiating compression at the suprascapular notch from that at the spinoglenoid level, since supraspinatus atrophy occurs only with the former.
- Palpation of the spinoglenoid notch and cross-body adduction may reproduce the patient’s symptoms.
- It is important to exclude other potential sources of pain, such as the cervical spine, acromioclavicular joint, or rotator cuff.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- An anesthetic injection into the suprascapular notch can be diagnostic if it results in complete but transient pain relief.
- Stryker notch views, or anteroposterior radiographs of the scapula, with a 15- to 30-degrees caudally directed beam, provide visualization of the suprascapular notch. Alternatively, a CT scan can provide good osseous detail in cases of posttraumatic deformity or ossification of the transverse scapular ligament.
- MRI can reveal a superior or posterior labral tear and the presence of a ganglion in the area of the suprascapular or spinoglenoid notch (FIG 3). Ganglion cysts present as homogeneous masses with low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.
- Electromyography and nerve conduction studies can often provide a conclusive diagnosis by showing denervation potentials, fibrillations, spontaneous activity, and prolonged motor latencies in the supraspinatus or infraspinatus, depending on the level of entrapment.

**DIFFERENTIAL DIAGNOSIS**

- Cervical radiculopathy
- Glenohumeral instability
- Rotator cuff pathology
- Acromioclavicular joint arthrosis

**NONOPERATIVE MANAGEMENT**

- Initial treatment for SSN neuropathy in the absence of a space-occupying lesion is conservative and will lead to near-complete resolution of symptoms in most cases.
- Complete resolution of pain and weakness can take more than 1 year.
- Supervised physical therapy, followed by a self-directed home exercise program, should consist of range-of-motion exercises, as well as strengthening of the rotator cuff muscles, the deltoid, and the periscapular musculature, including the trapezius, rhomboids, and serratus musculature. Restoring proper scapular function is beneficial in recovery and may prevent recurrence of the injury.
- Image-guided cyst aspiration has shown success in about half of patients, with persistence or recurrence in the other half.9,12
SURGICAL MANAGEMENT

- Surgical treatment is indicated in patients who have failed to respond to 6 to 12 months of nonoperative measures and continue to have significant pain and dysfunction. SSN neuropathy secondary to a mass is best treated with decompression, and evaluation and potential repair of the glenoid labrum.
- Other sources for shoulder pain and dysfunction should be ruled out if the mass is smaller than 1 cm in diameter or is not directly compressing the neurovascular bundle.

Preoperative Planning

- Oblique sagittal MR imaging allows visualization of the SSN in the supraspinatus fossa, the spinoglenoid notch, and the infraspinatus fossa.
- If a space-occupying lesion is present, this imaging will assist in preoperative planning by delineating the exact position of the mass and determining whether it is confined to the supraspinatus or the infraspinatus fossa or involves both areas.
- A paralabral ganglion or cyst that is confined to one area, especially when associated with a labral tear or other intra-articular pathology, is often amenable to arthroscopic decompression.
- We have found it useful first to perform a diagnostic shoulder arthroscopy and potential treatment of intra-articular pathology, followed by arthroscopic or open decompression of the SSN.

- Arthroscopic decompression has the potential advantages of treating associated intra-articular lesions, such as labral tears and avoiding the morbidity associated with open procedures.

Positioning

- Either the beach chair or the lateral decubitus position can be used.

OPEN DECOMPRESSION

Approach to the Suprascapular Notch

- Decompression of the suprascapular nerve at the suprascapular notch is best achieved through a trapezius-splitting approach.
- The anterior approach requires a more complex dissection and therefore carries a higher risk of neurovascular complications. It also offers incomplete visualization of the SSN posterior to the notch and is generally not recommended.
- A saber-type skin incision following the Langer lines is performed over the top of the shoulder. The incision begins posteriorly at the distal third of the scapular spine and extends anteriorly to a point 2 cm medially off the acromioclavicular joint (TECH FIG 1A).
- A transverse skin incision parallel to the scapular spine can be chosen instead but produces a less cosmetic scar.
- The trapezius fascia and muscle is divided in line with its fibers for a distance of 5 cm.
- Abduction of the arm decreases tension on the muscle, which if necessary can be elevated off the scapular spine for an extensile exposure.
- The supraspinatus muscle is bluntly dissected off the anterior aspect of the suprascapular fossa and retracted posteriorly to provide access to the suprascapular notch (TECH FIG 1B).

TECH FIG 1 • Schematic and intraoperative photograph demonstrating suprascapular nerve release at the suprascapular notch. A. The trapezius muscle is split in line with its fibers. B. The supraspinatus muscle is bluntly dissected off the suprascapular fossa and retracted to expose the suprascapular notch. C. The transverse scapular ligament has been released.
The overlying suprascapular artery and vein are gently retracted to expose the transverse scapular ligament.
- A small right-angle clamp can be used to bluntly dissect under the ligament and protect the underlying nerve while the ligament is transected with a scalpel.
- Occasionally the nerve is still tethered after release of the transverse ligament, requiring careful resection of the medial aspect of the suprascapular notch. The resected edge of the bone must be smooth at the completion of the procedure.
- If the trapezius was detached during the approach, it should be sutured back to the bone of the scapular spine. If the muscle was only split in line with its fibers, it is reaproximated with interrupted, absorbable sutures.

**Approach to the Spinoglenoid Notch**
- The posterior approach provides direct visualization of the suprascapular nerve at the spinoglenoid notch.
- A longitudinal skin incision is centered approximately 4 cm medial to the posterolateral corner of the acromion, approximately 5 cm in length. Following Langer lines provides a cosmetically acceptable scar.
- The underlying fascia and deltoid muscle is split in line with its fibers beginning at the level of the scapular spine and extending 5 cm distal from the posterior acromion (TECH FIG 2A). A stay suture placed at the distalmost extent of the incision protects against propagation of the split, which carries a risk of injury to the axillary nerve.
- The infraspinatus is identified, dissected off the scapular spine, and retracted inferiorly (TECH FIG 2B).
- Commonly, a small area of vascular fibrous tissue is encountered posterior to the site of the spinoglenoid notch, covering the suprascapular neurovascular structures.
- If a ganglion is present, the contents of the cyst should be removed along with the wall (TECH FIG 2C).
- A spinoglenoid ligament, if present, should be excised.
- Decompression is complete when the SSN can be followed along its entire length from the spinoglenoid notch until it arborizes into its infraspinatus branches (TECH FIG 2D).
- The infraspinatus muscle is allowed to return to its anatomic position.
- The deltoid muscle and fascia is reaproximated with interrupted, absorbable sutures.

**TECH FIG 2** • Schematics and intraoperative photographs showing suprascapular nerve release at the spinoglenoid notch. A. The deltoid muscle is split in line with its fibers, beginning about 4 cm medial to the posterolateral corner of the acromion. B. The spinoglenoid notch has been exposed. The retractors displace the infraspinatus muscles posteriorly and inferiorly. C. A multilobulated ganglion cyst. D. The suprascapular nerve is now visible after the soft tissue band has been divided.
**ARTHROSCOPIC DECOMPRESSION**

**Approach to the Suprascapular Notch**

- Routine glenohumeral arthroscopy is performed to assess concomitant pathology, especially tears of the superior-posterior labrum.
- The subacromial bursa is resected, extending more medially than what is usual for subacromial decompression.
- The bursectomy should allow adequate visualization from the acromioclavicular (AC) joint and coracoid anteriorly to the scapular spine posteriorly.
- The coracoid is palpated with a probe or switching stick, which can also be used to bluntly dissect the surrounding soft tissues to expose the coracoclavicular ligaments.
- Alternatively, the ligaments can be found approximately 15 mm medial to the AC joint and then followed inferiorly to their insertion on the coracoid.
- The conoid ligament attaches to the coracoid just laterally to the suprascapular notch. Fibers of the conoid ligament are in continuity with the transverse scapular ligament.

- The suprascapular notch is typically covered by the supraspinatus muscle and fat, complicating visualization of the neurovascular bundle (TECH FIG 3A).
- An accessory portal is created approximately 2 cm medial to the standard Neviser portal along a line that bisects the angle formed between the clavicle and spine of the scapula. An 18-gauge spinal needle helps with correct positioning of the portal (TECH FIG 3B).
- Use of a switching stick or smooth trocar through this accessory portal allows careful, blunt dissection of the fat to expose the suprascapular vessels coursing over the transverse scapular ligament, which presents as glistening white fibers.
- Once adequate visualization has been achieved, the nerve is protected with a probe or small trocar while the overlying ligament is cut with the arthroscopic scissors as far laterally as possible (TECH FIG 3C–E).
- The SSN is probed to ensure adequate decompression; any residual compression from the bony structures can be removed with the arthroscopic burr.

**TECH FIG 3** • Schematic and arthroscopic images showing arthroscopic suprascapular nerve release at the suprascapular notch. A. After soft tissue removal, the nerve (N) can be visualized underneath the superior transverse scapular ligament (STSL). A blunt trocar is retracting the overlying vessel. B. The arthroscope is positioned in the lateral portal and the instruments are introduced through a superior portal, medial to the standard Neviser portal. C. Arthroscopic scissors positioned to cut the STSL. D, E. The ligament has been released. A, artery. (A, C, E: Courtesy of Dr Laurence Higgins.)
Approach to the Spinoglenoid Notch

- Ganglion cysts associated with labral tears are most commonly located at the spinoglenoid notch. They often extend into the infraspinatus fossa.
- With an intact labrum, the joint capsule above the superior-posterior labrum is incised, beginning posterior to the biceps root and extending posteriorly for 2 to 3 cm.
- After incision of the capsule, the fibrous raphe between the supraspinatus and infraspinatus seen lateral to the spinoglenoid notch provides a useful landmark.
- The spinoglenoid notch can be palpated with an arthroscopic instrument, providing a bony landmark that can be correlated with the cyst position as seen on preoperative MR imaging.

POSTOPERATIVE CARE

- The arm is immobilized in a sling for 2 or 3 days for comfort.
- Pendulum exercises commence on postoperative day 1, and active motion is increased as tolerated.

OUTCOMES

- Nonoperative treatment is successful in 80% of patients without space-occupying lesions.8
- Open decompression with release of the transverse scapular ligament improved pain and weakness in 73% to 87% of patients.4,13

PEARLS AND PITFALLS

Arthroscopic decompression

- Hemostasis and visualization can be improved by increasing the fluid pressure to 50 mm Hg and using an electrothermal device to cauterize bleeders.
- The decompression should be performed before treatment of any concomitant pathology to avoid further complicating this procedure owing to fluid extravasation and swelling.
- A 70-degree scope is sometimes helpful to visualize the notch.
- Visualization should be performed through the lateral portal, with posterior and accessory medial working portals.

COMPLICATIONS

- Damage to the suprascapular nerve and vessels
- Damage to the spinal accessory nerve if mobilization of the trapezius muscle is carried out far medially
- Incomplete decompression, especially in rare cases of compression at both suprascapular and spinoglenoid notch

REFERENCES

PATIENT HISTORY AND PHYSICAL FINDINGS
- Distal humerus fractures occur in two age groups:
  - Younger patients who sustain high-energy trauma
  - Older patients with underlying osteopenia
- Comminution is the dominant feature of supracondylar and intercondylar fractures and complicates internal fixation.
- The goals of the initial evaluation are to:
  - Understand the fracture pattern.
  - Determine the existence of previous symptomatic elbow pathology.
  - Determine the extent of associated soft tissue (open fractures).
  - Identify associated musculoskeletal or neurovascular injuries.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Elbow radiographs in the anteroposterior and lateral planes are the first imaging studies obtained and should be carefully scrutinized to identify the fracture lines and fragments as well as the extent of comminution.
- A complete understanding of the fracture pattern is difficult to obtain based only on simple radiographs because of the complex geometry of the distal humerus and fragment overlapping (FIG 1A,B).
- CT with three-dimensional reconstruction is extremely helpful, especially in the more complex cases. It allows the surgeon to look for specific fractured fragments at the time of fixation, facilitating accurate fracture reduction (FIG 1C,D).
- Traction radiographs obtained in the operating room with the patient under anesthesia just before surgery also can be helpful, especially if a CT scan is not available.

SURGICAL MANAGEMENT
- Internal fixation is the treatment of choice for most fractures of the distal humerus.
- Modern fixation techniques seem to benefit from:
  - Fixation strategies designed to improve the mechanical stability of the construct
  - Use of precontoured periarticular plates
  - Use of screws locked to the plates
- Elbow arthroplasty should be considered in elderly patients with previous elbow pathology or in very low, comminuted fractures in patients with osteopenia.
- The goal of the internal fixation technique is to achieve a construct stable enough to allow immediate unprotected motion without fear of redisplacement. This can be attained in most distal humerus fractures—even the most complex—provided the following principles are adhered to (FIG 2):
  - Plates used for internal fixation are applied so that fixation in the distal fragments is maximized.
  - Distal screw fixation contributes to stability at the supracondylar level, where true interfragmentary compression is achieved.

Approaches
- Adequate exposure is necessary to achieve satisfactory reduction and fixation.
- Subcutaneous transposition of the ulnar nerve is associated with a decreased incidence of postoperative ulnar neuropathy.

FIG 1 • A,B. AP and lateral radiographs showing a comminuted intra-articular supracondylar fracture of the distal humerus. The complexity of the fracture is difficult to appreciate fully because of the geometry of the distal humerus, fracture comminution, and fragment overlapping. C,D. The use of CT with three-dimensional reconstruction and surface rendering helps understand the fracture configuration and anticipate the surgical findings.
Most fractures require mobilization of the extensor mechanism of the elbow through an olecranon osteotomy, triceps reflection, or triceps split.

Simple fractures occasionally may be addressed working on both sides of the triceps without mobilization of the extensor mechanism.

Olecranon osteotomy is the preferred surgical approach for internal fixation for most distal humerus fractures.\(^1\)

**Advantages**
- Provides excellent exposure
- Offers the potential of bone-to-bone healing, thereby limiting the risk of triceps dysfunction
- Complications: nonunion, intra-articular adhesions
- Hardware removal may be needed.
- Limits the ability for intraoperative conversion to elbow arthroplasty
- May devitalize the anconeus muscle
- The proximal ulna cannot be used as a template to judge reduction and motion.

Triceps reflection and triceps split\(^8\) allow preservation of the intact ulna.
- Avoids complications related to olecranon osteotomy
- Facilitates intraoperative conversion to total elbow arthroplasty
- Allows use of the proximal ulna as a template for reduction of the distal humerus articular surface
- Allows assessment of extension deficit after fracture fixation, which is especially useful in fractures requiring metaphyseal shortening
- Bilaterotricipital approach\(^1\)

**Goals and indications**
- The goal is to provide adequate exposure for fracture fixation without violating the extensor mechanism.
- This approach is used only for the more simple fracture patterns (eg, extra-articular or simple intra-articular distal humerus fractures [AO/OTA A, C1, C2]) or when elbow arthroplasty is being considered.

**Advantages**
- This approach avoids complications related to the extensor mechanism.
- No postoperative protection is needed.
- Surgical time is decreased.

**Disadvantage**
- The procedure provides limited exposure of the articular surface.

---

**SURGICAL APPROACH**

**Olecranon Osteotomy**
- Chevron osteotomy provides increased stability (TECH FIG 1A).
- The distal apex of the chevron osteotomy is centered with the bare area of the olecranon articular surface.
- The anconeus is divided with electrocautery in line with the lateral limb of the osteotomy.
  - Alternatively, the anconeus may be preserved by dissecting it free on its distal aspect and reflecting it proximally attached to the proximal ulnar fragment.\(^2\)
- Start the osteotomy with a thin oscillating saw.
- Complete the osteotomy with an osteotome.
  - Decreases risk of damage to the articular cartilage on ulna and humerus
  - Creates irregularities at the opposing cut surfaces, which may increase interdigitation
- Mobilize the fragment to facilitate exposure (TECH FIG 1B).
- Fixation (TECH FIG 1C)

---

**Triceps Reflection and Triceps Split**
- Bryan-Morrey triceps-sparing approach (TECH FIG 2)
  - The triceps is elevated from the medial intermuscular septum.
  - The forearm fascia and periosteum are incised just lateral to the flexor carpi ulnaris.
  - The triceps, forearm fascia, and anconeus are elevated in continuity from medial to lateral.
TECH FIG 1 • Olecranon osteotomy provides an excellent exposure for distal humerus fracture fixation. 
A. A chevron osteotomy is initiated with a microsagittal saw and completed with an osteotome. Drilling and tapping before performing the osteotomy facilitates fixation of the osteotomy if screw fixation is selected. 
B. Proximal mobilization of the osteotomized fragment and triceps allows ample exposure of the articular surface and columns. 
C. Fixation may be performed with a cancellous screw and tension band, wires and a tension band, or a plate.

- The anterior bundle of the medial collateral ligament and the lateral ulnar collateral ligament must be preserved to avoid postoperative instability.
- Mayo-modified extensile Köcher approach
  - The triceps is elevated from the lateral intermuscular septum.
  - The triceps and anconeus are elevated in continuity from lateral to medial.
- As noted earlier, the anterior bundle of the medial collateral ligament and the lateral ulnar collateral ligament must be preserved to avoid postoperative instability.

Bilaterotricipital Approach
- The triceps is elevated from the medial and lateral intermuscular septae.
- Lateral dissection can be extended anterior to the anconeus muscle (TECH FIG 3).
- Arthrotomy is performed posterior to the median collateral ligament and lateral collateral ligament complex.

TECH FIG 2 • The extensor mechanism (ie, triceps, anconeus, and forearm fascia) may be elevated off the ulna subperiosteally in continuity from medial to lateral (Bryan-Morrey approach) or from lateral to medial (Mayo-modified extensile Köcher approach).

TECH FIG 3 • Fractures with no or limited articular involvement may be fixed working on both sides of the triceps. As shown in this image, the extensor mechanism is left mostly undisturbed.
INTERNAL FIXATION

Technical Objectives

- Screws in the distal fragments (articular segment) should be placed according to the following principles:
  - Every screw should pass through a plate.
  - Each screw should engage a fragment on the opposite side that also is fixed to a plate.
  - As many screws as possible should be placed in the distal fragments.
  - Each screw should be as long as possible.
  - Each screw should engage as many articular fragments as possible.
  - The screws should lock together by interdigitation within the distal segment, thereby rigidly linking the medial and lateral columns together, creating an architectural structure similar to that of an arch or dome.

- Plates are used for fixation.
  - Plates should be applied such that compression is achieved at the supracondylar level for both columns.
  - Plates must be strong enough and stiff enough to resist breaking or bending before union occurs at the supracondylar level.

Provisional Assembly of the Articular Surface and Plate Placement

- Reduce the articular surface fragments anatomically.
  - The proximal ulna and radial head may be used as templates.
  - Rotational alignment should be carefully assessed.
  - Use smooth K-wires to maintain the reduction provisionally (TECH FIG 4A).
  - Two 2.0-mm smooth wires introduced at the medial and lateral epicondyles facilitate provisional placement of the plates and can be replaced by screws later.

- Fine-threaded wires or absorbable pins may be used for definitive fixation of small fracture fragments.
- Medial and lateral plates are placed so that one of the distal holes of each plate slides over the medial and lateral 2.0-mm smooth wires introduced at the medial and lateral epicondyles (TECH FIG 4B).
- One cortical screw is loosely introduced into a slotted hole of each plate to hold the plates in place; use of slotted holes for these screws facilitates later adjustments in plate positioning.

Articular and Distal Fixation

- Two or more distal screws are inserted through the plates medially and laterally. As noted, the screws should be as long as possible and engage the opposite column.
  - Before screw application, a large bone clamp is used to compress the articular fracture lines, unless there is comminution of the articular surface.
  - The two 2.0-mm smooth pins may be replaced with distal screws without previous drilling, to avoid accidental breakage of the drill when contacting the other screws. Usually, these last screws will interdigitate with the previously applied distal screws, thereby increasing the stability of the construct (TECH FIG 5).

Supracondylar Compression and Proximal Plate Fixation

- The proximal screw on one side is backed out, and a large bone clamp is applied distally on that side and proximally on the opposite side to apply maximum compression at the supracondylar level. Compression is maintained by application of one proximal screw in the compression mode (TECH FIG 6A,B).
  - The same steps are followed on the opposite side.

---

**TECH FIG 4** • A. Anatomic reduction of the articular surface is maintained provisionally with fine wires placed so that they will not interfere with plate and screw application. B. The medial and lateral plates are held in place provisionally with two distal 2.0-mm pins (which later will be replaced by screws) and two proximal screws through an oval hole to allow small adjustments in plate positioning. (Copyright Mayo.)
Chapter 33  ORIF OF SUPRACONDYLAR AND INTERCONDYLAR FRACTURES

The remaining diaphyseal screws are then introduced, providing additional compression as they push the undercontoured plates to gain intimate contact with the underlying bone (TECH FIG 6C,D).

Small posterior fragments can be fixed with threaded wires or absorbable pins.

Provisional wires are removed.

The elbow is put through range of motion. Motion should be smooth. If extension is limited, the tip of the olecranon may be removed.

**TECH FIG 5**  Maximal distal plate anchorage is then achieved by insertion of multiple long screws through the plates and into the distal fragments. Usually the screws from the medial and lateral directions will engage, creating an interlocked structure that increases fracture stability. (Copyright Mayo.)

**TECH FIG 6**  A,B. Supracondylar compression is achieved with the use of a large clamp, insertion of screws in the compression mode, and slight undercontouring of the plates. The same technique is applied laterally and medially. C. Internal fixation of a complex distal humerus fracture. (A,B: Copyright Mayo.)

**SUPRACONDYLAR SHORTENING**

- In cases with supracondylar comminution (ie, bone loss), compression at the supracondylar level cannot be achieved unless the humerus is shortened into a non-anatomic reduction that will provide adequate bone contact (TECH FIG 7A,B).
- The humerus may be shortened between a few millimeters and 2 cm with only minor losses in extension strength.\(^9\)
- Bone is trimmed from the diaphysis to ensure adequate bone contact with the distal fragments.
- The distal fragments are translated proximally and anteriorly. Anterior translation is necessary to create room for the radial head and the coronoid in flexion.
- The fracture is fixed in the desired position using the technique described previously.
- A new deep and wide olecranon fossa is created by removing bone from the distal and posterior aspect of the diaphysis (TECH FIG 7C). Otherwise, extension will be restricted.

POSTOPERATIVE MANAGEMENT

- After closure, the elbow is placed in a bulky noncompressive dressing with an anterior plaster splint to maintain the elbow in extension, and the upper extremity is kept elevated.
- Motion is initiated according to the extent of soft tissue damage. Motion usually can be initiated on the first or second postoperative day, but it may be necessary to wait for several days in the case of open fractures or severe soft tissue damage.
- Most patients benefit from a program of continuous passive motion for the first week or two after fixation; some may benefit from a longer period of passive motion.
- When postoperative motion fails to progress as expected, a program of patient-adjusted static flexion and extension splints is implemented.
- Treatment with indomethacin or single-dose radiation to the soft tissues shielding the fracture site may be considered for patients with high risk of heterotopic ossification, such as those with associated head or spinal trauma as well as those who require several surgeries in a short period of time.

OUTCOMES

- The results of internal fixation for fractures of the distal humerus using modern techniques are summarized in Table 1.
- The results of the different studies are difficult to interpret, because the severity of the injuries included cannot be compared, and there may be variations in the accuracy of range-of-motion measurements.
- Improvements in fixation techniques have resulted in a decreased rate of hardware failure and nonunion, but range of motion is not reliably restored in every patient.

COMPLICATIONS

- Infection
- Nonunion
- Stiffness, with or without heterotopic ossification
- Need for removal of the hardware used for fixation of the olecranon osteotomy
- Posttraumatic osteoarthritis or avascular necrosis requiring interposition arthroplasty or elbow replacement

REFERENCES

DEFINITION
- Capitellar fractures are uncommon, accounting for less than 1% of all elbow fractures and 6% of all distal humerus fractures.  
- They often are associated with radial head fractures and posterior elbow dislocations.
- A classification system for capitellar fractures has been proposed by Bryan and Morrey and modified by McKee:  
  - Type 1: complete fractures of the capitellum  
  - Type 2: superficial subchondral fractures of the capitellar articular surface  
  - Type 3: comminuted fractures  
  - Type 4: coronal shear fractures that include a portion of the trochlea as well as the capitellum as one piece (FIG 1)  
- Ring and Jupiter have proposed a new classification, expanding on the growing understanding that isolated capitellum fractures are rare and often are involved as part of articular shear fractures of the distal humerus. The classification includes five anatomic components:  
  - The capitellum and lateral aspect of the trochlea  
  - The lateral epicondyle  
  - The posterior aspect of the lateral column  
  - The posterior aspect of the trochlea  
  - The medial epicondyle

ANATOMY
- The two condyles of the distal humerus diverge from the humeral shaft to form the lateral and medial columns, which support the trochlea between them. The anterior aspect of the lateral column is covered with articular cartilage, forming the capitellum. Distally, these two condyles can be visualized as forming a triangle at the end of the humerus.
- The capitellum is the first epiphyseal center of the elbow to ossify.
- It is covered by articular surface anteriorly but devoid of it posteriorly.
- The capitellum is directed distally and anteriorly at an angle of 30 degrees to the long axis of the humerus.
- The radial head rotates on the anterior surface of the capitellum in elbow flexion and articulates with its inferior surface in elbow extension.
- The lateral collateral ligament inserts next to the lateral margin of the capitellum.
- The blood supply of the capitellum is derived posteriorly. It arises from the lateral arcade, which is the anastomosis of the radial collateral arteries of the profunda brachii and the radial recurrent artery.

PATHOGENESIS
- Capitellar fractures usually result from a fall on an outstretched hand or forearm as the radial head impacts the capitellum on impact.
- Capitellar–trochlear shear fractures involve impaction of the radial head against the lateral column of the distal humerus in a semi-extended position, resulting in a shearing mechanism of the distal humerus.
- Fracture fragments vary in size and displace superiorly and anteriorly into the radial fossa, resulting in impingement with elbow flexion.

NATURAL HISTORY
- Capitellar fractures occur almost exclusively in adults. These fractures do not occur in children, because in that age group the capitellum is largely cartilaginous, and a similar mechanism of injury would instead cause a supracondylar or lateral condyle fracture.
- Capitellar fractures are more common in females, a finding that has been attributed to the higher carrying angle of the elbow.
- Elderly patients of both genders are more susceptible to capitellum and complex capitellar–trochlear shear fractures because of the metabolic susceptibilities of osteoporosis.
- Displaced fractures that go untreated can have a poor outcome owing to progressive loss of motion and posttraumatic arthrosis.
PATIENT HISTORY AND PHYSICAL FINDINGS
- Symptoms of capitellar fractures are similar to those of radial head fractures, including pain and swelling along the lateral elbow and pain with elbow motion.
- Although there may be variable loss of forearm rotation, loss of flexion and extension is common, often accompanied by crepitus and pain.
- The association of concomitant radial head fractures and ligamentous injuries with capitellar fractures is high. 18
- The shoulder and wrist should be examined for concomitant injury.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard radiography is inadequate for accurate assessment of capitellar fractures.
- Lateral radiographs are best for obtaining an initial evaluation of capitellar fractures.
- Anteroposterior views do not reliably show the fracture, because the outline of the distal humerus is not consistently affected.
- The radial head–capitellum view can help identify fractures of the capitellum. This view is a lateral oblique projection taken with the x-ray beam pointing 45 degrees dorsoventrally, thereby eliminating the ulno- and radiohumeral articulation shadows.10
  - A type 1 fracture appears as a semilunar fragment sitting superiorly with its articular surface pointing up and away from the radial head in most cases.
  - Type 2 fractures are more difficult to diagnose, depending on the amount of subchondral bone accompanying the articular fragment. They may appear as a loose body lying in the superior part of the joint.
  - Type 3 fractures display variable amounts of comminution.
  - Coronal shear fractures show a characteristic “double arc” sign on lateral radiographic views (FIG 2A).
- CT scans are necessary for delineating the fracture pattern and should be performed in all cases.
  - CT scanning of the elbow should be done at 1- to 2-mm intervals using axial or transverse cuts.
  - Three-dimensional (3D) CT reconstructions provide the best detail and ability to appreciate the anatomic orientation of the fracture patterns and should be ordered if 3D imaging is available (FIG 2B,C).

DIFFERENTIAL DIAGNOSIS
- Radial head fracture
- Distal humeral lateral condyle fracture
- Elbow dislocation

NONOPERATIVE MANAGEMENT
- Truly nondisplaced and isolated capitellum fractures can be splinted for 3 weeks, followed by protected motion. We do not advocate nonoperative management for any other type of capitellum fracture.
- Closed reduction techniques, which have been described in the literature, should be performed with caution, and only complete anatomic reduction should be accepted.4,19
- Capitellar–trochlear shear fractures should not be treated nonoperatively because of their inherent instability and articular incongruity.

SURGICAL MANAGEMENT
- The goal of surgery is anatomic reduction and fixation of the fracture to allow for early motion without mechanical block.
  - Long-term goals are pain-free and maximal motion with minimal stiffness.
- Capitellar fractures are uncommon, and the wide array of treatment options presented in the literature is based on relatively small series.
- Treatment options include closed reduction,4,19 open excision,1,8,16 open reduction and internal fixation (ORIF), and arthroplasty.5,9
- With the improvement in techniques for fixation of small fragments and management of articular surfaces, ORIF has become the mainstay of treatment.
  - Advantages of ORIF include restoration of anatomy and stability.
  - Disadvantages include stiffness and failed fixation.
- In elderly patients, we do consider total elbow arthroplasty for complex intra-articular distal humerus fractures.
  - Advantages include early return to function and motion.
  - Disadvantages include functional limitations.

Preoperative Planning
- Before proceeding with surgery, a thorough understanding of the fracture and its orientation should be obtained with the help of a CT scan, and, if possible, 3D reconstructions.

FIG 2 • A. Characteristic “double arc” sign on lateral radiographs of coronal shear fractures. B,C. 3D CT reconstructions of a coronal shear fracture of the distal humerus.
The timing of surgery is important. Fractures preferably should be approached within 2 weeks, before osseous healing sets in, but after swelling has gone down. Ensure that the necessary implants and hardware are available. Reduction and fixation of the fracture will require K-wires, articular or headless screws, and small-fragment AO screws. An image intensifier should be used during surgery to confirm reduction of the fracture and proper positioning of implanted hardware.

**Positioning**

- General anesthesia is recommended.
- The patient usually is positioned supine on the operating table, with a radiolucent hand table.
- Alternatively, a lateral or prone position can be considered, with the anterior surface of the elbow supported by a padded bolster to use the universal posterior approach.

**CAPITELLAR FRACTURES**

**Exposure**

- The incision should begin 2 cm proximal to the lateral epicondyle and extend 3 to 4 cm distal toward the radial neck.
- If no large soft tissue or capsular defect is present, a direct lateral Köcher approach between the anconeus and ECU interval is recommended.
- The common extensor origin is sharply raised off the lateral epicondyle and reflected anteriorly to expose the lateral elbow joint.
  - Care must be taken to avoid damage to the radial nerve traveling between the brachialis and brachioradialis.
- Often the lateral ligamentous complex will be avulsed from the distal aspect of the humerus, with or without some aspect of the lateral epicondyle.
  - This ligamentous violation can be exploited to improve exposure by hinging open the joint on the medial collateral ligament with a varus stress.

- The capitellar fracture usually is displaced proximally and rotated and has no soft tissue attachments.

**Reduction and Fixation**

- The fragment is reduced under direct visualization, held with reduction tenaculums, and provisionally fixed with 0.045-inch K-wires from an anterior-to-posterior direction.
- Internal fixation options include fixation from posterior to anterior with AO cancellous screws or from either direction with headless compression screws.
- Cancellous screws are best for fracture fragments with a large subchondral component, as in type 1 fracture fragments. However, extending the dissection posteriorly around the lateral column theoretically increases the risk of osteonecrosis (TECH FIG 1).
- Headless compression screws, such as the Herbert screw, are best for fragments with less subchondral

**Approach**

- Either a lateral or posterior midline incision should be used, depending on the nature of the fracture, followed by a lateral approach into the elbow joint.
- Multiple intervals that can be exploited in the lateral approach to the elbow.
  - We advocate the Köcher approach, which uses the interval between the extensor carpi ulnaris and the anconeus and affords greater protection of the posterior interosseous nerve.
  - To increase exposure, the origin of the extensor carpi ulnaris (ECU), extensor digitorum communis, and extensor carpi radialis longus can be raised off of the lateral epicondyle anterior to its interval with the triceps.
- In many cases, a capsular violation has occurred. This can be exploited and used as the interval to expose the fracture, thereby avoiding the need to cause an additional soft tissue defect.

**TECH FIG 1** Fixation of a type 1 capitellum fracture with a headless screw anteriorly and AO screws from posterior to anterior.
bone, such as type 2 and small type 1 fracture fragments. The head of the screw must be buried below the articular surface.

- Excision of fracture fragments is recommended in type 2 fractures with small, thin articular pieces and type 3 comminuted fractures where the fragments are not amenable to internal fixation.
- Fragment reduction and hardware position should be confirmed by image intensifier.

- Unrestricted forearm rotation and elbow flexion-extension without mechanical block or catching should be confirmed intraoperatively.
- If the lateral collateral ligament is found to be avulsed, it should be repaired back to the lateral epicondyle with drill holes and nonabsorbable no. 2 suture or suture anchors.
- The capsule should be closed.
- The retracted extensor origin should be relaxed and closed to the surrounding soft tissue.

**CAPITELLAR-TROCHLEAR SHEAR FRACTURES**

**Exposure**

- A posterior midline incision should be made, and full-thickness flaps should be raised medially and laterally off of the extensor mechanism.
  - This incision provides extensile exposure, access to both sides, and ease of osteotomy if necessary (TECH FIG 2A).
- Beginning medially, the ulnar nerve should be decompressed in situ behind the medial epicondyle (TECH FIG 2B).
- Returning laterally, the interval between the anconeus and the ECU should be developed. In many cases, a capsular violation can be exploited (TECH FIG 2C).
- The common extensor origin, including the ECU, extensor digitorum communis, and extensor carpi radialis longus, is then sharply raised off the lateral epicondyle and reflected anteriorly to expose the lateral elbow joint and improve visualization medially.

- Care must be taken to avoid injury to the radial nerve proximally as it travels between the brachialis and brachioradialis, and to the posterior interosseous nerve distally when raising the ECU anteriorly. This may be done by keeping the forearm pronated.
- In many cases, the lateral epicondyle will have avulsed off of the distal humerus, and this traumatic osteotomy can be exploited.
- Otherwise, a formal lateral epicondyle osteotomy can be performed to enhance visualization while maintaining the integrity of the lateral ligamentous complex.
- Additionally, an olecranon osteotomy may be performed to improve visualization and fixation of fractures extending medially and posteriorly.
- The fracture fragments should now be visualized and accounted for. They are most commonly displaced proximally and internally rotated (TECH FIG 2D).

**TECH FIG 2** • A. Posterior midline incision used to for capitellar-trochlear shear fractures. B. Ulnar nerve compression medially. C. Lateral approach to elbow taking advantage of violation of the capsule and extensor muscles at the level of the extensor carpi ulnaris (ECU) and anconeus. D. The fracture fragments tend to displace proximally and become internally rotated.
**Reduction and Fixation**

- The fragment is reduced under direct visualization, held with reduction tenaculums, and provisionally fixed with 0.045-inch K-wires from anterior to posterior (TECH FIG 3A).
- Inability to reduce the fracture anatomically may represent fracture impaction, requiring either disimpaction or bone grafting, or both.
- Options for internal fixation include fixation from posterior-to-anterior with AO screws or from either direction with headless compression screws.
- Cancellous screws are best when the fracture fragment has a large subchondral component, but they make it necessary to extend the dissection posteriorly around the lateral column, theoretically increasing the risk of osteonecrosis.

- Headless compression screws, such as the Herbert screw, are best for fragments with less subchondral bone and provide the added benefit that they can be used in either direction, anteriorly or posteriorly. Diligence must be maintained to confirm that the head of the screw is buried below the articular surface when placed anteriorly.
- Fragment reduction and hardware position should be confirmed by image intensifier.
- Unrestricted forearm rotation and elbow flexion–extension without mechanical block or catching should be confirmed intraoperatively.
- The lateral epicondyle, if avulsed or osteotomized, should be repaired with a tension band technique or plate and screws (TECH FIG 3A,B).
- The capsule should be closed.
- The interval and released extensor origin should be relaxed and closed to the surrounding soft tissue.

POSTOPERATIVE CARE

- If secure fixation has been obtained, immediate mobilization can be initiated postoperatively.
- If fixation is tenuous, splint or cast the elbow for 3 to 4 weeks, followed by active and assisted range-of-motion exercises.

OUTCOMES

- Focusing initially on outcomes after ORIF of types 1 and 2 capitellar fractures, multiple small series have shown good results using Herbert screws in an anterior to posterior direction.6,13,14,20
- More recently, Mahirogullari et al15 reported on 11 cases of type 1 capitellum fractures treated with Herbert screws, which yielded 8 excellent and 3 good results. They recommended fixation in a posterior-to-anterior direction with at least two Herbert screws.
- Reported outcomes on type 4 capitellar–trochlear shear fractures are limited. McKee et al17 originally described this pattern and reported on 6 cases.
  - Each case involved an extended lateral Köcher approach and fixation with Herbert screws from an anterior to posterior direction. Good or excellent results were achieved in all cases, with average elbow motion of 15 to 141 degrees, and forearm rotation of 83 degrees pronation and 84 degrees supination.
- Ring and Jupiter examined 21 cases of articular fractures of the distal humerus treated with Herbert screw fixation and found 4 excellent results, 12 good results, and 5 fair results.
  - All of the fractures healed and had an average range of motion of 96 degrees. No ulnohumeral instability, arthrosis, or osteonecrosis was reported.
  - The authors stressed the importance of proper evaluation of these fractures and awareness that apparent capitellum fractures often are complex articular fractures of the distal humerus.21
- Dubberley et al7 further subclassified type 4 fractures in their series of 28 cases. They achieved an average range of motion of flexion-extension of 25 degrees less than the contralateral elbow and 4 degrees of supination-pronation less than the contralateral elbow.
  - Two comminuted cases required conversion to a total elbow arthroplasty.
  - Varied fixation methods were used, including Herbert screws, cancellous screws, absorbable pins, and supplementation with K-wires.

COMPLICATIONS

- The most common complication of capitellar fractures is loss of elbow motion and residual pain. The compromised motion most commonly is manifested in loss of flexion and extension.
- Ulnar neuropathy has been noted after ORIF, and some recommend routine ulnar nerve decompression.21
- Osteonecrosis may occur from the initial fracture displacement or surgical exposure. Blood is supplied to the capitellum from a posterior to anterior direction and may be compromised by surgical dissection.
  - In symptomatic cases in which revascularization after fixation has not occurred, delayed excision is indicated.
- Malunions may occur when the patient has delayed seeking treatment, when inadequate reduction or loss of closed reduction occurs, or after ORIF. Malunions result in loss of motion and may require excision of the fragment and soft tissue releases.
- Nonunions may occur, although this is uncommon. They most likely result secondary to inadequate reduction or lack of revascularization of the fragment.

REFERENCES

DEFINITION
• The radial head is distinctive in anatomy and function with unique considerations regarding the diagnostic and treatment options available to the surgeon.
• Radial head and neck fractures are the most common elbow fractures in adults, representing 33% of elbow fractures.
• The original Mason classification was modified by Johnson, then Morrey. Hotchkiss proposed that the classification system be used to provide guidance for treatment. It has poor intraobserver and interobserver reliability (FIG 1).9
  • Type I fractures are nondisplaced and offer no block to pronation and supination on examination.
  • Type II fractures have displaced marginal segments that block normal forearm rotation. We only include fractures with three or fewer articular fragments, which meet criteria for fractures that can be operatively reduced and fixed with reproducibly good results.
  • Type III fractures are comminuted or impacted articular fractures that are optimally managed with prosthetic replacement.
  • Type IV fractures are associated with elbow instability and should never be resected in the acute setting.

ANATOMY
• The radial head is entirely intra-articular. It has two articulations, one with the humerus, via the radiocapitellar joint, and another with the ulna, via the proximal radioulnar joint (PRUJ).
  • The radiocapitellar joint has a saddle-shaped articulation allowing both flexion and extension as well as rotation.
  • The PRUJ, constrained by the annular ligament, allows rotation of the radial head in the lesser sigmoid notch of the proximal ulna.
  • To avoid creating a mechanical block to pronation and supination, implants must be limited to a 90-degree arc (the “safe zone”) outside the PRUJ (FIG 2).4
• Blood supply to the radial head is tenuous, with a major contribution from a single branch of the radial recurrent artery in the safe zone and minor contributions from both the radial and interosseous recurrent arteries, which penetrate the capsule at its insertion into the neck (FIG 3).13
• There is considerable variability in the shape of the radial head, from nearly round to elliptical, as well as variability in the offset of the head from the neck.
• The anterior band of the medial collateral ligament (MCL) is the primary stabilizer to valgus stress. The radial head, a secondary stabilizer, maintains up to 30% of valgus resistance in the native elbow. Therefore, in cases where the MCL is ruptured:
  • A radial head that is not reparable should be replaced with a prosthesis and not excised given its biomechanical importance.
  • It may be prudent to protect a repaired radial head from high valgus stress during early range of motion by placing a hinged external fixator.
• The radial head also functions in the transmission of axial load, transmitting 60% of the load from the wrist to the elbow.10 This is a crucial consideration when the interosseous membrane is disrupted in the Essex-Lopresti lesion.5 Resection of the radial head in this setting results in devastating longitudinal radioulnar instability, proximal migration of the radius, and possible ulnar-carpal impingement.

PATHOGENESIS
• Radial head fractures result from trauma. A fall on an outstretched hand with the elbow in extension and the forearm in pronation produces an axial or valgus load (or both) driving the radial head into the capitellum, fracturing the relatively osteopenic radial head.
  • Loading at 0 to 35 degrees of extension causes coronoid fractures.
  • Loading at 0 to 80 degrees of extension produces radial head fractures.
Associated soft tissue injuries can lead to considerable complications, including pain, arthrosis, stiffness, and disability:
- MCL injury in 50%
- Lateral ligament disruption in about 80%
- Capitellar bone bruises in 90%
- Capitellar cartilage defects in about 50%

The axial loading may also rupture the interosseous membrane, causing longitudinal radioulnar instability with dislocation of the distal radioulnar joint (DRUJ) (FIG 4).

The “terrible triad” injury results from valgus loading of the elbow, disrupting the MCL or lateral ulnar collateral ligament and fracturing the radial head and coronoid process.

**NATURAL HISTORY**

Results are mixed regarding the efficacy of radial head excision for treatment of radial head fracture. Good or fair results may be possible, with a few caveats:

**FIG 2** The “safe zone” is a roughly 90-degree arc of the radial head that does not articulate with the ulna in the proximal radioulnar joint with full supination and pronation. With the wrist in neutral rotation, the safe zone is anterolateral.
There is a demonstrable increase in ulnar variance at the wrist and increased carrying angle.

10% to 20% loss of strength is expected.

It is contraindicated in the face of associated soft tissue injuries.

Radiographic, but usually clinically silent, degenerative changes such as cysts, sclerosis, and osteophytes occur radiographically in about 75% of elbows after radial head excision (FIG 5).

Results of excision are poor in patients with concomitant MCL, coronoid, or interosseous membrane injury.

Radial head resection should be reserved for patients with low functional demands or limited life expectancy, and when the surgeon has excluded elbow instability with a fluoroscopic examination.

Delayed excision of the radial head after failed nonoperative management may be considered with modest increase in function; it has shown 23% fair or poor results at 15 years of follow-up. Other studies suggest that there is no difference between delayed and primary excision.

Although open reduction and fixation of a comminuted fracture can be attempted, a large series by experienced elbow surgeons found that fixation of a radial head with more than three articular fragments is fraught with poor results.

Nonanatomic reduction of the shaft or joint may result in limited range of motion due to a cam effect in the PRUJ, but no literature or prospective studies indicate what parameters are “acceptable.”

PATIENT HISTORY AND PHYSICAL FINDINGS

The history typically involves a fall on an outstretched hand followed by pain and edema over the lateral elbow, accompanied by limited range of motion.

The examiner should note the patient’s activity level and profession.

Physical examination should include neurovascular status and examination of the skin to look for medial ecchymosis, which may suggest injury to the MCL.

A detailed examination of the elbow must include bony palpation of the medial and lateral epicondyles, olecranon process, DRUJ, and radial head, as well as the squeeze test of the interosseous membrane and DRUJ to screen for potential longitudinal instability.

Varus and valgus stress testing, with or without fluoroscopy, can indicate injury to the anterior band of the MCL or to the lateral ulnar collateral ligament, respectively.

Range-of-motion and stress examinations are vital to proper decision making and may obviate the need for advanced imaging if performed correctly with adequate anesthesia. If omitted, this will lead to undiagnosed associated injuries and may result in flawed decision making.

In the emergency department or office, adequate anesthesia may be obtained by aspirating hematoma, then injecting the elbow joint with 5 mL of local anesthetic and examining the elbow under fluoroscopy. This may be performed by the traditional lateral injection in the “soft spot” or posteriorly into the olecranon fossa (FIG 6).

If operative intervention is clearly indicated, this examination can be performed under a general anesthetic, provided the surgeon and patient are prepared for a change in operative plan as dictated by the examination.

Normal values are 0 to 145 degrees of flexion–extension, 85 degrees of supination, and 80 degrees of pronation. The examiner should check for a bony block to motion.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Radiography

Anteroposterior (AP), lateral, and oblique views are the standard of care, but they underestimate or overestimate joint impaction and degree of comminution (FIG 7A, B).

A radiocapitellar view with forearm in neutral and at 45 degrees cephalad gives an improved view of the articular surfaces.
If the examination reveals wrist or forearm tenderness, the examiner should have a low threshold for obtaining bilateral wrist posteroanterior (PA) views to rule out an Essex-Lopresti lesion.

**Magnetic Resonance Imaging**

- Magnetic resonance imaging (MRI) is a useful adjunct to physical examination for evaluating associated injuries such as collateral ligament tears, chondral defects, and loose bodies, but it is not routinely indicated (FIG 7C).

**DIFFERENTIAL DIAGNOSIS**

- Simple elbow dislocation
- Distal humerus fracture
- Olecranon fracture
- Septic elbow

**NONOPERATIVE MANAGEMENT**

- The standard protocol for treating radial head fractures is shown in FIGURE 8.

![FIG 7 • A,B. AP and lateral radiographs reveal a type 2 displaced radial head fracture. With standard radiography it is difficult to judge comminution and associated injuries. C. A T2-weighted MR image demonstrating a bony medial collateral ligament avulsion with surrounding edema associated with a radial head fracture. The ligament can be seen inserting distally to the sublime tubercle.](image)

![FIG 8 • Treatment algorithm for radial head fractures.](image)
Conservative management, with a week of sling immobilization followed by range of motion once the acute pain resolves, is the treatment of choice in nondisplaced radial head fractures, where universally good and excellent results have been reported.

Nonoperative management is also the treatment of choice in fractures with less than 2 mm of displacement, with minor head involvement, and without bony blockage to range of motion.

A 7-day period of cast or splint immobilization is followed by aggressive motion after the inflammatory phase.

Our current practice for fractures that are more than 2 mm displaced is to determine whether there is a blockage of motion on fluoroscopic examination.

If there is maintenance of at least 50 degrees of both pronation and supination, we recommend conservative treatment.

If there is a blockage or instability, excision, fixation, or arthroplasty is recommended based on patient factors and instability.

A recent report regarding the long-term results of nonoperative management (similar to that described) of 49 patients with radial head fractures encompassing over 30% of the joint surface and displaced 2 to 5 mm revealed that 81% of patients had no subjective complaints and minimal loss of motion versus the uninjured extremity. Only one patient had daily pain.1

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- It is essential to review all radiographs and, most importantly, perform thorough history, physical, and fluoroscopic examinations before making an incision.
- The presence of instability or associated fractures warrants a more extensile approach (FIG 9).

**Positioning**

- Positioning depends on the planned approach and the surgeon’s preference.
- We prefer the patient supine with the affected extremity brought across the chest over a bump to allow access to the posterolateral elbow.
- A tourniquet is placed high on the arm.

**Approach**

- Two approaches, the extensile posterior (Boyd) and posterolateral (Köcher), will be presented (FIG 10).
- The extensile posterior (Boyd) approach2 with an interval between the ulna and anconeus allows for excellent visualization compared to traditional approaches. This versatile approach facilitates ORIF or arthroplasty of the radial head if the fracture proves to be more comminuted than preoperative imaging would predict. It can be easily accessed through a universal extensile incision that allows the surgeon to address ligamentous injuries in addition to the radial head fracture.

**BOYD APPROACH**

- An 8-cm straight longitudinal incision is made just lateral to the olecranon (TECH FIG 1A).
- Full-thickness skin flaps are developed bluntly over the fascia.
- The fascia is longitudinally incised in the interval between the anconeus and ulna (TECH FIG 1B).
- The anconeus is dissected off the ulna, elevating proximal to distal to preserve the distal vascular pedicle. Great care is taken not to violate the joint capsule or lateral ulnar collateral ligament by using blunt fashion (TECH FIG 1C).
- The lateral ulnar collateral ligament and annular ligament complex are sharply divided and tagged from their insertion on the crista supinatoris of the ulna. The radial head and its articulation with the capitellum are now evident (TECH FIG 1D).
- After repair or replacement, the ligaments are repaired to their insertion with suture anchors.
**KÖCHER APPROACH**

- The traditional posterolateral (Köcher) approach between the anconeus and extensor carpi ulnaris is cosmetic and spares the lateral ulnar collateral ligament.
- We recommend not using an Esmarch tourniquet to allow visualization of penetrating veins that help identify the interval.
- A 5-cm oblique incision is made from the posterolateral aspect of the lateral epicondyle obliquely to a point three fingerbreadths below the tip of the olecranon in line with the radial neck (TECH FIG 2A).
- The radial head and epicondyle are palpated and the fascia is divided in line with the skin incision.
- The Köcher interval is identified distally by small penetrating veins and bluntly developed, revealing the lateral ligament complex and joint capsule (TECH FIG 2B).
- The anconeus is reflected posteriorly and the extensor carpi ulnaris origin anteriorly. The capsule is incised obliquely anterior to the lateral ulnar collateral ligament (TECH FIG 2C,D).
- The proximal edge of the annular ligament may also be divided and tagged, with care taken not to proceed distally and damage the posterior interosseous nerve.

**TECH FIG 1** • Boyd approach. **A.** Make an 8-cm longitudinal incision at the junction of the ulna and anconeus starting about four fingerbreadths distal to the olecranon and extending 2 cm proximal to the olecranon. **B.** The interval between the ulna and anconeus is incised sharply, with care taken not to violate the periosteum or muscle to minimize the risk of proximal radioulnar synostosis. **C.** Blunt elevation of the anconeus is crucial to avoid damaging the capsule or lateral ligament complex. **D.** The capsule and lateral ligament complex are tagged during the approach to facilitate final repair with suture anchors.

**TECH FIG 2** • Köcher approach. **A.** The skin incision proceeds distally from the posterolateral aspect of the lateral epicondyle to the posterior aspect of the proximal radius. **B.** Full-thickness flaps are made and the fascial interval between the extensor carpi ulnaris and anconeus muscles is identified. (continued)
FRACTURE INSPECTION AND PREPARATION

- The fracture is now visible (TECH FIG 3).
- The wound is irrigated and loose bodies are removed.
- The forearm is rotated to obtain a circumferential view of the fracture and appreciate the safe zone for hardware placement.
- If comminution (more than three pieces) is evident at this step, we elect to replace the radial head.

TECH FIG 3 • Here the fractured radial head fragment has violated the lateral capsule, indicating a high-energy injury. The proximal radius is now exposed for fixation or prosthetic replacement.

REDUCTION AND PROVISIONAL FIXATION

- Any joint impaction is elevated and the void filed with local cancellous graft from the lateral epicondyle.
- The fragments are reduced provisionally with a tenaculum and held with small Kirschner wires placed out of the zone where definitive fixation is planned.
- It is acceptable to place this temporary fixation in the safe zone (TECH FIG 4).

TECH FIG 4 • We prefer to use 0.062-inch Kirschner wires placed outside the zone of planned definitive fixation to provisionally hold the reduction.
POSTOPERATIVE CARE

- The elbow is immobilized in a splint for 7 to 10 days.
- Active range of motion is allowed as soon as tolerable. Supervised therapy may be considered if the patient is not making adequate progress.
- Associated injuries may call for more protected range of motion.
- Light activities of daily living are allowed at 2 weeks, with increased weight bearing at 6 weeks.

RESULTS

- The results of open reduction and internal fixation depend both on host factors such as the type of fracture, smoking, compliance, demand, as well as surgical and rehabilitation protocols.
- In uncomplicated fractures, over 90% satisfactory results can be expected.
- Complications and resultant secondary procedures will be more likely in cases with undiagnosed instability and associated injury.
COMPLICATIONS

- Stiffness is the most common complication, with loss of terminal extension, supination, and pronation being most evident.
- Arthritis of the radiocapitellar joint or proximal radioulnar joint
- Heterotopic ossification
- Symptomatic hardware may require secondary removal (FIG 11A).
- Infection
- Early and late instability from missed or failed treatment of associated injuries
- The rate of avascular necrosis is about 10%, significantly higher in displaced fractures. This is expected given that the radial recurrent artery inserts in the safe zone where hardware is placed. This is generally clinically silent.
- Loss of reduction
- Nonunion (FIG 11B,C)

REFERENCES

DEFINITION
- Radial head fractures are the most common fracture of the elbow and usually can be managed either nonoperatively or with open reduction and internal fixation.
- Radial head arthroplasty is indicated for unreconstructable displaced radial head fractures with an associated elbow dislocation or a known or possible disruption of the medial collateral, lateral collateral, or interosseous ligaments.  
- Most comminuted radial head fractures have an associated ligament injury, so radial head excision without replacement is uncommonly indicated in the setting of an acute radial head fracture.
- Biomechanical studies have shown that the kinematics and stability of the elbow are altered by radial head excision, even in the setting of intact collateral ligaments, and are improved with a metallic radial head arthroplasty.
- Radial head replacement is also indicated to treat posttraumatic conditions such as radial head nonunion and malunion and to manage elbow or forearm instability after radial head excision.

ANATOMY
- The radial head has a circular concave dish that articulates with the spherical capitellum and an articular margin that articulates with the lesser sigmoid notch of the ulna.
- The articular dish has an elliptical shape that varies considerably in size and shape and is variably offset from the axis of the radial neck.
- There is a poor correlation between the size of the radial head and the medullary canal of the radial neck, making a modular implant desirable for an optimal fit.
- Elbow stability is maintained by joint congruity, capsuloligamentous integrity, and an intact balanced musculature.
- The radial head is an important valgus stabilizer of the elbow, particularly in the setting of an incompetent medial collateral ligament, which is the primary stabilizer against valgus force.
- The radial head is also important as an axial stabilizer of the forearm and resists varus and posterolateral rotatory instability by tensioning the lateral collateral ligament.
- The radial head accounts for up to 60% of the load transfer across the elbow.
- The lateral ulnar collateral ligament is an important stabilizer against varus and posterolateral rotational instability of the elbow and should be preserved or repaired after radial head arthroplasty (FIG 1).

PATHOGENESIS
- Displaced radial head fractures typically result from a fall on the outstretched arm.
- Axial, valgus, and posterolateral rotational patterns of loading are all thought to be potentially responsible for these fractures.
- Injuries of the medial collateral or lateral collateral ligament or the interosseous ligament are typically associated with comminuted displaced unreconstructable radial head fractures.
- In more severe injuries, dislocations of the elbow and forearm and fractures of the coronoid, olecranon, and capitellum can occur and further impair stability.

NATURAL HISTORY
- Long-term follow-up studies suggest a high incidence of radiographic arthritis with radial head excision, although the incidence of symptomatic arthritis varies widely between series.
- Biomechanical data have demonstrated an alteration in the kinematics, load transfer, and stability of the elbow after radial head excision that may lead to premature cartilage wear of the ulnohumeral joint and secondary pain due to arthritis.
- Metallic radial head replacement in elbows with intact ligaments restores the kinematics and stability similar to that of a native radial head and has been shown to provide good clinical and radiographic outcome in most patients at medium-term follow-up; however, long-term outcome studies are lacking.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The mechanism of injury is typically a fall on the outstretched hand.
- The patient will complain of pain and limitation of elbow or forearm motion.

FIG 1 • The ligaments on the lateral aspect of the elbow include the lateral ulnar collateral ligament, the radial collateral ligament, and the annular ligament. The lateral ulnar collateral ligament is an important stabilizer against varus and posterolateral rotational instability of the elbow and should be preserved or repaired after radial head arthroplasty.
■ A history of forearm or wrist pain should be sought.
■ Inspection may reveal ecchymosis along the forearm or medial aspect of the elbow. Deformity may be evident if there is an associated dislocation.
■ Careful palpation of the radial head, the medial and lateral collateral ligaments of the elbow, the interosseous ligament of the forearm, and the distal radioulnar joint should be performed. Local tenderness over one or all of these structures implies a possible derangement of the relevant structure.
■ Since associated injuries of the shoulder, forearm, wrist, and hand are common, these areas should be carefully examined.
■ Range of motion, including forearm rotation and elbow flexion-extension, should be evaluated. The presence of palpable and auditory crepitus should be noted.
■ Loss of terminal elbow flexion and extension is expected as a consequence of a hemarthrosis in acute fractures, while loss of forearm rotation typically is caused by a mechanical impingement.
■ A careful neurovascular assessment of all three major nerves that cross the elbow should be performed.
■ The examiner should observe for localized or diffuse swelling in the elbow. Effusion represents hemarthrosis due to intra-articular fracture.
■ The examiner should compare active and passive range of motion to the uninjured side. Reduced range of motion may be a result of hemarthrosis or mechanical block from a broken fragment. Intra-articular injection of a local anesthetic helps differentiate between reduced range of motion due to a mechanical block versus pain inhibition.
■ The examiner should look for varus-valgus instability. Any gapping on the medial or lateral side beneath the examiner’s hand is noted. Positive findings suggest mediolateral collateral ligament insufficiency. Typically, this test is positive only when performed under a general anesthetic.
■ The lateral pivot shift test is performed. Positive apprehension or a clunk that is seen or felt when the ulna and radius reduce on the humerus suggests posterolateral rotatory instability.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

■ Anteroposterior (AP), lateral, and oblique elbow radiographs, with the x-ray beam centered on the radiocapitellar joint, usually provide sufficient information for the diagnosis and treatment of radial head fractures.
■ Bilateral posteroanterior radiographs of both wrists in neutral rotation should be performed to evaluate ulnar variance in patients with wrist discomfort or a comminuted radial head fracture, since there is a higher incidence of an associated interosseous ligament injury in these patients.6
■ Computed tomography with sagittal, coronal, and 3D reconstructions may assist with preoperative planning and can help the surgeon predict whether a displaced radial head fracture can be repaired with open reduction and internal fixation or if an arthroplasty will likely be needed.

**DIFFERENTIAL DIAGNOSIS**

■ Acute radial head fractures
■ Other fractures or dislocations about the elbow (eg, supracondylar, capitellar, coronoid, osteochondral fractures)
■ Radial head nonunion or malunion, posttraumatic arthritis
■ Congenital dislocation of the radial head
■ Forearm or elbow instability
■ Lateral epicondylitis
■ Rheumatoid arthritis or osteoarthritis
■ Synovitis, inflammatory or infectious
■ Tumors

**NONOPERATIVE MANAGEMENT**

■ The indications for surgical management of radial head fractures are not well defined in the literature. Fragment size, number of fracture fragments, degree of displacement, and bone quality influence decision making regarding the optimal management.
■ Nondisplaced fractures or small (less than 33% of radial head) minimally displaced fractures (less than 2 mm) can be treated with early motion with an excellent outcome in the majority of patients.
■ Associated injuries and a block to motion are also important factors to consider when deciding between nonoperative and surgical management.

**SURGICAL MANAGEMENT**

■ Small displaced fractures that cause painful crepitus or limited motion are managed with fragment excision if they are too small (typically less than 25% of the diameter of the radial head) or osteopenic to be internally fixated.
■ Larger displaced fractures are typically managed with ORIF with good outcomes in most patients.
■ Radial head fractures that are displaced but too comminuted to be anatomically reduced and stably fixed and that are too large to consider fragment excision (involve more than a quarter to a third of the radial head) should be managed by radial head excision with or without arthroplasty.
■ Patients who are known to have, or are likely to have, an associated ligamentous injury of the elbow or forearm should have a radial head arthroplasty because radial head excision is contraindicated (FIG 2).
■ The decision as to what fracture is reconstructable depends on surgeon factors (eg, experience), patient factors (eg, osteoporosis), and fracture factors (eg, fragment number and size, comminution, associated soft tissue injuries). The final decision is often made only at the time of surgery.
■ Other indications for radial head arthroplasty include radial head nonunion or malunion, primary or secondary management of forearm or elbow instability (eg, Essex-Lopresti injury), rheumatoid arthritis or osteoarthritis, and tumors.

**Preoperative Planning**

■ Currently available devices include spacer implants, press-fit and ingrowth stems, and bipolar and ceramic articulations.
■ Silicone radial head implants offer little in the way of axial or valgus stability to the elbow and have been complicated by a high incidence of implant wear, fragmentation, and silicone synovitis leading to generalized joint damage. As a result, they have fallen out of favor and have been replaced by metallic implants.
■ Most metallic radial head implants that have been developed and used to date employ a monoblock design, making size matching suboptimal and implant insertion often difficult because of the need to subluxate the elbow to allow for insertion of these devices.10
■ Recently, modular metallic radial head prostheses have become available with separate heads and stems, allowing improved size matching of the native radial head and neck18 and easier placement in the setting of competent lateral ligaments.17
Precise implant sizing and placement are critical with these devices to ensure correct capitellar tracking and to avoid a cam effect with forearm rotation, which may cause premature capitellar wear due to shearing of the cartilage and stem loosening due to increased loading of the stem–bone interface. Preoperative radiographic templating of the contralateral normal radial head should be employed in the setting of a secondary radial head replacement but is not needed for acute fractures because the excised radial head is available for accurate implant sizing.

Positioning
- The patient is placed supine on the operating table and a sandbag is placed beneath the ipsilateral scapula to assist in positioning the arm across the chest.
- Alternatively, the patient can be positioned in a lateral position with the affected arm held over a bolster.
- Prophylactic intravenous antibiotics are administered.
- General or regional anesthesia is employed.
- A sterile tourniquet is applied.

**Surgical Approach**
- A midline posterior elbow incision is made just lateral to the tip of the olecranon (TECH FIG 1A).
- A full-thickness lateral fasciocutaneous flap is elevated on the deep fascia. This extensile incision decreases the risk of cutaneous nerve injury and provides access to the radial head, coronoid, and medial and lateral collateral ligaments for the management of more complex injuries (TECH FIG 1B).
- Alternatively, a lateral skin incision centered over the lateral epicondyle and passing obliquely over the radial head can be used (see Tech Fig 1A).
COMMON EXTENSOR SPLIT

- The extensor digitorum communis tendon is identified.
  - The landmarks for this plane are a line joining the lateral epicondyle and the tubercle of Lister.
  - The extensor digitorum communis tendon is split longitudinally at the middle aspect of the radial head, and the underlying radial collateral and annular ligaments are incised (TECH FIG 2A).
  - Dissection should stay anterior to the lateral ulnar collateral ligament to prevent the development of posterolateral rotatory instability (see Fig 1).
  - The forearm is maintained in pronation to move the posterior interosseous nerve more distal and medial during the surgical approach.7
- If further exposure is required:
  - The humeral origin of the radial collateral ligament and the overlying extensor muscles are elevated anteriorly off the lateral epicondyle to improve the exposure if needed (TECH FIG 2B).
  - Release of the posterior component of the lateral collateral ligament can be considered, but careful ligament repair is required at the end of the procedure in order to restore the varus and posterolateral rotatory stability of the elbow.9
TECH FIG 2 • (continued) B. The humeral origin of the radial collateral ligament and the overlying extensor muscles are elevated anteriorly off the lateral epicondyle to improve the exposure if needed.

PREPARATION OF THE RADIAL HEAD AND NECK

- All fragments of the radial head are removed, as well as a minimal amount of radial neck at a right angle to the medullary canal, to make a smooth surface for seating of the prosthetic radial head.
  - Complete fragment excision can be confirmed with the use of an image intensifier.
  - The capitellum is evaluated for chondral injuries or osteochondral fractures.
- The radial head prosthesis is sized in one of several ways:
  - The resected radial head is reassembled in the provided sizing template to assist in the accurate sizing of the prosthesis (TECH FIG 3A–C).
  - The diameter of radial head prosthesis should be based on the size of the articular dish. This is typically 2 mm smaller than the outer diameter of the excised radial head.
  - Alternatively, if the radial head has been previously excised, radiographic templating of the contralateral normal radial head may be used to determine the appropriate diameter and height of the radial head implant.
  - If the native radial head is in between available implant sizes, the implant diameter or thickness should be downsized.
- The radial neck is delivered laterally using a Hohmann retractor carefully placed around the posterior aspect of the proximal radial neck (TECH FIG 3D).
  - An anteriorly based retractor should be avoided because of the risk of injury from pressure on the posterior interosseous nerve.
  - The medullary canal of the radial neck is reamed using hand reamers until cortical contact is encountered.
  - A trial stem one size smaller than the rasp is inserted to achieve a nontight press-fit.
TECH FIG 3 • (continued) and height (C), and to ensure that all the fragments have been removed from the elbow. D. The radial neck is delivered laterally using a Hohmann retractor carefully placed around the posterior aspect of the proximal radial neck. An anteriorly based retractor should be avoided because of the risk of injury to the posterior interosseous nerve.

RADIAL HEAD REPLACEMENT

- A trial head is inserted onto the stem, and the diameter, height, tracking, and congruency of the prosthesis are evaluated both visually and with the aid of an image intensifier.
- The radial head prosthesis should articulate at the same height as the radial notch of the ulna and about 1 mm distal to the tip of the coronoid (TECH FIG 4A).
- The alignment of the distal radioulnar joint, ulnar variance, as well as the width of the lateral and medial portions of the ulnohumeral joint, are checked and compared to the contralateral wrist and elbow, respectively, under fluoroscopy.
- Overlengthening the radiocapitellar joint with a radial head implant that is too thick should be avoided to reduce the risk of cartilage wear on the capitellum from excessive pressure; a nonparallel medial ulnohumeral joint space that is wider laterally is suggestive of overstuffing.
- Some modular and bipolar implants allow insertion of the stem first, then placement of the head onto the stem with coupling in situ, which significantly reduces the surgical exposure needed (TECH FIG 4B).
- If the prosthesis is maltracking on the capitellum with forearm rotation, a smaller stem size should be trialed to ensure that the articulation of the radial head with the capitellum is controlled by the annular ligament and articular congruency and not dictated by the proximal radial shaft.

TECH FIG 4 • A. A trial stem is inserted. A trial head is inserted onto the stem and the diameter, height, tracking, and congruency of the prosthesis are evaluated both visually and with the aid of an image intensifier. B. Some modular and bipolar implants allow insertion of the stem first, then placement of the head onto the stem with coupling in situ, which significantly reduces the surgical exposure needed.
LATERAL SOFT TISSUE CLOSURE

- After radial head replacement, the lateral collateral ligament and extensor muscle origins are repaired back to the lateral condyle.
- If the posterior half of the lateral collateral ligament is still attached to the lateral epicondyle, then the anterior half of the lateral collateral ligament (the annular ligament and radial collateral ligament) and extensor muscles are repaired to the posterior half using interrupted absorbable sutures (TECH FIG 5A).
- If the lateral collateral ligament and extensor origin have been completely disrupted either by the injury or surgical exposure, they should be securely repaired less equalize to the lateral epicondyle using drill holes through bone and nonabsorbable sutures or suture anchors.
- A single drill hole is placed at the axis of motion (the center of the arc of curvature of the capitellum) and connected to two drill holes placed anterior and posterior to the lateral supracondylar ridge.
- A locking (Krackow) suture technique is employed to gain a secure hold of the lateral collateral ligament and common extensor muscle fascia (TECH FIG 5B–D).
- The ligament sutures are pulled into the holes drilled in the distal humerus using suture retrievers and the forearm is pronated, and varus forces are avoided, while tensioning the sutures before tying (TECH FIG 5E).
- The knots should be left anterior or posterior to the lateral supracondylar ridge to avoid prominence.

TECH FIG 5 • A. If the posterior half of the lateral collateral ligament is still attached to the lateral epicondyle, then the anterior half of it (the annular ligament and radial collateral ligament) and extensor muscles are repaired to the posterior half using interrupted absorbable sutures. ECU, extensor carpi ulnaris; EDC, extensor digitorum communis. B–D. If the lateral collateral ligament and extensor origin have been completely disrupted by the injury or detached by the surgical exposure, they should be securely repaired to the lateral epicondyle. A single drill hole is placed at the center of the arc of curvature of the capitellum and connected to two drill holes placed anterior and posterior to the lateral supracondylar ridge. A locking (Krackow) suture technique is employed to gain a secure hold of the lateral collateral ligament (B) as well as of the annular ligament (C). D. A second stitch is used in a similar manner to repair the common extensor muscle fascia. (continued)
The sutures are pulled into the holes drilled in the distal humerus using suture retrievers, tensioned while keeping the forearm pronated and while avoiding varus forces, and eventually tied over the lateral supracondylar ridge.

**COMPLETION**

- After replacement arthroplasty and lateral soft tissue closure, the elbow should be placed through an arc of flexion–extension while carefully evaluating for elbow stability in pronation, neutral, and supination.²
- Pronation is generally beneficial if the lateral ligaments are deficient,⁹ supination if the medial ligaments are deficient,¹ and neutral position if both sides have been injured.
- In patients who have an associated elbow dislocation, additional repair of the medial collateral ligament and flexor pronator origin should be performed if the elbow subluxates at 40 degrees or more of flexion.
- Tourniquet deflation and hemostasis should be secured before wound closure.

**KÖCHER APPROACH**

- Alternatively, the radial head may be approached by using the Köcher interval²⁰ between the extensor carpi ulnaris and anconeus.
- The fascial interval between these muscles is identified by noting the diverging direction of the muscle groups and small vascular perforators that exit at this interval (TECH FIG 6).
- Care should be taken to preserve the lateral ulnar collateral ligament, which is vulnerable as the dissection is carried deeper through the capsule.

**TECH FIG 5** • (continued) E. The sutures are pulled into the holes drilled in the distal humerus using suture retrievers, tensioned while keeping the forearm pronated and while avoiding varus forces, and eventually tied over the lateral supracondylar ridge.

**TECH FIG 6** • The extensor carpi ulnaris is elevated anteriorly and an arthrotomy is performed at the midportion of the radial head. Care should be taken to preserve the lateral ulnar collateral ligament, which is vulnerable as the dissection is carried deeper through the capsule.
The surgeon should avoid overstuffing the thickness or diameter of the radial head because of the risk of capitellar synovitis due to particulate debris.25 If the radial head does not track well on the capitellum, the stem should be downsized. The radial head implant is typically 2 mm smaller than the outer diameter of the radial head. Radial head articular surface height should be at the level of the proximal radioulnar joint. If the radial head does not track well on the capitellum, the stem should be downsized. If the native radial head is in between implant sizes, the implant should, in general, be downsized. Intraoperative fluoroscopy is used to assess the alignment of the radiocapitellar and distal radioulnar joints and to avoid overlengthening of the radius.

**PEARLS AND PITFALLS**

**Indications**
- Displaced unreconstructable fracture of the radial head with known or probable associated medial or lateral collateral or interosseous ligament injury

**Pearls**
- A preoperative radiographic template of the contralateral native radial head should be used in the setting of a secondary radial head replacement.
- Dissection should stay anterior to the lateral ulnar collateral ligament to prevent the development of posterolateral rotatory instability.
- The radial head should be sized based on the diameter of the articular disk and thickness of the excised radial head.
- The radial head implant is typically 2 mm smaller than the outer diameter of the radial head.
- Radial head articular surface height should be at the level of the proximal radioulnar joint.
- If the radial head does not track well on the capitellum, the stem should be downsized.
- If the native radial head is in between implant sizes, the implant should, in general, be downsized.
- Intraoperative fluoroscopy is used to assess the alignment of the radiocapitellar and distal radioulnar joints and to avoid overlengthening of the radius.

**Pitfalls**
- Hohmann retractors should not be used around the anterior aspect of the radial neck and the forearm should be kept pronated to avoid damage to the posterior interosseous nerve.
- The surgeon should avoid overstuffing the thickness or diameter of the radial head because of the risk of capitellar wear and pain. Filling the gap between the capitellum and radial neck is not a useful landmark for prosthesis thickness because lateral soft tissues are often deficient owing to the surgical exposure or initial injury.

**POSTOPERATIVE CARE**

- The elbow with stable ligaments should be splinted using anterior plaster slabs in extension and elevated for 24 to 48 hours to diminish swelling, decrease tension on the posterior wound, and minimize the tendency to develop a flexion contracture.
- In the setting of a more tenuous ligamentous repair or the presence of some residual instability at the end of the operative procedure, the elbow should initially be splinted in 60 to 90 degrees of flexion in the optimal position of forearm rotation to maintain stability.
- Perioperative antibiotics are continued for 24 hours postoperatively.
- Indomethacin 25 mg three times daily for 3 weeks may be considered in patients undergoing radial head arthroplasty to decrease postoperative pain, reduce swelling, and potentially lower the incidence of heterotopic ossification.
- Indomethacin should be avoided in elderly patients and those with a history of peptic ulcer disease, asthma, known allergy, or other contraindications to anti-inflammatory medications.
- For an isolated radial head replacement treated with a lateral ulnar collateral ligament-sparing approach, active range of motion should be initiated on the day after surgery.
- A collar and cuff with the elbow maintained at 90 degrees is employed for comfort between exercises.
- A static progressive extension splint is fabricated for nighttime use for patients without associated ligamentous disruptions and is employed for a period of 12 weeks. The splint is adjusted weekly as extension improves.
- In patients with associated elbow dislocations or residual instability, extension splinting is not implemented until 6 weeks after surgery.
- Patients with associated fractures, dislocations, or ligamentous injuries should commence active flexion and extension motion within a safe arc 1 day postoperatively.
- Active forearm rotation is performed with the elbow in flexion to minimize stress on the medial or lateral ligamentous injuries or repairs.
- Extension is performed with the forearm in the appropriate rotational position—that is, pronation if the lateral ligaments are deficient,9 supination if the medial ligaments are deficient,1 and neutral position if both sides have been injured.
- A resting splint with the elbow maintained at 90 degrees and the forearm in the appropriate position of forearm rotation is employed for 3 to 6 weeks.
- Passive stretching is not permitted for 6 weeks to reduce the incidence of heterotopic ossification.
- Strengthening exercises are initiated once the ligament injuries and any associated fractures have adequately healed, usually at 8 weeks postoperatively.

**OUTCOMES**

- Silicone radial head arthroplasty, while initially successful in many patients,5,24 has fallen out of favor because of problems with residual instability and arthritis, implant fracture, and silicone synovitis due to particulate debris.25
- While the short- and medium-term results of metallic radial head implants are encouraging, there is a paucity of literature demonstrating the long-term outcome with respect to loosening, capitellar wear, and arthritis.
- Metallic radial head replacement in elbows with intact ligaments restores the kinematics and stability similar to that measured with a native radial head. Moreover, when the fractured radial head occurs in combination with ligamentous and soft tissue disruption, a metallic prosthesis restores elbow stability, with only mild residual deficits in strength and motion.
- Moro et al.21 reported the functional outcome of 25 cases managed with a metallic radial head arthroplasty for unreconstructable fractures of the radial head at an average follow-up of 39 months. The results were rated as 17 good or excellent, 5 fair, and 3 poor.
- The radial head prosthesis restored elbow stability when the fractured radial head occurred in combination with a dislocation of the elbow, rupture of the medial collateral ligament, fracture of the coronoid, or fracture of the proximal ulna.
- There were mild residual deficits in strength and motion, and no patient required removal of the implant.
Harrington et al\(^\text{12}\) reported their experience with metallic radial head arthroplasty in 20 patients at an average follow-up of 12 years. The results were excellent or good in 16 and fair or poor in 4.

Improvements in radial head arthroplasty designs, sizing, and implantation techniques may lead to improved outcomes for unreconstructable radial head fractures.

COMPLICATIONS

- Posterior interosseous nerve injury can occur as a consequence of dissection distal to the radial tuberosity and placement of anterior retractors around the distal radial neck.
- Infection
- Loss of motion, mainly terminal extension due to capsular contracture, heterotopic ossification, or retained cartilaginous or osseous fragments
- Prosthetic loosening or polyethylene wear
- Capitellar wear and pain due to implant overstuffing
- Complex regional pain syndrome
- Instability or recurrent dislocations of the elbow due to an inadequate or failed ligament repair
- Osteoarthritis of the capitellum as a consequence of articular cartilage damage from the initial injury, from component insertion, from persistent instability, or due to loading from a radial head implant that is too thick.

REFERENCES

DEFINITION
- Fracture of the olecranon process is common, usually displaced, and nearly always treated operatively.
- Important injury characteristics include displacement, comminution, and subluxation or dislocation of the elbow, and all are accounted for in the Mayo classification (FIG 1). A
- Fracture-dislocations of the olecranon can be anterior (trans-olecranon) or posterior (the most proximal type of posterior Monteggia according to Jupiter and colleagues3) in direction.2,3,9,10
- Open injuries are unusual.

ANATOMY
- The greater sigmoid notch of the ulna is formed by the coronoid and olecranon processes and forms a nearly 180-degree arc capturing the trochlea.
- The region between the coronoid and olecranon articular facets is the nonarticular transverse groove of the olecranon, a common location of fracture and a place where precise articular reduction is not critical.
- The triceps has a broad and thick insertion from just superior to the point of the olecranon and the tip of the olecranon process that can be used to enhance fixation of small, osteoporotic, or fragmented fractures and can be split longitudinally, if needed, when applying a plate.

PATHOGENESIS
- Fractures of the olecranon are most often the result of a direct blow to the point of the elbow, but occasionally they result from indirect forces during a fall on the outstretched hand.

NATURAL HISTORY
- Stable nondisplaced or minimally displaced fractures are uncommon.
- The majority of olecranon fractures are displaced and benefit from operative treatment.
- The occasional untreated displaced simple olecranon fracture demonstrates a slight flexion contracture, some weakness of extension, no arthrosis, and little if any pain.
- In contrast, undertreated or poorly treated fracture-dislocations lead to severe arthrosis with or without instability.
- Even well-treated complex injuries are at risk for stiffness, heterotopic ossification, arthrosis, and occasionally nonunion.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Knowledge of the characteristics of the patient (age, gender, medical health) and the injury (mechanism, energy) will help the surgeon understand the injury and determine optimal treatment.
- First the patient is assessed for life-threatening injuries (ATLS protocol) and any medical problems that may have contributed to the injury.
- A secondary survey is performed to identify any other fractures, ipsilateral arm injuries in particular.
- The skin is carefully inspected for any wounds associated with the fracture.
- The pulses are palpated, capillary refill inspected, and an Allen test performed if necessary.
- Peripheral nerve function is assessed.
- Patients with high-energy injuries, particularly those with ipsilateral wrist or forearm injuries, are at risk for compartment syndrome. If the clinical examination is suggestive or unreliable (owing to problems with mental status), compartment pressure monitoring should be performed.

FIG 1 • The Mayo classification of olecranon fractures accounts for the factors that will influence treatment decisions: displacement, comminution, and dislocation or subluxation of the articulations.
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) and lateral radiographs are used for initial characterization of the injury.
- Radiographs after reduction or splinting, or oblique views can be useful.
- Computed tomography (CT) is useful for characterization of fracture-dislocations. In particular, 3D CT reconstructions can be useful for assessment of the coronoid and radial head.

DIFFERENTIAL DIAGNOSIS
- Elbow dislocation
- Monteggia and Essex-Lopresti fracture-dislocations of the forearm
- Distal humerus fracture

NONOPERATIVE MANAGEMENT
- Nonoperative management is appropriate for the rare fracture of the olecranon that is less than 2 millimeters displaced with the elbow flexed 90 degrees.
- Four weeks of splint immobilization followed by active assisted mobilization of the elbow will usually result in a healed fracture and good elbow function.

SURGICAL MANAGEMENT
- The vast majority of olecranon fractures are displaced and merit operative treatment.

TENSION BAND WIRING
Reduction and Kirschner Wire Fixation
- Blood clot and periosteum are cleared from the fracture site to facilitate reduction.
- Limited periosteal elevation is performed at the fracture site to monitor reduction.
- A large tenaculum clamp is used to secure the fracture in a reduced position (TECH FIG 1A,B). A drill hole can be made in the dorsal cortex of the distal fragment to facilitate clamp application.

Preoperative Planning
- The fracture characteristics that determine treatment are defined on radiographs and CT.
- Templating the surgery with tracings of the radiographs is a useful way of running through the surgery in detail before performing it, familiarizing oneself with the anatomy, anticipating problems, and ensuring that all of the implants and equipment that might be necessary are available.

Positioning
- In most patients a lateral decubitus position with the arm over a bolster or support is best.
- Some patients with fracture-dislocations that require both medial and lateral access may be positioned supine with the arm supported on a hand table.
- A sterile pneumatic tourniquet is used.

Approach
- A dorsal longitudinal skin incision is used.

Two 1.0-mm smooth Kirschner wires are drilled across the fracture site (TECH FIG 1C).
- If these are drilled obliquely from dorsal proximal to volar distal, they will exit the anterior ulnar cortex distal to the coronoid process, providing an anchoring point of cortical bone to limit the potential for pin migration.
- In anticipation of later impaction of the proximal ends of the wires, the Kirschner wires should be retracted 5 to 10 mm after drilling through the anterior ulnar cortex.
**Wiring**

- The apex of the ulnar diaphysis just distal to the flat portion of the proximal ulna is drilled with a 2.0-mm drill, with or without prior subperiosteal dissection.
- When two wires are used, a second drill hole is made a centimeter more distal.
- If one wire is used, it should be 18 gauge. My preference is to use two 22-gauge stainless steel wires to limit the size of the knots, which may diminish implant prominence. The wires are passed through the drill holes. A large-bore needle can be used to facilitate passage of the wire through the drill hole (TECH FIG 2A).
- The two tension wires are each passed over the dorsal ulna in a figure 8 fashion, then around the Kirschner wires, and underneath the insertion of the triceps tendon using a large-bore needle (TECH FIG 2B).

**TECH FIG 1 • (continued)**

C. Two 1-mm Kirschner wires are drilled obliquely across the fracture site so that they exit the anterior ulnar cortex distal to the coronoid process. (A,B: Copyright David Ring, MD.)

- Each wire is tensioned both medially and laterally by twisting the wire with a needle holder (TECH FIG 2C,D).
- This should be done to take up slack only. These small wires will break if they are firmly tightened, which is not necessary.
- The tightening should be done in a place that will make the wire knots less prominent.
- After tightening the knots are trimmed and bent into the soft tissues to either side.
- The Kirschner wires are then bent 180 degrees and trimmed.
- These bent ends are then impacted into the proximal olecranon, beneath the triceps insertion, using an osteotome (TECH FIG 2E-H).

**TECH FIG 2 • A.** Two 22-gauge stainless steel tension wires are passed in a figure 8 fashion through drill holes in the ulnar shaft. **B.** They engage the triceps insertion proximally. **C,D.** The wires are tensioned on both sides. These do not need to be tight, but simply snug, with all slack taken up. Attempts to tighten these smaller 22-gauge wires will break them. (continued)
TECH FIG 2 • (continued) E. The proximal ends of the Kirschner wires are bent 180 degrees and impacted into the olecranon process, beneath the triceps insertion. F. The resulting fixation has a relatively low profile and is unlikely to migrate. G,H. Even these small wires are strong enough for active exercises to regain elbow motion. (A,B,D,F–H: Copyright David Ring, MD.)

PLATE AND SCREW FIXATION OF OLECRANON FRACTURES

- Contour the plate to wrap around the proximal aspect of the olecranon or use a precontoured plate (TECH FIG 3A–C).
- A straight plate will have only two or three screws in metaphyseal bone proximal to the fracture.
- Bending the plate around the proximal aspect of the olecranon provides additional screws in the proximal fragment. The most proximal screws can be very long, crossing the fracture line into the distal fragment. In some cases, these screws can be directed to engage one of the cortices of the distal fragment, such as the anterior ulnar cortex.
- A plate contoured to wrap around the proximal ulna can be placed on top of the triceps insertion. Alternatively, the triceps insertion can be incised longitudinally and partially elevated medially and laterally sufficiently to allow direct plate contact with bone.
- If the proximal (olecranon) fragment is small, fragmented, or osteoporotic, it can be useful to add a figure

TECH FIG 3 • A. A lateral radiograph illustrates a comminuted olecranon fracture with a small proximal olecranon fragment. B. An oblique view shows the fragmentation. C. A 3.5-mm limited-contact dynamic compression plate and screws contoured to wrap around the dorsal surface of the olecranon is used for fixation. (continued)
8 tension wire that engages the triceps insertion and passes over the top of the plate and around one of the screws at the metaphyseal level.

- Distally, a dorsal plate will lie directly on the apex of the ulnar diaphysis. The muscle need only be split sufficiently to gain access to this apex—there is no need to elevate the muscle or periosteum off either the medial or lateral flat aspect of the ulna.
- No attempt is made to precisely realign intervening fragmentation—once the relationship of the coronoid and olecranon facets is restored and the overall alignment is restored, the remaining fragments are bridged, leaving their soft tissue attachments intact.
- Bone grafts are rarely necessary if the soft tissue attachments are preserved.
- If the olecranon fragment is small, osteoporotic, or fragmented, a wire engaging the triceps insertion should be used to reinforce the fixation (TECH FIG 3D).
- The plate and screws will serve to hold the coronoid and olecranon facets in proper alignment and bridge fragmentation, and the wire will help ensure fixation even if screw purchase is lost.

Exposure

- In the setting of a fracture-dislocation of the olecranon (TECH FIG 4A), fractures of the radial head and coronoid process can be evaluated and often definitively treated through the exposure provided by the fracture of the olecranon process.
- With little additional dissection, the olecranon fragment can be mobilized proximally as one would do with an olecranon osteotomy, providing exposure of the coronoid through the ulnohumeral joint.
- If the exposure of the radial head through the posterior injury is inadequate, a separate muscle interval (eg, Köcher or Kaplan intervals) accessed by the elevation of a broad lateral skin flap can be used.
- If the exposure of the coronoid is inadequate through posterior injury and olecranon fracture, a separate medial or lateral exposure can be developed.
■ A medial exposure, between the two heads of the flexor carpi ulnaris, or by splitting the flexor-pronator mass more anteriorly, or by elevating the entire flexor–pronator mass from dorsal to volar, may be needed to address a complex fracture of the coronoid, particularly one that involves the anteromedial facet of the coronoid process.

■ When the lateral collateral ligament is injured, it is usually avulsed from the lateral epicondyle. This facilitates repair that can be performed using suture anchors or suture placed through drill holes in the bone.

■ The fracture of the coronoid can often be reduced directly through the elbow joint using the limited access provided by the olecranon fracture (TECH FIG 4B, C).

**Fixation**

■ Provisional fixation can be obtained using Kirschner wires to attach the fragments either to the metaphyseal or diaphyseal fragments of the ulna, or to the trochlea of the distal humerus when there is extensive fragmentation of the proximal ulna.

■ An alternative to keep in mind when there is extensive fragmentation of the proximal ulna is the use of a skeletal distractor (a temporary external fixator; TECH FIG 5A).

■ External fixation applied between a wire driven through the olecranon fragment and up into the trochlea and a second wire in the distal ulnar diaphysis can often obtain reduction indirectly when distraction is applied between the pins.

■ Definitive fixation can usually be obtained with screws applied under image intensifier guidance.

The screws are placed through the plate when there is extensive fragmentation of the proximal ulna.

■ A second, medial plate may be useful when the coronoid is fragmented.

■ If the coronoid fracture is very comminuted and cannot be securely repaired, the ulnohumeral joint should be protected with temporary hinged or static external fixation, or temporary pin fixation of the ulnohumeral joint, depending on the equipment and expertise available.

■ A long plate is contoured to wrap around the proximal olecranon (TECH FIG 5B).

■ A very long plate should be considered (between 12 and 16 holes), particularly when there is extensive fragmentation or the bone quality is poor.

■ When the olecranon is fragmented or osteoporotic, a plate and screws alone may not provide reliable fixation.

■ In this situation, it can be useful to use ancillary tension wire fixation to control the olecranon fragments through the triceps insertion (TECH FIG 5C).
**POSTOPERATIVE CARE**

- When good fixation is obtained (which occurs in most patients), active assisted and gravity-assisted elbow and forearm exercises can be initiated immediately after surgery. A delay of several days for comfort is reasonable.
- If the lateral collateral ligament was repaired, the patient must be instructed not to abduct the shoulder for the first month.
- If the fixation is tenuous, it is reasonable to immobilize the arm in a splint for a month or so before beginning exercises.

**OUTCOMES**

- Nonunion is nearly unheard of after simple olecranon fractures, and early implant failure is usually due to noncompliance.6
- The appeal of tension band wiring has been limited by prominence of the implants; however, if the techniques described herein are followed, few patients will request a second surgery specifically for implant removal.8
- Macko and Szabo pointed out that it was initial implant prominence and not migration that led to implant-related problems after tension band wiring of olecranon fractures.5
- In any case, a second surgery for implant removal is not unreasonable, and it may not be appropriate to consider this a complication.
- Some surgeons have considered plate-and-screw fixation of simple, noncomminated olecranon fractures.1 However, plates can also cause symptoms, and if only a few screws can be placed in the olecranon fragment, particularly in the setting of fragmentation or osteoporosis, it may be preferable to use the soft tissue attachments to enhance fixation rather than relying on implant–bone purchase alone.
- Medial and lateral plates have been associated with early failure, malunion, and nonunion in the treatment of complex proximal ulna fractures.10,11
- Dorsal plates perform better, but the elbow is often compromised in the setting of such complex injuries.

**COMPlications**

- Implant loosening
- Implant breakage
- Nonunion
- Malunion
- Instability
- Arthrosis

**REFERENCES**

DEFINITION

- Simple elbow dislocation is a dislocation of the ulnohumeral joint without concomitant fracture.
- Complex instability denotes the presence of a fracture associated with dislocation.
- The elbow is the second most commonly dislocated large joint (excluding phalanx dislocations and so forth).

PATHOANATOMY

- Elbow stability is conferred by both the osseous anatomy as well as the ligamentous anatomy.
- Primary stabilizers of the ulnohumeral joint include the osseous architecture of the joint, including the coronoid process and greater sigmoid notch of the ulna, and the trochlea of the humerus.
  - The anterior band of the medial collateral ligament (aMCL) and the lateral ulnar collateral ligament (LUCL) are the primary ligamentous stabilizers of the elbow.8,12
  - The aMCL originates on the anterior inferior face of the medial epicondyle and inserts on the sublime tubercle of the ulna.
  - The LUCL originates from an isometric point on the lateral supracondylar column and traverses across the inferior aspect of the radial head, inserting on the supinator crest of the ulna.8
- Secondary stabilizers include the radial head and dynamic constraints such as the flexor and extensor muscles of the forearm.
  - The anterior joint capsule is also felt to play a role in ulnohumeral stability.
- O’Driscoll12 has proposed the term “posterolateral rotatory instability” (PLRI) to describe the series of pathologic events that result in ulnohumeral dislocation.
- PLRI is felt to start with disruption of the LUCL and progresses medially with tearing of the anterior and posterior capsular tissue. This allows the ulna to “perch” on the distal humerus. Further soft tissue or osseous injury results in dislocation11 (FIG 1A).
  - Most traumatic injuries to the LUCL result in avulsion of the ligament from the lateral humerus (FIG 1B).
  - As forces continue from lateral to medial across the joint, the anterior and posterior capsular tissue and eventually the MCL may be disrupted.
  - It is possible to dislocate the ulnohumeral joint with disruption of the LUCL and preservation of the aMCL.12
- Common fractures that occur with elbow dislocation include radial head or neck and coronoid fractures, although any fracture about the elbow may be observed.
  - Radial head fractures are usually readily apparent on plain radiographs.
  - Coronoid fractures may be subtle, and even a “fleck” of coronoid is often a hallmark of a more significant injury (eg, “terrible triad” injury), and its importance should not be underestimated.
  - Recently, a variant of elbow instability termed posteromedial rotatory instability (PMRI) has been described, which is a consequence of LUCL injury and medial coronoid facet fracture. This injury pattern is most commonly observed without radial head fracture, making it potentially very subtle on plain radiographs. A computed tomography (CT) scan can delineate this injury in detail and should be obtained if any suspicion exists (FIG 1C–E).2,11

ETIOLOGY AND CLASSIFICATION

- Most elbow dislocations occur with a fall on an outstretched arm.
- Forces of valgus, extension, supination, and axial load across the joint can result in the ulna rotating away from the humerus, disrupting lateral–anterior soft tissues initially, and dislocating the elbow.
- Simple elbow dislocations are classified by the direction of displacement of the ulna in reference to the humerus, with posterolateral dislocation the most common.
  - Less common variants include anterior, medial, or lateral dislocations.

PATIENT HISTORY AND PHYSICAL FINDINGS

- History is aimed at determining the timeline and mechanism of injury, frequency of dislocations, and previous treatment.
  - Unlike the shoulder, recurrent instability of the elbow is rare after an initial simple dislocation that was treated expeditiously.
  - Recurrent instability is more common in association with fractures (eg, the “terrible triad” injury).
  - Chronic instability, although rare in the United States, does occasionally occur, and management often requires reconstructive surgery or elbow replacement. Closed treatment is rarely successful in these patients.
  - Iatrogenic injury of the LUCL (during procedures such as open tennis elbow release or radial head fracture management) is a known cause of recurrent PLRI. However, these patients often complain of subtle lateral elbow pain due to subluxation of the joint with activities, such as rising from a chair, but rarely have recurrent dislocation.
  - Examination at the time of injury requires attention to the neurovascular anatomy.
  - Nerve injury can occur after elbow dislocation, and a thorough neurologic examination of the extremity is mandatory before any treatment of the dislocation.
  - Most nerve injuries are neuropraxia that often resolve.
  - The ulnar nerve is most frequently involved, although median or radial nerve injury may also occur.14
  - The dislocated elbow has obvious deformity, with the elbow often held in a varus position and the forearm supinated.
After initial reduction, the neurovascular status of the limb is re-evaluated. Loss of neurologic function after closed reduction is rare but can be an indication for surgical exploration to rule out an entrapped nerve.

Stability of the joint is assessed based on the amount of extension obtainable and association of pronation or supination with instability (see the treatment algorithm section).

It is helpful to evaluate the stability throughout the elbow range of motion while the patient is still anesthetized, as this may guide treatment (examination under anesthesia).

Stressing of the lateral soft tissues is performed with the lateral pivot-shift maneuver, which can be performed under anesthesia and with fluoroscopic imaging. This test can be used to assess the degree of posterolateral rotatory instability, and may aid in determining treatment.

Medial ecchymosis may be a sign of an aMCL injury, and often is apparent 3 to 5 days after dislocation when the MCL has been injured.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standard orthogonal radiographs of the elbow are obtained before and after reduction to assess for fracture and confirm relocation of the joint.
- Congruency of the trochlea-ulna and radial head-capitellum is assessed.
- Valgus stress views, once the joint is reduced, may help demonstrate an aMCL injury.
- With the elbow flexed 30 degrees and the forearm in pronation, a valgus stress is placed under fluoroscopic evaluation to see if the medial ulnohumeral joint opens compared to the resting state.
- Varus stress views are often not helpful.
- CT scans with 3D reconstructions are obtained in any situation where a fracture may be suspected, as it is critical to identify PMRI variants or subtle coronoid fractures, which may be an indication for surgical management.
- Magnetic resonance imaging (MRI) is usually not necessary in the management of simple dislocation, although if questions regarding the integrity of the MCL exist, an MRI can delineate this structure well.

**NONOPERATIVE MANAGEMENT**

- Most simple dislocations may be managed nonoperatively with splinting or bracing, guided by the degree of instability determined during the examination under anesthesia after reduction. Once reduced, elbow stability is assessed during flexion-extension in neutral forearm rotation.
- If the elbow is stable throughout an arc of motion, it is immobilized in a sling or splint for 3 to 5 days for comfort and then range-of-motion exercises are begun.

---

**FIG 1** A. Posterolateral rotatory instability follows a typical progression of disruption, allowing the joint to become perched and then dislocate as soft tissue injury progresses. B. Intraoperative photograph demonstrating avulsion of the origin of the lateral ulnar collateral ligament (LUL) after traumatic dislocation of the elbow. The origin of the LUL and the extensor muscles are avulsed as one layer, held by the forceps. C–E. Posteromedial rotatory instability is a variant of elbow instability in which the elbow dislocates, rupturing the LUL, and the medial coronoid sustains an impaction fracture. In this injury pattern, the radial head remains intact, making appropriate diagnosis of the severity of the injury difficult on standard radiographs. CT scans help better delineate the injury pattern. Impaction fracture can be seen on the 3D CT reconstruction. (A: Adapted from O’Driscol SW, Morrey BF, Korinek S, et al. Elbow subluxation and dislocation: a spectrum of instability. Clin Orthop Relat Res 1982;280:194. C–E: Copyright the Mayo Foundation, Rochester, MN.)
If instability is present in less than 30 degrees of flexion, the forearm is pronated and stability is reassessed. If pronation confers stability, then a hinged orthosis that maintains forearm pronation is used, after 3 to 5 days of splinting, to allow protected range of motion.

Elbows that sublux (confirmed by fluoroscopic imaging) in less than 30 degrees of flexion and pronation of the forearm are managed with a brief period of splinting, followed by a hinged orthosis that controls rotation of the forearm and has an extension block.

Elbows that are unstable in more than 30 degrees of flexion and pronation often are managed surgically.

Hinged bracing is maintained for 6 weeks, with progressive advancement of extension and rotation, as allowed by stability of the joint.

Weekly radiographs are needed to ensure maintenance of a congruent joint during the first 4 to 6 weeks.

After 6 weeks bracing is discontinued and terminal stretching to regain motion is used if flexion contractures exist.

**SURGICAL MANAGEMENT**

**Indications**

Surgical management is indicated in elbows that are unstable, even when placed in flexion (more than 30 degrees) and pronation, elbows that recurrently sublux or dislocate during the treatment protocol, or those with associated fractures (“complex” instability).

Management of simple dislocation requires repair or reconstruction of those ligamentous injuries resulting in instability. By definition, simple dislocation occurs without fracture.

An algorithmic approach to ligament repair is used to stabilize the elbow. The LUCL is felt to be the primary lesion of dislocation, and therefore this ligament is addressed first, followed by assessment of stability.

The LUCL usually avulses from its origin during dislocation, and therefore most often can be repaired after acute injury.

Repair may be performed via bone tunnels in the humerus or with suture anchors, depending on the surgeon’s preference.

Reconstruction of the LUCL is rarely needed in acute management but is more commonly needed in chronic instability.

Reconstruction, when necessary, uses autograft (either palmaris or gracilis) or allograft.

Often, repair or reconstruction of the LUCL confers stability, even in the face of MCL injury, as the intact radial head is a secondary stabilizer to valgus instability.

Persistent instability after LUCL repair is rare and is more commonly observed with fracture-dislocations or chronic instability.

If persistent instability exists, the MCL is repaired or reconstructed, a hinged external fixator is placed, or both are performed.

This section will discuss the surgical technique of LUCL repair and reconstruction.

**Preoperative Planning**

Planning should include the possibility of reconstruction of the LUCL using autograft, which will be harvested at surgery, or by having allograft available.

If autograft is to be harvested, a tendon stripper is needed.

For allograft we routinely use semitendinosus tendon.

A hinged external fixator should be available in the rare case that the elbow remains unstable after ligamentous repair or reconstruction.

2.0- and 3.2-mm drill bits or burrs are used to make bone tunnels for LUCL repair or reconstruction.

Alternatively, some surgeons prefer suture anchor repair of ligament avulsions; if desired, these should be available.

Fluoroscopy is useful for confirming reduction and is required for placement of a hinged external fixator.

A sterile tourniquet is used if exposure of the proximal humerus is necessary for placement of proximal external fixator pins.

**Patient Positioning**

Patients are positioned supine with the arm on a radiolucent hand table.
A small bump is placed under the scapula to aid in arm positioning.
- The forequarter is draped free to ensure the entire brachium is kept in the surgical field.

If hamstring autograft is to be used for LUCL, the leg should be draped free and a bump is placed under the hemipelvis to aid in exposure.

**LATERAL ULNAR COLLATERAL LIGAMENT REPAIR**

**Surgical Approach and Arthrotomy**

- Tourniquet control is used during this procedure.
- Two different surgical approaches are used to manage elbow instability.
- Often, a posterior midline skin incision can be used to gain access to both the medial and lateral aspects of the joint; therefore, it is a very extensile approach to the elbow.
- Alternatively, a “column” incision, centered over the lateral epicondyle, may be used (TECH FIG 1A). If medial-sided exposure is needed, a similar “column” incision may be made over the medial epicondyle to gain access.
- There are benefits to both approaches, and currently no data exist delineating which approach is better.
- For simple dislocation we routinely use a lateral column approach.
- After skin incision, skin flaps are raised anteroposterior at the level of the deep fascia.
- Often the lateral soft tissues are avulsed off the epicondyle, exposing the joint. Occasionally, however, the extensor origin is intact with an underlying ligament injury.
- If the extensor muscles are intact, the interval between the extensor carpi ulnaris (ECU) and anconeus (the Köcher approach), which directly overlies the LUCL, is used. This interval is often readily identified by the presence of a “fat stripe” in the deep fascia (TECH FIG 1B).
- The elbow joint is then exposed by incising the proximal capsule along the lateral column of the humerus, continuing distally along the radial neck (through the supinator muscle and underling capsule) in line with the ECU–anconeus interval.
- The posterior interosseous nerve (PIN) is at risk with this exposure, and therefore the forearm is kept in pronation to protect the PIN.

**Ligament Repair**

- The radiocapitellar joint and coronoid are inspected to confirm no fractures are present and that no soft tissue is interposed in the joint, preventing reduction.
- Once the joint is clear of debris, the ability to obtain a concentric reduction is confirmed with fluoroscopy.

**TECH FIG 1 • A.** Lateral column skin incision. The lateral incision is centered over the epicondyle and radiocapitellar joint and is often the primary incision, as the lateral ulnar collateral ligament (LUCL) rupture is thought to be the primary injury in simple dislocations. **B.** The deep interval between the extensor carpi ulnaris and anconeus is used to gain exposure to the joint. This is often identified by a “fat stripe” in the fascia. Care should be taken not to violate the LUCL, which traverses in line with this interval deep to the fascia and supinator muscle.
with a 2.0-mm drill bit or burr, connected to the distal humeral tunnel at the isometric point.

- Once the humeral tunnels are completed, the limbs of the running suture are passed through the humeral tunnels.
- The joint is concentrically reduced with fluoroscopic confirmation and the LUCL repair sutures are then tied with the joint reduced and the elbow in 30 degrees of flexion and neutral rotation.

- The elbow is ranged through an arc of motion to assess stability, with careful attention placed on the radial head’s articulation with the capitellum, looking for posterior sag in extension, indicating either a lax LUCL or a nonisometric repair.
- If the elbow is stable through an arc of motion, the extensor origin is repaired with interrupted, heavy (no. 0) nonabsorbable suture and the skin is closed in layers.

**TECH FIG 2** - A. The origin of the lateral ulnar collateral ligament (LUCL), which often avulses during elbow dislocation, is identified by a “fold” of tissue on the deep surface of the capsule. The isometric point of the joint is in the center of rotation of the capitellum (B), and confirmation is made using the previously placed sutures in the ligament remnant to ensure that an isometric repair will be obtained (C). D. It is important to make the humeral tunnel so that the most anterior aspect of the tunnel is placed at the isometric point. Exit holes for the humeral tunnel are made anterior and posterior to the lateral supracondylar ridge (B).
**Lateral Ulnar Collateral Ligament Reconstruction**

- Occasionally, the native LUCL is damaged beyond repair (more often with iatrogenic PLRI than with primary instability) or attenuated after recurrent or chronic elbow instability, and reconstruction is necessary.
- Autograft palmaris or gracilis or allograft may be used.
- Autograft and allograft options should be discussed with the patient and decisions made preoperatively. We routinely use semitendinosus allograft unless the patient desires autograft.
- This section will cover the technique of ligament graft reconstruction once tendon graft has been harvested.

**Bone Tunnel Preparation**

- We use a “docking” technique, similar to those described for MCL reconstruction, for LUCL reconstruction.
- The insertion of the LUCL is at the supinator crest of the ulna, and reconstruction begins with creation of the ulnar tunnels at the supinator crest.
- Reflecting the supinator origin from the ulna posterior to the radial head exposes the supinator crest.
  - The forearm is held in pronation to protect the PIN.
- Once the crest is exposed, the ulnar tunnel is made at the level of the radial head using two 3.4-mm burr holes placed 1 cm apart. Care is taken to connect the holes using small curettes or awls without fracturing the roof of the tunnel (TECH FIG 3).
- Once the ulnar tunnel is made, a suture is placed in the tunnel to aid in graft passage and to help identify the isometric point on the humerus, similar to the technique described with ligament repair.
- Once the isometric origin on the humerus is confirmed, humeral bone tunnels are made as mentioned in the LUCL repair section.
  - With LUCL reconstruction the isometric tunnel is deepened to about 1 cm to allow graft docking.
  - Further, the docking tunnel is widened using a 3.4-mm burr to be able to accept both limbs of the graft.
  - It is important to widen the docking hole anterior and proximal to the isometric point, as the most posterior aspect of the tunnel needs to be at the isometric point.

**Graft Preparation**

- One end of the graft is freshened and tubularized using a no. 2 nonabsorbable suture in a running Krackow fashion.
- The graft is then passed through the ulnar bone tunnels using the passage suture previously placed.
- The limb of the graft with locking suture is then fully docked into the humeral origin, and the joint is reduced.
- The final length of the graft is determined by tensioning the graft and identifying the point at which the free limb of the graft meets the isometric origin. This point is marked on the graft.
  - Care should be taken to ensure appropriate graft tension and length by fully docking the first limb and then marking the free limb at the point of initial contact with the humerus, thereby allowing some overlap of graft limbs in the humeral tunnel but minimizing the likelihood of slack in the final construct.
- The marked graft end is then freshened and tubularized in an identical fashion as the other limb.

**Final Reconstruction**

- Once the graft is placed and ready for final tensioning and fixation, the capsule and remnant of the LUCL is repaired back to the humerus in an effort to make the ligament reconstruction extra-articular, if possible.
- Each limb of the graft is then placed into the isometric docking tunnel on the humerus with corresponding limbs from each locking suture exiting the proximal humeral tunnels.
  - Both limbs of locking suture from one end of the graft are passed through one proximal tunnel in the humerus, followed by the limbs from the other end of the graft through the second proximal tunnel.
- The joint is then reduced and the graft is finally tensioned to ensure there is no slack and neither graft end has “bottomed out” in the humeral docking tunnel.
- The locking sutures are then tied together over the lateral column of the distal humerus with the joint concentrically reduced in 30 degrees of flexion and neutral rotation.
- The joint is then ranged and stability assessed. If the joint is stable, no further reconstruction is necessary and the extensor muscles are repaired using a nonabsorbable interrupted stitch, followed by skin closure.
HINGED EXTERNAL FIXATION

- A hinged fixator may be necessary in chronic dislocations, some fracture-dislocations, or rarely in patients with persistent instability after LUCL repair or reconstruction for simple dislocation.\(^\text{4,16}\)
- Once any soft tissue blocking reduction is removed and a concentric reduction can be obtained, the fixator is placed.
- All hinged elbow fixators are constructed around the axis or rotation of the elbow to allow range of motion to occur while maintaining a concentric reduction.
  - Most implants are built around an axis pin, placed in this center of rotation.
  - The center of rotation is identified as the center of the capitellum on a lateral aspect of the elbow, and on the medial side it is just anteroinferior to the medial epicondyle, in the center of curvature of the trochlea (TECH FIG 4).
  - The axis pin is placed through both of these points, parallel to the joint surface, and the position is confirmed by fluoroscopy.
- After placement of the axis pin, the humeral and ulnar pins are placed after confirmation of concentric reduction of the elbow is made.
- Once the external fixator is fully constructed, the elbow is taken through an arc of motion and maintenance of reduction is confirmed.
- Fixators are kept on for 6 to 8 weeks.
- Meticulous pin care is necessary to minimize pin tract infections or loosening.

TECH FIG 4 • The center of rotation of the elbow, along which an axis pin for hinged fixators is placed, is identified by the center of the capitellum and just anteroinferior to the medial epicondyle.

PEARLS AND PITFALLS

- LUCL avulsion is the primary ligamentous injury in most simple dislocations of the elbow.
- If the radial head and coronoid are intact (as is the case in a simple dislocation), the MCL rarely needs to be repaired or reconstructed, as the radial head acts as a secondary stabilizer in the elbow with a repaired lateral ligament complex.
- The LUCL origin can be identified by a capsular fold of tissue. This is the point at which repair sutures should be placed, not at the origin of the more superficial extensor tendons.
- The isometric origin of the LUCL is in the center of the capitellum, as projected onto the lateral column, and repair or reconstruction needs to be brought to this point to have an isometric ligament.
- Bone tunnels in the humerus for repair or reconstruction are made so the anteroinferior aspect of the tunnel is at the isometric origin.
- A hinged external fixator may be necessary in management of elbow dislocation, especially chronic or recurrent situations, and should be available.
- All hinged fixators are constructed around the axis of rotation of the elbow, identified by a line between the isometric point on the lateral capitellum and the center of rotation of the trochlea on the medial aspect of the joint.
- Stiffness is the most common adverse sequela of elbow dislocation, and therefore range of motion should be started as soon as soft tissue and skin healing allows, with care taken to avoid varus or valgus stress.

POSTOPERATIVE CARE

- After operative stabilization without external fixation, the elbow is splinted in flexion for 3 to 5 days to allow wound healing.
- Range-of-motion exercises are then begun in flexion, extension, and rotation, with care taken to avoid varus or valgus stress.
  - A hinged orthosis can be helpful in protecting the ligament repair or reconstruction.
  - Active and passive motion is continued for 6 weeks, when strengthening is added.
- Residual contractures, often loss of extension, can be managed with static splinting and terminal stretching.

OUTCOMES

- Most series have reported the results of closed management of simple dislocation.
  - Mehlhoff and colleagues\(^\text{7}\) reported the results of 52 simple dislocations managed, with most patients having normal elbows. Length of immobilization, especially greater then 3 weeks, was found to be more likely to result in persistent loss of extension.
Part 7 SHOULDER AND ELBOW • Section VIII  ELBOW TRAUMA

- Similarly, Eygendaal and colleagues reported the long-term results of 50 patients after closed management of simple dislocations. Sixty-two percent of patients described their elbow function as good or excellent, and 24 of 50 (48%) patients had loss of extension of 5 to 10 degrees.

- Some series have examined the surgical management of PLRI, often as a result of recurrent instability after traumatic dislocation.

- Nestor and colleagues reported the results of 11 patients with recurrent PLRI managed with either repair or reconstruction of the LUCL. Ten of 11 (91%) remained stable and 7 of 11 (64%) had an excellent result.

- More recently, Sanchez-Sotelo and colleagues reported the results of 44 patients treated for recurrent PLRI (9 occurred after simple dislocation). Thirty-two (75%) of the patients had an excellent result by Mayo score.

- Lee and Teo found that in patients with chronic PLRI, reconstruction offered more predictable outcomes over repair.

COMPLICATIONS

- Stiffness
- Heterotopic ossification
- Neurovascular injury
- Recurrent instability
- Compartment syndrome
- Hematoma or infection

REFERENCES

DEFINITION

- Simple dislocations of the elbow can most often be treated successfully with closed means: reduction and short-term immobilization followed by early motion.
- Fracture-dislocations of the elbow are more troublesome in that they often require operative intervention.
- Fractures associated with elbow dislocations often involve the radial head and coronoid. When both are combined with dislocation, this is termed the “terrible triad.”
- The principle of treating fracture-dislocations of the elbow is to provide sufficient stability through reconstruction of bony and ligamentous restraints such that early motion can be instituted without recurrent instability.
- Failure to achieve this will result in either recurrent instability or severe stiffness after prolonged immobilization.

ANATOMY

- Posterolateral dislocations of the elbow are associated with disruption of the medial and lateral collateral ligaments.
- The medial collateral ligament (MCL) is the primary stabilizer to valgus stress (FIG 1).
- The lateral collateral ligament (LCL) is the primary stabilizer to posterolateral rotatory instability. Most often the disruption is from the lateral epicondyle, leaving a characteristic bare spot. Less commonly, the ligament may rupture mid-substance. Secondary restraints on the lateral side that may also be disrupted are the common extensor origin and the posterolateral capsule.
- Radial head fractures have been classified by Mason:
  - Type I: small or marginal fracture with minimal displacement
  - Type II: marginal fracture with displacement
  - Type III: comminuted fractures of the head and neck
- Coronoid fractures have been classified by Regan and Morrey (FIG 2):
  - Type I: tip fractures (not avulsions)
  - Type II: less than 50% of the coronoid
  - Type III: more than 50% of the coronoid
  - The insertion of the MCL is at the base of the coronoid and it may be involved in type III fractures.
PATHOGENESIS
- Fracture-dislocations of the elbow occur during falls onto an outstretched hand, falls from a height, motor vehicle accidents, or other high-energy trauma (FIG 3).
- Typically there is a hyperextension and valgus stress applied to the pronated arm.

NATURAL HISTORY
- Elbow dislocations with associated coronoid or radial head fractures have a poor natural history. Redislocation or subluxation is likely with closed treatment.
- Treatment of the radial head fracture by excision alone in the context of an elbow dislocation has a high rate of failure due to recurrent instability.
- Problems of recurrent instability, arthrosis, and severe stiffness lead to poor functional results.¹⁰

PATIENT HISTORY AND PHYSICAL FINDINGS
- Fracture-dislocations of the elbow are acute and traumatic, so the history should be straightforward.
- It is not unusual for these injuries to occur with high-energy trauma, so a diligent search for other musculoskeletal and systemic injuries must accompany evaluation of the elbow. The ipsilateral shoulder and wrist should be evaluated.
- The evaluation and documentation of peripheral nerve and vascular function in the injured extremity is critical.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- High-quality plain radiographs in the anteroposterior (AP) and lateral plane should be obtained before and after closed reduction.
- Cast material can obscure bony detail after closed reduction.
- If there is any evidence of forearm or wrist pain associated with the elbow injury, these should be imaged as well.
- Computed tomography (CT) scans with reformatted images and 3D reconstructions are helpful in understanding the configuration of bony injuries and are helpful in treatment planning (FIG 4).

DIFFERENTIAL DIAGNOSIS
- Radial head or neck fractures without associated dislocation
- Coronoid fracture associated with posteromedial instability. This results from a varus force and is associated with rupture of the LCL. The radial head is not fractured, making diagnosis more difficult.

NONOPERATIVE MANAGEMENT
- Initial treatment involves closed reduction and splinting with radiographs to confirm reduction (FIG 5).
- If reduction cannot be maintained because of bone or soft tissue injury, repeated attempts at closed reduction should not be attempted. This is thought to contribute to the formation of heterotopic ossification.
- The ability of nonoperative management to meet treatment goals in these situations is rare and surgery is indicated in almost all cases.
SURGICAL MANAGEMENT

- The goals of surgery are to obtain and maintain a concentric and stable reduction of the ulnohumeral and radiocapitellar joint such that early motion within a flexion–extension arc of 30 to 130 degrees can be initiated. Early motion is key to avoid elbow stiffness and resultant poor function.
- Management of elbow dislocations with associated radial head and coronoid fractures should follow an established protocol (Table 1) that has produced reliable results.8
- The radial head is an important secondary stabilizer of the elbow to valgus stress and posterior instability.7
- It is also a longitudinal stabilizer of the forearm to proximal translation.
- If fractured in this setting, it must be fixed or replaced, as excision leads to recurrent instability and unacceptable results.10

Preoperative Planning

- Before surgery, the surgeon must ensure that the proper equipment and implants are available.

Positioning

- Most commonly, the patient is positioned supine on the operating table under general anesthesia.
- The operative limb is supported on a hand table and a tourniquet is applied to the upper arm before preparation and draping (FIG 6).
- Alternatively, the lateral decubitus position can be used with the operative limb supported by a padded bolster. This position is used if hinged fixation is deemed likely.

Approach

- The lateral approach is the workhorse for treatment of these injuries where the coronoid, radial head, and LCL can be addressed. A direct lateral incision with the patient supine and the arm on a hand table is used.
- Landmarks and skin incision are shown in FIGURE 7A.
- The surgeon should use the traumatic dissection that occurred at the time of injury to gain exposure of the elbow.
- Typically the LCL has been avulsed from the lateral distal humerus, leaving a bare spot (FIG 7B).8
- Some cases require a medial approach as well for either medial ligament reconstruction or plating of a coronoid fracture.
fracture. This can be accomplished through a second medial incision.
- The ulnar nerve is at risk in this approach and should be identified and protected. The common flexor origin is split distal to the medial epicondyle to expose the coronoid medially.
- Alternatively, a posterior skin incision can be used with elevation of full-thickness flaps at the fascial level to approach both laterally and medially.
- The patient can be placed in the lateral decubitus position or supine with the arm across the chest for this approach.

**TECHNIQUES**

**LATERAL EXPOSURE**
- Make an incision along the lateral supracondylar ridge of the humerus curving at the lateral epicondyle toward the radial head and neck.
- At the fascial level, elevate full-thickness flaps and insert a self-retaining retractor (TECH FIG 1).
- Split the common extensor origin in line with its fibers.
- Make use of the traumatic dissection that occurred at the time of injury.
  - Most commonly, the LCL will have avulsed from the distal humerus, leaving a bare spot. The common extensor origin is avulsed as well two thirds of the time.\(^7\)
  - Reconstruction occurs in an orderly fashion from deep to superficial.
  - If the radial head is to be replaced, its excision provides excellent exposure of the coronoid through the lateral approach.
  - If, on the other hand, it is to be fixed, set free fragments aside to allow access to the coronoid.

**ORIF OF CORONOID FRACTURE**

**Type I Coronoid Fractures**
- For type I fractures, we recommend fixation with a non-absorbable (no. 2 braided) suture passed through the anterior elbow capsule just above the bony fragment (TECH FIG 2).
- Two parallel drill holes are made from the dorsal surface of the ulna through a separate small incision and directed toward the coronoid tip. These are made with a small drill or Kirschner wire.
- Once the suture is passed through the capsule, its ends are brought out each of the drill holes and tied over the ulna to plicate the anterior elbow capsule.
- The suture ends can be retrieved through the drill holes using an eyeleted Kirschner wire, a Keith needle, or a suture retriever.
Radial head or neck fracture

Radial head fracture is addressed after treatment of the coronoid injury because once the head is fixed or replaced, access to the coronoid from the lateral approach is limited.

The decision to fix a radial head is largely based on the fracture configuration. If fracture comminution is limited such that the head is in two or three fragments, reduction and fixation is usually possible.

Fractures that are comminuted or with articular surface damage require replacement.

Expose the head and neck as necessary for fracture reduction and fixation by extending the Köcher interval.

The posterior interosseous nerve is at risk during more distal radial neck exposures. Its distance from the operative site can be maximized by keeping the forearm in full pronation.

ORIF of Radial Head Fractures

For radial head fragments, reduce and hold the fragment to the intact head with a pointed reduction clamp.

We secure the fragments with Herbert screws. The fragments can be held temporarily with a 2-mm Kirschner wire and then replaced with a Herbert screw.

If the screw is inserted through articular cartilage, its head must be countersunk.

Radial neck fractures, once reduced, can be held provisionally with a Kirschner wire.

Definitive fixation is with a small fragment T plate over the "safe zone" (TECH FIG 4).

Care is taken to not injure the posterior interosseous nerve while exposing the shaft or by trapping it under the plate distally.

If the radial head cannot be reconstructed, it is replaced.
TECH FIG 4 • The “safe zone” for plating radial neck fractures. The 90-degree arc outlined does not articulate with the proximal ulna throughout the full range of forearm rotation. Plating a radial neck fracture in this zone will not interfere with rotation.

Radial Head Replacement
- The replacement used must be metallic as silicone implants are inadequate both biomechanically and biologically.6
- We use a modular implant such that the stem diameter can be varied independent of the head diameter and thickness.

TECH FIG 5 • Radial head implant. An appropriately sized radial head implant has been inserted. It is held reduced with the forearm in full pronation. Note the anatomic alignment with the capitellum.
- If required, cut the proximal radius at the level of the neck with a micro-sagittal saw.
- Ream the canal of the proximal radius to cortical bone with sequentially larger reamers.
- Radial head size can be judged by assembling the fractured fragments that have been removed. In general, downsizing the head slightly is recommended such that the elbow joint is not overstuffed.
- A trial implant should be inserted to test stability and motion. Elbow range of motion, both flexion–extension and forearm rotation, should be checked. View the articulation between the proximal radius and ulna to see if the diameter of the implant seems appropriate.
- Once satisfied with sizing, the definitive implant is inserted (TECH FIG 5).

REPAIR OF THE LATERAL COLLATERAL LIGAMENT COMPLEX
- Repair of the LCL complex is critical to re-establish elbow stability (TECH FIG 6A).
- It is most often avulsed from the distal humerus. Its anatomic attachment point is slightly posterior to the lateral epicondyle at the center of the arc of the capitellum.
- The LCL is a discrete structure deep to the common extensor origin, which runs from the lateral epicondyle to the supinator crest of the ulna (TECH FIG 6B).
- Use a no. 2, braided, nonabsorbable suture for the repair.

TECH FIG 6 • A. Elbow instability associated with deficient lateral collateral ligament. Without repair of the lateral collateral ligament, the radial head subluxes into a posterolateral position with forearm supination. Note that the radial head and capitellum are no longer in normal alignment. B. The lateral collateral ligament is held by the forceps. It is a distinct structure easily identified in this acutely injured elbow. (continued)
PERSISTENT INSTABILITY

- On occasion, repair of the coronoid, radial head, and LCL from the lateral approach is insufficient to restore elbow stability such that early motion may be initiated.
- In these cases, further efforts must be made to obtain such stability.
- Repair of the MCL through a separate medial incision is one option if a lateral approach has been used for coronoid and radial head fracture fixation.
  - Alternatively, a posterior skin incision can be used with full-thickness flaps created to access both sides. Positioning the patient in the lateral decubitus position facilitates this approach.
- A deep approach to the medial aspect of the elbow puts the ulnar nerve at risk, and it must be identified and protected during the procedure.
- Usually the MCL is torn in its mid-substance. Suture repair of this is often unsatisfying. Using a graft to replace the MCL is not recommended in the acute injury setting.
- If elbow stability remains unsatisfying, applying a hinged fixator is the final option. If the hinge is not available or the surgeon is not familiar with its use, a static fixator can be applied to maintain elbow reduction.

Hinged External Fixation

- Application of the hinged fixator starts with the insertion of a guide pin through the center of elbow rotation.
  - The ligament can be reattached to the distal humerus through bone tunnels or using suture anchors. We prefer bony tunnels.
  - Using a drill, Kirschner wire, or pointed towel clip, make holes in the distal lateral humerus above the epicondyle.
  - Pass the suture through the holes and into the lateral ligament such that it will tighten on tying the sutures.
  - At least two, preferably three, sutures through bone are required. Pass, cut, and snap all of the sutures (TECH FIG 6C).
  - Ensure that the elbow is now held in 90 degrees of flexion and full forearm pronation.
  - Incorporate the more superficial common extensor origin in the repair.
  - Tie the sutures once they have all been passed and then close the lateral wound in layers.

PEARLS AND PITFALLS

POSTOPERATIVE CARE

- The injured elbow is placed in a well-padded plaster splint at 90 degrees of flexion and full pronation. The patient is given a sling for comfort.
- AP and lateral radiographs are obtained in the operating room to ensure congruent reduction and verify hardware placement.
- The patient typically stays in hospital one night to receive adequate analgesia and prophylactic antibiotics.
- We do not routinely give prophylaxis for heterotopic ossification unless the patient has a concomitant head injury: in this case, indomethacin 25 mg three times a day is prescribed with a cytoprotective agent for 3 weeks.
- The patient returns to our clinic at 7 to 10 days postoperatively for staple removal. The splint is typically removed at this point.
- Range-of-motion exercises are initiated at this time under the supervision of a physiotherapist.
- Active and active-assisted flexion–extension between 30 and 130 degrees and forearm rotation with the elbow at 90 degrees of flexion is initiated.
- A lightweight resting splint is made for the injured elbow that is removed for hygiene and physiotherapy.
- The patient returns at 4, 8, and 12 weeks after surgery for clinical review with plain radiographs. Thereafter the interval of clinic visits is widened, but we follow our patients out to 2 years.
- At 4 weeks we allow unrestricted range of motion and at 8 weeks unrestricted strengthening.
- Evidence of fracture union is usually present between 6 and 8 weeks.
- Progress with range of motion can be slow and frustrating for the patient but does not plateau until 1 year of follow-up.

OUTCOMES

- Following the protocol outlined for fracture-dislocations of the elbow should yield satisfactory functional results.
- Pugh et al.8 reported the results of this treatment protocol for 36 elbows at 34 months.
  - The flexion–extension arc averaged 112 degrees and rotation 136 degrees.
  - Fifteen patients had excellent results, 13 good, 7 fair, and 1 poor by the Mayo Elbow Performance Score.
  - Eight patients had a complication requiring reoperation.

COMPLICATIONS

- The most likely complication after treatment is unacceptable elbow stiffness with a resultant nonfunctional range of motion.
  - An acceptable range is 30 to 130 degrees of flexion.
  - At about 1 year after surgery, once motion has plateaued, patients are candidates for release with hardware removal if they are not happy with their range of motion and the flexion–extension arc is less than 100 degrees.
  - This is done through the lateral approach with an anterior and posterior capsulectomy plus manipulation under anesthesia.
  - A radial head implant in place can be downsized to improve motion, but it should not be simply removed. The lateral ligament complex is preserved.
  - In our series, this was necessary in 11% of cases.
  - Synostosis around the elbow is another possible cause of rotational forearm stiffness.
  - A resection can be planned to improve motion.
  - CT scanning preoperatively helps to define the extent of the lesion. Resection is technically demanding.
  - Superficial and deep wound infection is possible after repair. Immediate and aggressive treatment is recommended with antibiotics initially and irrigation with débridement if rapid improvement is not seen.
  - Persistent instability is rare but may occur despite best efforts at repair.
  - Posttraumatic arthritis may be a long-term problem.

REFERENCES

DEFINITION

- This injury was initially reported by Giovanni Monteggia in 1814 as a fracture of the ulna associated with an anterior dislocation of the radial head.\(^6\)
- The term “Monteggia lesions” was coined by Bado to describe any fracture of the ulna associated with a dislocation of the radiocapitellar joint.\(^1\)
- The Bado classification of Monteggia lesions,\(^1\) with the Jupiter subclassification of type II fractures,\(^4\) is shown in Table 1.
- Equivalent injuries in adults
  - Variable pathology that is thought to be equivalent to injuries classified by the Bado system
  - Equivalent injuries do not always fall within the traditional definition of a Monteggia fracture in that they do not always have a concomitant radiocapitellar dislocation. Therefore, it can be argued that these injuries are not necessarily equivalent to Monteggia fractures.
- Type I and II injuries are the only ones that have equivalent injury patterns.

PATHOGENESIS

- The exact mechanism of injury for Monteggia fractures is controversial.
- Proposed mechanisms of injury for type I injuries include the following:
  - Direct blow to the posterior aspect of the elbow
  - Fall on outstretched arm with hyperpronated hand (forearm pronation levers radial head anteriorly)
  - Fall on outstretched arm
  - Violent contraction of biceps pulling radial head anteriorly
- Proposed mechanism for type II injuries: hypothesized to occur when a supination force tensions the ligaments that are stronger than bone
- Proposed mechanism for type III injuries: direct blow to the inside of the elbow with or without rotation

PATIENT HISTORY AND PHYSICAL FINDINGS

- The initial examination should systematically evaluate:
  - Skin integrity
  - Neurovascular status of the extremity
  - Bony injury
- Ulna fracture
  - Injury pattern
    - Noncomminuted
    - Comminution
    - Associated injury to key structural elements of the ulna (coronoid, olecranon)
- Radial head injury
  - Isolated dislocation without fracture
  - Radial head or neck fracture

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs (FIG 1): Orthogonal radiographs of the elbow, forearm, and wrist are required.
  - Ulna fracture is easily identified.
  - Radial head fracture or dislocation can be subtle, especially if radial head dislocation reduces.
- Computed tomography (CT) scans can be helpful to determine the extent of the bony injury and the location of fracture fragments. They are particularly helpful in fractures involving the coronoid, olecranon, and radial head.
- 3D CT reconstructions provide information on the spatial relationship of fracture fragments in comminuted fractures.

DIFFERENTIAL DIAGNOSIS

- Isolated ulna fracture
- Nightstick fracture
- Olecranon fracture
- Fracture-dislocation of the elbow ("terrible triad" injury)
- Transolecranon fracture-dislocation

NONOPERATIVE MANAGEMENT

- Monteggia fracture-dislocations in the adult population are generally treated surgically.
- Improved fixation methods and surgical technique have remarkably improved the results of surgery, making it a more reliable treatment option.

SURGICAL MANAGEMENT

Preoperative Planning

- The timing of surgery depends on the condition of the soft tissues and the availability of necessary equipment and personnel.
  - The surgeon should define all injuries that need to be addressed.
  - Equipment requirements:
    - Small fragment plates and screws or anatomic plating system
    - Minifragment system
    - Threaded Kirchner wires
    - Radial head replacement
    - Bone graft (allograft or autograft)

Patient Positioning

- Lateral decubitus position with the arm over a padded arm support (FIG 2)
- Supine positioning is an alternative approach (although it is not preferred because of difficulty in maintaining the arm across the chest). If this approach is used, a saline bag under the ipsilateral shoulder will help keep the arm across the chest.

**FIG 1** - Plain AP and lateral radiographs typically demonstrate fracture pattern.

**FIG 2** - Lateral decubitus positioning is preferred.
**SURGICAL APPROACH**

- A midline posterior skin incision is placed lateral to the tip of the olecranon (TECH FIG 1A).
- Subcutaneous flaps are elevated on the fascia of the forearm. The medial antebial cutaneous nerve does not need to be identified if dissection is performed on the fascia of the flexor–pronator muscles since it is mobilized with the medial skin flap.
- The interval between the flexor carpi ulnaris (FCU) and anconeus is developed along the subcutaneous border of the ulna to expose the fracture site. The amount of dissection required for exposure is dictated by the fracture pattern and the type of fixation to be used (TECH FIG 1B).
- If the radial head needs to be addressed surgically, the anconeus can be mobilized more extensively through a Boyd approach (TECH FIG 1C). If the ulna fracture permits, the radial head can be fixed through the fracture bed of the ulna before definitive fixation of the ulna. Once the ulna is fixed, access to the radial head is not possible.

**TECH FIG 1 • A.** Posterior midline incision positioned just off the lateral aspect of the olecranon. **B.** Deep surgical interval uses the internervous plane between the anconeus and flexor carpi ulnaris. **C.** Exposure of the radial head can be accomplished by releasing the anconeus from the humerus and reflecting it proximally to expose the radial head.

**RADIAL HEAD MANAGEMENT**

- Radial head fractures are typically fixed before the ulna fracture is addressed. If the lesser sigmoid notch of the ulna is involved, determining radial length if radial head replacement is required can be difficult. Therefore, fractures are generally fixed before the ulna while replacement may need to be performed after ulnar fixation is completed in order to establish appropriate radial head sizing.
- Reconstructable fractures of the radial head are fixed (TECH FIG 2A,B).
- Unreconstructable fractures of the radial head are replaced (TECH FIG 2C).

**TECH FIG 2 • A,B.** Preoperative and postoperative radiographs demonstrating open reduction and internal fixation of the radial head component of the Monteggia fracture. (continued)
ULNA FRACTURE FIXATION

No Articular Involvement of the Ulnohumeral Joint
- Ulna fractures distal to the coronoid can be plated laterally or on the subcutaneous border of the ulna.
- Lateral plate placement is preferred by some to prevent hardware prominence.

Articular Involvement of the Ulnohumeral Joint
- Fractures extending proximal to the coronoid require the plate be placed on the subcutaneous border of the ulna to accommodate the complex geometry of this region.
- In general, the ulna fracture is reconstructed from distal to proximal. Ensure that any associated injury to the coronoid is identified and addressed.
- The fracture is reconstructed by fixing the distal fragments; this may require interfragmentary fixation or subarticular Kirschner wires (TECH FIG 3A). As fixation progresses proximally, reconstruction of the coronoid and greater sigmoid notch is performed. Particular attention is directed at anatomic reconstruction of the articular surface.
- Coronoid involvement with a Monteggia fracture-dislocation often extends distally into the volar cortex of the ulna, as opposed to the axial-plane fracture patterns characterized by Regan and Morrey\(^9\) (TECH FIG 3B).
- Larger fragments can be definitively fixed with antegrade lag screws from the dorsal aspect of the ulnar or can be provisionally fixed with threaded wires and ultimately definitively fixed once the plate is applied to the dorsal aspect of the ulna.
- Coronoid fracture exposure can typically be obtained through the olecranon fracture. If this does not provide sufficient exposure, the FCU can be elevated from the dorsal aspect of the ulna.
- The final fragment to be fixed is the olecranon fragment. The attached triceps will obscure fracture reduction if reduced before distal reconstruction (TECH FIG 3C).

Definitive fixation is performed with a dorsal plate. The triceps is partially split to allow the proximal aspect of the plate to oppose the olecranon (TECH FIG 3D).
The olecranon fragment with attached triceps is reduced and provisionally held with medial and lateral Kirschner wires pending definitive fixation. Final fixation for most Monteggia fractures is with a rigid plate applied to the dorsal cortex.

WOUND CLOSURE

- The tourniquet is deflated and hemostasis is obtained.
- The fascia between the FCU and anconeus is closed with interrupted absorbable 0 or 1 suture.
- Subcutaneous tissues are closed with 3-0 absorbable suture and skin is closed with staples.
- I prefer to close the wound over a drain placed in the subcutaneous tissues to avoid hematoma.
- A well-padded dressing is applied and an anterior splint is placed with the elbow in full extension.

PEARLS AND PITFALLS

Indications
- Monteggia fracture-dislocations in adults require surgical intervention.

Goals of treatment
- The first goal is to restore ulnar length and location of the radial head. When the articulation is involved, the goal is to obtain a concentric reduction with sufficient elbow stability that early range of motion is possible.
- The second goal is to avoid complications that compromise function.

Ulna fractures
- Fractures distal to the coronoid need only to be fixed such that ulnar length is re-established.
- When plating these fractures, avoiding malreduction of the ulna is critical to reduction of the radial head. Failure to re-establish ulnar geometry can result in persistent subluxation or dislocation of the radial head (FIG 3).
- Fractures involving the articulation require stable fixation to re-establish a competent joint.

Radial head
- Radial head fractures are fixed or replaced.

Physical therapy
- Early range of motion is the goal of treatment but may be delayed if fixation is questionable.

FIG 3 • Malunion of the ulna with resulting apex dorsal angulation results in dislocation of the radial head.
POSTOPERATIVE CARE
- The arm is splinted in full extension to take pressure off the posterior soft tissues.
- If a drain is used, the splint and dressing are removed when the drain output is less than 30 mL in 8 hours. If no drain is used, the dressing is removed on postoperative day 1.
- Active or active-assisted flexion and gravity-assisted extension is begun once the surgical dressings are removed.
- If fixation is tenuous because of poor-quality bone or comminution, mobilization is delayed.

OUTCOMES
- Historically, the results of operative treatment of Monteggia fracture-dislocations have been unpredictable.\(^3,7,8,11\)
- The advent of rigid internal fixation has improved the results of operative treatment.\(^2,4,7\)
- Certain factors have been associated with a poor clinical result:\(^5\):
  - Bado type II injury
  - Jupiter type Ila injury
  - Fracture of the radial head
  - Coronoïd fracture
  - Complications requiring further surgery

COMPLICATIONS
- Complications associated with Monteggia fracture-dislocations occur with frequency. A multicenter study evaluating Monteggia fracture-dislocations in adults demonstrated complications in 43% of the patients treated, with an unsatisfactory outcome in 46% of the patients treated.\(^10\)
- Radial nerve palsy
  - Most commonly posterior interosseous nerve
  - Causes of injury include:
    - Compression at the arcade of Frosche
    - Direct trauma
    - Traction with lateral displacement of the radial head
- Most common with type III fractures
- Complete resolution typically occurs.
- Malunion
  - Most common in type II fractures with volar comminution that is not appreciated or addressed
  - If radial head subluxation persists, malunion must be considered.
- Nonunion
  - Causes of nonunion include:
    - Infection
    - Inadequate internal fixation
    - Compression plate fixation required, particularly if fracture is comminuted
    - Semitubular and reconstruction plates are not structurally strong enough.
- Radioulnar synostosis
  - Seen with high-energy injuries with associated comminution
  - Higher incidence if radial head fracture associated with ulna fracture at the same level
  - Boyd approach implicated since the radius and ulna are exposed through the same incision

REFERENCES
DEFINITION
- Lateral collateral ligament (LCL) injuries most often occur after significant elbow trauma, most commonly dislocation.
- Attenuation of the LCL can also occur after multiple surgeries to the lateral side of the elbow and after multiple corticosteroid injections and has recently been reported to occur in patients who have residual cubitus varus after malunion of supracondylar humerus fractures.
- Significant injury to the LCL complex can result in posterolateral rotatory instability (PLRI).

ANATOMY
- The LCL is made up of four major components: the lateral ulnar collateral ligament (LUCL), also called the radial ulnohumeral ligament (RUHL); the radial collateral ligament proper (RCL); the annular ligament; and the accessory collateral ligament (FIG 1).
- The ligaments originate from a broad band over the lateral epicondyle, deep to the extensor muscle mass, and separate distally into more discrete structures.
- The RUHL is the most important stabilizer against PLRI, and it attaches distally on the supinator crest of the ulna.
- The RCL is more anterior and primarily resists varus stress.
- The annular ligament sweeps around the radial head and stabilizes the proximal radioulnar joint.
- The capsule acts as a static stabilizer, especially at the anterior portion, while the arm is extended.
- The anconeus and extensor muscle groups act as dynamic stabilizers.

PATHOGENESIS
- Multiple studies have shown that injury to the LCL can lead to PLRI, which is the first stage in elbow instability that can lead to frank elbow dislocation.
- It is controversial whether injury to the RUHL alone can lead to PLRI or whether further injury to the LCL complex is necessary.
- When the forearm is supinated and slightly flexed, a valgus stress with an attenuated LCL causes the ulnohumeral joint to rotate, compresses the radiocapitellar joint, and ultimately causes the radial head to subluxate or dislocate posteriorly.

NATURAL HISTORY
- PLRI is not a new condition, but it has only recently been described and studied.
- The prevalence and natural history of this condition are currently not known.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients typically report trauma but may have had recurrent lateral epicondyliitis or previous surgery.
- Elderly patients may not have frank dislocation of the elbow, but 75% of patients younger than 20 years report elbow dislocation.
- Patients report mechanical-type symptoms (clicking, popping, and slipping) during elbow supination and extension and rarely report recurrent dislocations.
- Physical examination can be difficult; provocative tests are described below. It is often necessary to conduct these tests with the patient under anesthesia or with the aid of fluoroscopy.
- Inspection for effusion: With acute injuries, effusion is likely to be present, but in more chronic situations, it may be absent.
- Range of motion (ROM): Locking of the elbow could represent loose bodies; stiffness may indicate intrinsic capsular contracture.

FIG 1 • A. The lateral collateral ligament complex is made up of four major components: the lateral ulnar collateral ligament, also called the radial ulnohumeral ligament; the radial collateral ligament proper; the annular ligament; and the accessory collateral ligament. B. Osseous anatomy of the lateral collateral ligament insertion.
Supine lateral pivot-shift test: When the elbow is slightly flexed, the radial head can be palpated to subluxate or frankly dislocate, and as the elbow flexes past 40 degrees, it relocates, often with a palpable clunk. This test is difficult to perform on an awake patient because often apprehension is felt and the patient does not allow the test to continue.

Prone pivot-shift test: Radial head or ulnohumeral subluxation constitutes a positive test, same as the supine lateral pivot-shift test. Examination under anesthesia may be required.

Push-up test: Reproduction of the patient’s symptoms of apprehension during supination and not pronation constitutes a positive test. Inability to complete the push-up also constitutes a positive test.

Chair push-up: Elicited pain constitutes a positive test.

Table-top relocation test: Elicited pain or apprehension as the elbow reaches 40 degrees constitutes a positive test.

Elbow drawer test: Ulnohumeral subluxation constitutes a positive test.

A thorough examination of the elbow should also be completed to rule out other injuries.

Valgus instability with the forearm in pronation and 30 degrees of flexion suggests medial collateral ligament (MCL) injury.

Lateral epicondylitis or radial tunnel syndrome can present with tenderness over the proximal extensor mass and with resisted extension of the wrist (Thompson test) and long finger.

Loose bodies may present with crepitus or locking of the elbow during ROM.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standard anteroposterior (AP) and lateral view radiographs often indicate normal findings but may reveal small lateral epicondyle avulsion fractures and radiocapitellar wear.
- Stress AP and lateral view radiographs may reveal widening of the ulnohumeral joint and posterior subluxation of the radial head (**FIG 2A**).
- Magnetic resonance imaging (MRI), especially with intra-articular contrast enhancement, may reveal injuries to the LCL complex. The proximal extensor mass requires attention (**FIG 2B**).

Diagnostic arthroscopy of the elbow can be performed, although we do not recommend routine diagnostic arthroscopy for this injury.

The drive-through sign occurs when the scope can easily be “driven through” the lateral gutter into the ulnohumeral joint from the posterolateral portal.

The pivot-shift test also can be performed during arthroscopy, and the radial head will subluxate posteriorly.

**DIFFERENTIAL DIAGNOSIS**

- Lateral epicondylitis
- Loose bodies
- Elbow fracture-dislocation
- MCL injury
- Radial head dislocation

**NONOPERATIVE MANAGEMENT**

- If the injury is diagnosed early, immobilization in a hinged elbow brace in pronation for 4 to 6 weeks may prevent chronic instability.
- Removable neoprene sleeves may offer support.
- A trial of elbow extensor strengthening can be performed.

**SURGICAL MANAGEMENT**

**Indications**

- Recurrent symptomatic PLRI despite nonoperative treatment

**Preoperative Planning**

- All imaging studies should be reviewed and informed consent obtained.
- An examination of the elbow should be performed with the patient under anesthesia, especially the pivot-shift test.
- If there is any doubt regarding the diagnosis, a pivot-shift test should be performed under fluoroscopy.

**Positioning**

- The patient is placed supine on the operating room table.
- The arm can be placed on an arm board or across the patient’s chest with a sterile tourniquet applied to the upper arm and the entire arm draped free (**FIG 3**).
- During the approach, the forearm should be pronated to protect the posterior interosseous nerve.
Approach

- The main approach is the Köcher interval between the anconeus and extensor carpi ulnaris muscles.
- This can be accomplished through a lateral skin incision or through a utilitarian posterior incision.
- A posterior incision should be considered if a medial approach will also be needed to repair concomitant ligamentous or bony injury.

FIG 3 • The patient is placed supine on the operating room table. The arm is placed on an arm board with a sterile tourniquet applied to the upper arm and the entire arm draped free. During the approach, the forearm should be pronated to protect the posterior interosseous nerve.

FIGURE 8 YOKE TECHNIQUE

Surgical Approach

- A 10-cm incision is made over the Köcher interval.
- The interval between the anconeus and the extensor carpi ulnaris is developed, and the remainder of the LCL complex is identified along with the supinator crest and the lateral epicondyle.
- The lateral epicondyle and 2 cm of the supracondylar ridge are exposed.

Tunnel Placement

- Two drill holes for the graft insertion site are made in the ulna.
- One is drilled near the tubercle of the supinator crest (palpate in supination and varus stress), the other 1.25 cm proximal to that, near the insertion of the annular ligament (TECH FIG 1A).
- A suture is passed through the two holes and tied to itself. The suture is then held up against the lateral epicondyle as the elbow is ranged in flexion and extension to determine its isometric point.
- The isometric ligament insertion occurs at the point where the suture does NOT move.
- The isometric point is usually more anteroinferior than expected (TECH FIG 1B,C).
- A Y-shaped tunnel is made with the base exiting at the isometric point.
- The hole is widened to accept a three-ply graft. (Palmaris longus is usually harvested; if not present, gracilis or allograft is used.) A 16-cm graft is usually sufficient.

Graft Passage and Tensioning and Wound Closure

- The graft is passed through the ulnar tunnel with enough length to just reach the isometric point.
- The end is then sutured to the long end of the graft (the Yoke stitch).
- The long end is then passed through the isometric point and exits the superior humeral tunnel (TECH FIG 2A).
The long end is wrapped around the supracondylar ridge and passed through the distal tunnel, exiting back through the isometric point and into the ulnar tunnel.

The graft is then tensioned in 40 degrees of flexion, full pronation, and axial tension.

If the graft is not long enough to reach the ulnar tunnel, it can be sutured back to itself (TECH FIG 2B).

The reconstruction can be reinforced by weaving a no. 2 Fiberwire suture (Arthrex, Inc., Naples, FL) from distal to proximal through the course of the figure 8, thus sewing the graft to itself.

Plicate the anterior and posterior capsule as needed.

The extensor origin is repaired to the lateral epicondyle, and the extensor carpi ulnaris fascia is reapproximated to the anconeus muscle with absorbable sutures.

### TECH FIG 1
C. A suture is passed through the two holes and tied to itself. The suture is then held up with a hemostat against the lateral epicondyle as the elbow is ranged in flexion and extension to determine its isometric point. No movement occurs if the suture is at the isometric point.

### TECH FIG 2
A. A Y-shaped tunnel is made with the base exiting at the isometric point (3). The hole is widened to accept a three-ply graft. The tendon graft is passed through the ulnar tunnel (1→2) with enough length to just reach the isometric point. The end is then sutured to the long end of the graft (the Yoke stitch). The long end is then passed through the isometric point and exits the superior humeral tunnel (3→4).
B. The long end is then passed through the distal tunnel, exiting back through the isometric point (5→3) and into the ulnar tunnel (3→1→2). The graft is then tensioned in 40 degrees of flexion, full pronation, and axial tension. If the graft is not long enough to reach the ulnar tunnel, it can be sutured back to itself.

### SPLIT ANCONEOUS FASCIA TRANSFER
- We have developed a reproducible technique for LCL reconstruction that has proved biomechanical strength and reproducibility.
- Advantages include using only local autograft tissue and the minimal creation of bone tunnels.\(^1\)\(^2\)

### Surgical Approach
- A 6- to 8-cm skin incision is made over the Köcher interval, exposing the underlying Köcher interval between the extensor carpi ulnaris and anconeus (TECH FIG 3A,B).
- The interval between the anconeus and extensor carpi ulnaris muscles is developed, taking care to preserve the remainder of the underlying LCL complex.
- The annular ligament, lateral epicondyle, and 2 cm of supracondylar ridge are isolated (TECH FIG 3C).

### Graft Preparation
- The anconeus and distal triceps fascia are isolated in continuity. A 1.0-cm-wide by 8.0-cm-long band of fascia is mobilized off the underlying muscle, leaving the ulnar insertion intact (TECH FIG 4A,B).
A 6- to 8-cm skin incision is made over the Kocher interval. SR, supracondylar ridge; L, lateral epicondyle; RH, radial head; UC, ulnar crest. The underlying Kocher interval between the extensor carpi ulnaris (E) and anconeus (A) is exposed. The interval between the anconeus (A) and the extensor carpi ulnaris (E) is developed, taking care to preserve the remainder of the underlying lateral collateral ligament complex (held in forceps). The annular ligament (AL), lateral epicondyle (L), and 2 cm of the supracondylar ridge are isolated.

The band is then divided longitudinally into two bands of equal width (TECH FIG 4C).

The anterior band is passed through an incision just distal to the annular ligament while the posterior band is passed under the anconeus muscle (TECH FIG 4D).

The isometric point of the lateral epicondyle is then located by holding the two bands against the epicondyle while ranging the elbow (TECH FIG 4E).

The final lengths of the fascial bands are estimated by holding the bands along their respective paths. The bands are then trimmed appropriately to prevent them from “bottoming out” prematurely in the humeral docking tunnel.

Separate Krackow sutures are placed in each band with no. 0 FiberWire suture.

**Tunnel Preparation**

A 5-mm round burr is used to create a 1.5-cm-long (depth) docking tunnel into the humerus at the isometric point. A 1-mm side-cutting burr is then used to make anterior and posterior bone bridge holes. The holes are separated by 1.5 cm. Individual suture lassos are placed from proximal to distal into the docking tunnel from the separate humeral tunnels (TECH FIG 5).
Graft Passage and Tensioning and Wound Closure

- The anterior band sutures are brought out the anterior humeral exit hole by using suture passers. The posterior band passes superficial to the annular ligament, and its sutures are brought out the posterior humeral exit tunnel.
- The ends of the fascial bands are docked into the humeral tunnel, and the grafts are tensioned with the elbow in 40 degrees of flexion, in full pronation, and with a valgus stress.
- The sutures are then tied over the bony bridge on the supracondylar ridge (TECH FIG 6A).
- The extensor origin is then repaired to the lateral epicondyle and the extensor carpi ulnaris fascia is reapproximated to the anconeus muscle with absorbable sutures.
- The skin is closed with a running subcuticular suture (TECH FIG 6B).
TECH FIG 6 • A. The ends of the fascial bands are docked into the humeral tunnel, and the grafts are tensioned with the elbow in 40 degrees of flexion, full pronation, and valgus stress. Sutures are then tied over the bony bridge on the supracondylar ridge (clamp on posterior band). B. The incision is closed with subcuticular suture.

DOCKING TECHNIQUE

- As previously discussed, the Köcher approach is used for the docking technique.
- Preparation of the ulnar drill holes is described in the section on the figure 8 yoke technique elsewhere in this chapter.
- A 5-mm round burr is used to create a 1.5-cm-long (depth) docking tunnel into the humerus at the isometric point. A 1-mm side-cutting burr is then used to make anterior and posterior bone bridge holes. The holes are separated by 1.5 cm. Individual suture lassos are placed from proximal to distal into the docking tunnel from the separate humeral tunnels (see Tech Fig 5).
- After passage of the graft through the ulnar tunnels, the final lengths of the two graft strands are estimated by holding the strands against the docking tunnel with the arm in the “reduced” position of 40 degrees of flexion, full pronation, and axial tension.
- The strands are then trimmed appropriately to prevent the strands from “bottoming out” prematurely in the humeral docking tunnel.
- Separate Krackow sutures are placed in each graft strand with no. 0 FiberWire suture for 1 cm.
- The anterior graft strand sutures are brought out the anterior humeral exit hole by using suture passers. The posterior graft strand sutures are brought out the posterior humeral exit tunnel.
- The ends of the humeral graft portion are docked into the humeral tunnel, and the grafts are tensioned with the elbow in 40 degrees of flexion, in full pronation, and with a valgus stress.
- The sutures are then tied over the bony bridge on the supracondylar ridge.
- Standard incision closure is performed.

DIRECT REPAIR

- As previously discussed, the Köcher approach is used for direct repair.
- If the LCL complex is intact but avulsed from its ulnar or humeral attachments (or both), it can be directly repaired to its correct anatomic location with suture anchors or bone tunnels.
- A running locked no. 2 FiberWire suture is placed into the detached LCL complex and repaired back to its origin on the lateral epicondyle through the anterior and posterior drill holes (TECH FIG 7).
- A careful repair of the extensor origin and the interval between the anconeus and the extensor carpi ulnaris is performed.

TECH FIG 7 • Primary lateral ulnar collateral ligament repair. Running locked suture placed through detached lateral ulnar collateral ligament. A relaxing incision can be made at its attachment to the base of the annular ligament. Repair through drill holes in the lateral epicondyle.
PEARLS AND PITFALLS

Indications
- Iatrogenic causes (e.g., “tennis elbow” surgery) very common
- Careful history and physical examination to exclude other pathologic conditions
- History of numerous lateral elbow corticosteroid injections

Split anconeus fascia technique: exposure
- Isolate Köcher interval; fatty stripe within interval.
- Anconeus fibers oblique to extensor carpi ulnaris
- Identify LCL disruption.
- Isolate annular ligament; protect posterior interosseous nerve.

Split anconeus fascia preparation
- Be careful to harvest long enough fascial band (proximal to humeral bone tunnels).
- Be careful not to detach from ulnar insertion.
- Isolate LCL complex isometric point of origin.
- Harvest fascial band in line with old LUCL.

Figure 8 yoke technique
- Carefully isolate isometric point on lateral epicondyle, usually more anterior and inferior; err on inferior placement.
- Make ulnar tunnel perpendicular to direction of LUCL.
- Chamfer bone tunnels to prevent graft impingement and breakage.

Bone tunnel preparation
- Maintain sufficient bony bridge between tunnels.
- Smooth edges to prevent graft irritation.

Arm position for final graft tensioning
- 40 degrees of elbow flexion
- Full pronation
- Axial load, valgus stress

POSTOPERATIVE CARE

- Stage I (0 to 3 weeks)
  - Elbow immobilization in posterior splint or brace at 40 degrees of flexion
  - Wrist and hand isometrics as tolerated
  - Shoulder active and passive ROM
- Stage II (3 to 6 weeks)
  - Hinged elbow brace or orthoplast splint, with limits set by surgeon
  - Begin flexor–pronator isometrics
  - Continue with wrist and hand strengthening
  - Continue shoulder as above
  - Active-assisted ROM: 20 to 120 degrees of flexion; keep forearm pronated at all times
- Stage III (6 to 12 weeks)
  - Discontinue immobilization
  - Passive ROM and active-assisted ROM to full motion, including supination
  - Begin unrestricted strengthening of flexor–pronators and extensors
- Stage IV (3 to 6 months)
  - Avoid varus stress to elbow and ballistic movement in terminal elbow ranges
  - Begin shoulder strengthening with light resistance (emphasis on cuff)
  - Start total body conditioning
  - Terminal elbow stretching in flexion and extension
  - Resistive elbow exercises as tolerated

OUTCOMES

- Nestor et al. have shown successful functional outcomes in patients using the figure 8 reconstruction technique with reproducible results.

- Our early experience with the split anconeus fascia reconstruction technique has shown excellent results, with no failures to date in 22 patients at an average follow-up of 2 years. All elbows have achieved stability without loss of motion.

COMPLICATIONS

- Recurrent elbow instability
- Elbow stiffness
- Infection
- Graft harvest site morbidity (if remote autograft is used for reconstruction)
- Humerus stress fracture through bone tunnels
- Ulnar stress fracture through bone tunnels
- Bone bridge compromise

REFERENCES

2. Chebli CM, Murthi AM. Split anconeus fascia transfer for reconstruction of the elbow lateral collateral ligament complex: anatomic and biomechanical testing. 22nd Open Meeting of the American Shoulder and Elbow Surgeons. Chicago, IL, March 2006.
DEFINITION
- Primary osteoarthritis of the elbow is a relatively uncommon but limiting disorder that affects mostly middle-aged men who use the upper extremity in a repetitive fashion. Typically, patients are heavy manual workers or athletes. Osteoarthritis affects the elbow less frequently than other major joints.
- Early stages of arthritis of the elbow may be characterized primarily by pain at the extremes of motion, with some loss of terminal extension and flexion. Some patients present with pain carrying an object with the arm in extension. More advanced stages may present with pain and crepitus throughout the range of motion, stiffness, or locking. Rotation of the forearm may be spared, depending on radiohumeral involvement.
- Radiographs show osteophyte formation on the coronoid and olecranon but relatively preserved joint space at the early stages. More advanced stages may be associated with significant joint space narrowing.
- Multiple operative techniques have been described for treatment of primary osteoarthritis of the elbow: débridement arthroplasty, interposition arthroplasty, the Outerbridge-Kashiwagi procedure, arthroscopic débridement, and total elbow replacement.
- Ulnohumeral (Outerbridge-Kashiwagi) arthroplasty was first described in 1978 and became popular a few years later. It is based on a posterior approach to the elbow, removal of olecranon spur and bony overgrowth of the olecranon fossa, and drilling of a hole in this fossa with a trephine to expose the anterior capsule and excise the coronoid osteophyte.

ANATOMY
- The elbow joint consists of three separate articulations: the ulnohumeral, the radiocapitellar, and the proximal radioulnar joints.
- The elbow has two main functions: position the hand in space and stabilize the upper extremity for motor activities and power.
- The normal range of elbow flexion–extension is 0 to 150 degrees and normal forearm pronation–supination is 80 and 80 degrees.
- A 100-degree flexion–extension arc of motion, from 30 to 130 degrees, is quoted for normal activities of daily living. Functional forearm rotation is quoted as 100 degrees, with 50 degrees pronation and 50 degrees supination.
- The condyles articulate at the elbow joint, as the trochlea medially and the capitellum laterally. The articular surface is angled about 30 degrees anterior to the axis of the humeral shaft and has a slight valgus position, about 6 degrees, compared to the epicondylar axis.
- The coronoid fossa and the olecranon fossa, just proximal to the articular surface, accommodate the coronoid process and olecranon process of the ulna in the extremes of flexion and extension, respectively.
- The olecranon and coronoid process coalesce to form the greater sigmoid notch, the articulating portion of the proximal ulna. It is often not completely covered with articular cartilage centrally.

PATHOGENESIS
- Symptomatic osteoarthritis of the elbow has been found to affect about 2% of the general population and represents only 1% to 2% of all patients diagnosed with degenerative arthritis.
- It has a predilection for males, with a ratio of 4 or 5 to 1. It is most commonly seen in middle-aged and older patients.
- The majority of patients experience symptoms in their dominant extremity.
- The exact etiology of primary degenerative elbow arthritis is still unknown. It is generally attributed to overuse. About 60% of patients report employment or hobbies or sports requiring repetitive use of the limb. The few younger patients who present likely have a predisposing condition such as osteochondritis dissecans.
- There are characteristic pathologic changes that occur within the elbow joint: osteophyte formation on the olecranon, olecranon fossa, coronoid, and coronoid fossa.
- In early stages the joint space is relatively preserved. The periarticular bone is typically hard.
- Very often, loose bodies may be present into the joint and cause clicking or locking of the elbow, or both.
- Capsular contracture and fibrosis of the anterior capsule contribute to loss of extension.

NATURAL HISTORY
- Early stages of primary osteoarthritis of the elbow are characterized by pain at the extremes of motion and some loss of terminal extension and flexion. As the severity of the arthritis progresses, pain, stiffness, and loss of range of motion increase.
- When symptoms do not improve with nonoperative treatment, surgical intervention is indicated.
- Because osteoarthritis is a progressive disease, symptoms and pathologic condition may recur. The most common problem is recurrence of impingement pain and flexion contractures.
- Prognostic factors include the etiology of arthritis, the degree of motion loss, mid-arc versus end-range discomfort, the presence of loose bodies, mechanical symptoms, and the presence or absence of cubital tunnel syndrome.
PATIENT HISTORY AND PHYSICAL FINDINGS

- The typical patient with primary degenerative elbow arthritis is a man older than 45 years of age, exposed to repetitive manual labor, who presents with pain at the end ranges of motion, especially in extension.
- Younger patients also may provide a history of sports such as weightlifting, boxing, and other throwing-intensive activities. Arthritic elbows in athletes frequently will include a spectrum of pathologic changes, such as loose bodies and bone spurs.
- Some patients report a history of chronic use of crutches or wheelchairs.
- The chief complaint is pain, especially terminal extension pain, as a result of mechanical impingement.
- Patients usually feel pain while carrying objects with the elbow in full extension.
- The intensity of pain is mild to moderate and only occasionally is described as severe.
- Pain is not usually noted in the mid-range of motion until later stages of arthritis.
- Loss of motion is the most common presenting symptom.
- Loss of extension is often partially the result of posterior olecranon and humeral osteophytes or anterior capsule contracture.
- Loss of flexion is secondary to osteophytes on the coronoid or its fossa and to loose bodies.
- Supination–pronation is not restricted or is only minimally restricted, owing to limited involvement of the radiohumeral joint.
- Catching or locking may be present with articular incongruity, or when loose bodies are present.
- Crepitus may be present throughout the range of motion.
- Swelling may occur but is not typical.

- Ulnar nerve symptoms may also be present owing to excessive osteophyte formation. They should actively be sought out because they may influence treatment decisions and even direct the surgical approach.
- Physical examination may reveal a positive Tinel sign and a positive elbow flexion test, with decreased sensation and weakness in the ulnar nerve distribution. Cubital tunnel syndrome may be present in up to 20% of patients.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Anteroposterior (AP), lateral, and oblique radiographs (FIG 1) are diagnostic and illustrate characteristic features of the condition.
- The AP view should be taken with the beam perpendicular to the distal humerus for distal humerus pathology and perpendicular to the radial head for proximal forearm pathology. These views will show ossification and osteophyte formation of the olecranon and coronoid fossa.
- The lateral view should be taken in 90 degrees of flexion with the forearm in neutral rotation. This view will show an anterior osteophyte on the coronoid fossa and process and a posterior osteophyte on the olecranon fossa and process.
- The lateral oblique view provides better visualization of the radiocapitellar joint, medial epicondyle, and radioulnar joint.
- The medial oblique view provides better visualization of the trochlea, olecranon fossa, and coronoid tip.
- A cubital tunnel view may be useful if there is ulnar nerve symptomatology.
- A lateral tomogram and computed tomography are helpful for preoperative planning to assess the presence and location of loose bodies and subtle osteophyte formation (especially in earlier stages).

FIG 1 • A. Lateral radiograph of a 50-year-old heavy laborer’s elbow. The patient had severe pain at the extremes of motion. The radiograph reveals characteristic osteophytes of the olecranon and of the coronoid process. B. AP radiograph of the elbow (same patient). This view shows ossification and osteophytes of the olecranon and coronoid fossa. C. Lateral oblique radiograph. This view provides better visualization of the radiocapitellar and radioulnar joint. There is an osteophyte at the tip of the olecranon, which causes pain during full extension.
DIFFERENTIAL DIAGNOSIS
- Posttraumatic arthritis
- Rheumatoid (inflammatory) arthritis

NONOPERATIVE MANAGEMENT
- Nonoperative treatment may be helpful in the early stages.
- Patients should limit activities that require heavy elbow use.
- Physical therapy is used to maintain range of motion and strength. Modalities such as heat and cold may be effective.
- Nonsteroidal anti-inflammatory drugs can decrease pain and are of some value. Intra-articular corticosteroid injections may also improve symptoms, but their benefits are usually temporary.
- Avoidance of pressure on the cubital tunnel and avoidance of prolonged elbow flexion are recommended if ulnar nerve symptoms are present.

SURGICAL MANAGEMENT
- Surgical treatment is indicated when symptoms do not improve with appropriate nonoperative management.
- The procedure is indicated in patients with pain in terminal extension or flexion (or both), radiographic evidence of coronoid or olecranon osteophytes (or both), ulnar neuropathy, and functional limitations due to pain or loss of motion.
- The procedure is contraindicated in patients with pain throughout the entire arc of motion, marked limitation of motion with an arc of less than 40 degrees, or severe involvement of the radiohumeral or proximal radioulnar joints.

Preoperative Planning
- It is very important to carefully review all radiographs (AP, lateral, oblique) before surgery to assess the severity of arthritic changes and evaluate for the presence of loose bodies. A lateral tomogram or CT scan may assist in this evaluation. Care should be taken not to overlook any loose bodies, as these may lead to persistent mechanical symptoms postoperatively.
- Specific attention should be paid to the presence of ulnar nerve pathology. If present, this must be addressed at the time of the procedure.

Positioning
- There are two options for positioning:
  - The patient may be positioned in the lateral decubitus position with the elbow flexed at 90 degrees and resting on an armrest.

EXPOSURE
- After the skin incision is made, the subcutaneous tissue is reflected from the medial aspect of the triceps.
- The ulnar nerve is identified and decompressed at the cubital tunnel if there is evidence of ulnar nerve pathology.
- The triceps muscle-tendon unit is split longitudinally or reflected.
- The triceps is elevated from the posterior aspect of the distal humerus by blunt dissection using a periosteal elevator.
- A capsulotomy is then performed (TECH FIG 1).
Chapter 42  ULNOHUMERAL (OUTERBRIDGE-KASHIWAGI) ARTHROPLASTY

**OSTEOPHYTE REMOVAL AND OLECRANON RESECTION**

- To minimize impingement in extension, the posterior osteophyte and the tip of the olecranon are removed using an oscillating saw. An osteotome is then used to complete the resection. The orientation of the osteotomy should be parallel to each face of the trochlea.

- A rongeur is used to smooth the edges.

- A hole is drilled in the olecranon fossa to gain access to the anterior elbow compartment and the coronoid process. This requires removal of osteophytes around the olecranon fossa (TECH FIG 2).

**TECH FIG 1** • The triceps muscle has been split to expose the posterior joint. The prominent olecranon osteophyte and the tip of the olecranon process are then removed. The initial cut should be made with an oscillating saw to provide optimal orientation. The osteotomy of the olecranon is completed with an osteotome parallel to each face of the trochlea.

**FORAMINECTOMY**

- A 1.5-cm neurosurgical dowel is applied to a reaming drill bit, and a drill hole is developed. Proper placement of this foraminectomy is of great importance. The dowel should follow the curvature of the trochlea.

- Once the foraminectomy is complete, a core of bone is removed from the distal humerus. This may include osteophytes from the anterior aspect of the joint (TECH FIG 3A,B).
TECH FIG 3 • A,B. Once the foraminectomy is completed, the core of bone is removed from the distal humerus. This allows access to the anterior elbow compartment and to the coronoid. At this time, loose bodies of the anterior compartment may be identified and removed. C. With maximum elbow flexion, the anterior osteophyte from the coronoid process is removed, using a curved osteotome. D. An instrument is then introduced through the foramen and the osteophyte and a portion of the coronoid are removed.

This hole is used to clean debris and remove loose bodies from the anterior aspect of the elbow (TECH FIG 3C,D).

With maximum elbow flexion, the anterior osteophyte from the coronoid process is removed using a curved osteotome.

Occasionally it is necessary to strip the anterior capsule from the anterior humerus using a blunt periosteal elevator, to regain better extension.

Care must be taken to ensure that no osteophytes or loose bodies are overlooked.

Bone wax is used to cover the margins of the foramen, and Gelfoam is inserted into the defect to fill the dead space.

The wound is meticulously irrigated and closed in standard fashion.

The elbow is carefully manipulated to maximize the total arc of motion.

PEARLS AND PITFALLS

Indications

- Primary osteoarthritis of the elbow presenting with pain at the extremes of motion due to osteophyte formation on the olecranon or coronoid process (or both) and in the olecranon or coronoid fossa (or both)

Contraindications

- Severe involvement of the radiohumeral joint
- Pain throughout the entire arc of motion

Assessment

- Careful selection of patients is important.
- Appropriate imaging studies should be obtained to identify all loose bodies or osteophytes. A preoperative lateral tomogram may be indicated.
- The surgeon should always evaluate for coexisting ulnar nerve pathology, which should be addressed during surgery.

Operation

- Proper placement of foraminectomy
- Meticulous inspection of posterior and anterior aspects of the joint
- Removal of all loose bodies and osteophytes
POSTOPERATIVE CARE

- A splint is applied with the elbow in 15 degrees of extension for 1 week.
- Active range of motion is allowed 7 to 10 days after surgery.
- The patient is re-evaluated at 3 weeks, 6 weeks, and 3 months after surgery.
- Continuous passive motion can be initiated on the day of surgery and is discontinued after 3 weeks.

OUTCOMES

- A review of the literature shows satisfactory results in over 80% of patients.
- Satisfactory pain relief is achieved in about 90% of patients.
- Extension improves by about 10 to 15 degrees and flexion improves by about 10 degrees. Overall improvement in the motion arc is about 20 to 25 degrees (FIG 3).
- There have been no reports of postoperative instability.

COMPLICATIONS

- The complication rate for this procedure is very low, in contrast to most reconstructive procedures of the elbow.
- The recurrence rate is less than 10%.
- Iatrogenic ulnar nerve palsy is unusual, but can occur as a result of overzealous use of retractors intraoperatively.
- Improper placement of the foraminectomy may result in a column fracture.

REFERENCES

DEFINITION
- Extrinsic elbow contracture refers to elbow stiffness secondary to fibrosis, thickening, and, occasionally, ossification of the elbow capsule and periarticular soft tissues.
- In contrast to intrinsic contracture, the articular surface is either uninjured or minimally involved, without the presence of intra-articular adhesions or articular cartilage destruction.
- While a distinction is made between extrinsic and intrinsic causes of contracture, these entities often overlap.

ANATOMY
- The elbow is a compound uniaxial synovial joint comprising three highly congruous articulations.
- The ulnohumeral joint is a ginglymus, or hinge, joint. The radiocapitellar and proximal radioulnar joints are gliding joints.
- All three articulations exist within a single capsule and are further stabilized by the proximity of the articular surface and capsule to the intracapsular ligaments and overlying extracapsular musculature.

PATHOGENESIS
- The propensity for elbow stiffness after even trivial elbow trauma is well recognized. After even seemingly trivial injuries, the capsule can undergo structural and biochemical alterations leading to thickening, decreased compliance, and loss of motion.
- Causes of extrinsic elbow contracture include capsular contracture, damage to and fibrosis of the flexor–extensor muscular origins, collateral ligament scarring, heterotopic bone, and skin contracture.
- Prolonged immobilization after trauma may be a separate risk factor for the development of stiffness.

NATURAL HISTORY
- Little consensus exists regarding the natural history of capsular contracture. It is felt that appropriate recognition and treatment of acute elbow injuries, avoidance of prolonged immobilization, and early active range of motion may limit the severity of posttraumatic extrinsic contracture.
- Patients typically do not tolerate elbow stiffness well since adjacent joints do not provide adequate compensatory motion.
- Morrey\(^\text{10}\) showed that the performance of most activities of daily living requires a functional arc of motion from 30 to 130 degrees.
- Vasen and colleagues\(^\text{11}\) have demonstrated that volunteers with uninjured elbows may adapt to a functional arc of motion from 70 to 120 degrees to perform 12 tasks of daily living.
- Patients typically request treatment for elbow contracture when loss of extension approaches 40 degrees and flexion does not exceed 120 degrees.
- Patients who do not improve with a concerted effort at nonoperative treatment often require surgical release.
- Stiffness of the elbow typically is incited by soft tissue trauma, hematrhrosis, and the patient’s response to pain. Elbow trauma may cause tearing and contusion of the periarticular soft tissues. The patient typically holds the injured elbow in a flexed position to reduce pain. A fibrous tissue response then ensues within the hematoma and damaged muscular tissues. This fibrous tissue may ossify. In addition, overly aggressive therapy may further exacerbate these injuries, potentiating the cycle of pain, swelling, and limitation in motion that leads ultimately to frank contracture.
- Collateral ligament injury may contribute to contracture. Primary fibrosis may develop within the collateral ligaments because of the initial injury. Alternatively, secondary fibrosis may result from immobilization and scar formation.
- Significant injury to the anterior joint capsule and the overlying brachialis muscle may also result in capsular hypertrophy and fibrotic reaction contributing to ankylosis. This is particularly common in association with fracture-dislocations of the elbow.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The cause of contracture should generally be easily elucidated from the history. Particular notation should be made of concomitant injuries, including closed head injury or associated burn injury.
- The duration and possible progression of symptoms should be noted.
- The impact of the contracture on the patient’s upper extremity function and any limitations in activities of daily living should be noted.
- Any previous treatment for contracture should be elucidated. This should include the appropriateness, duration, and results of prior physical therapy, splinting, intra-articular injections, and surgeries.
- For patients with prior elbow surgery, the presence and type of any residual internal fixation devices should be noted. In addition, attention should be paid to any remote history of elbow infection.
- Physical examination should include a general physical examination as well as a detailed examination of the involved extremity.
- Attention must be paid to the examination of the skin and soft tissue envelope about the elbow, with notation made of prior incisions, skin grafts, flaps, or areas of wound breakdown.
- Elbow motion should be measured with a goniometer and active and passive motion should be compared.
- Notation should be made whether motion improves with the forearm in full pronation, which may suggest posterolateral rotatory instability. This effectively “spins” the forearm away from the humerus, causing gapping of the ulnohumeral joint and posterior subluxation of the radial head from the...
capitellum. While frank dislocation is not possible in the unanesthetized patient, guarding is effectively a positive sign.
- While rare, symptomatic incompetence of the ulnar collateral ligament may elucidated by examination.
- Strength of the involved limb should be assessed, as a joint without adequate strength is unlikely to maintain motion after release.
- Since many posttraumatic and inflammatory contractures about the elbow are associated with ulnar nerve symptoms, a careful neurologic examination should be performed. A positive Tinel test over the cubital tunnel as well as a positive elbow flexion test should increase the suspicion for concomitant ulnar nerve pathology.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Anteroposterior (AP) and lateral radiographs are often all that is needed for preoperative planning (FIG 1).
- Cross-sectional imaging with computed tomography is helpful in visualizing the articular surfaces, particularly after fracture.
  - We advocate the use of computed tomography for preoperative planning in cases of moderate to severe heterotopic ossification.
- Extracapsular contracture is typically not painful through the remaining arc of motion and is not painful at rest. If pain is a significant component of the patient’s symptoms, serologic workup for infection, including a complete blood count, erythrocyte sedimentation rate, and C-reactive protein, is indicated.

**DIFFERENTIAL DIAGNOSIS**
- Conversion disorder
- Infection
- Inflammatory arthropathy
- Intracapsular contracture

**NONOPERATIVE MANAGEMENT**
- Alternative measures to improve elbow stiffness include conservative modalities to decrease joint swelling and inflammation and relax or stretch contracted soft tissues. For protracted swelling, edema control sleeves, ice, elevation, active motion (including the forearm, wrist, and hand), and oral agents such as anti-inflammatory medication can be useful.
- A short-term oral prednisone taper can be very effective in difficult cases. In addition, one can consider an intra-articular cortisone injection to decrease inflammation and joint synovitis.
- Rarely, when patients exhibit guarding and involuntary co-contraction, biofeedback may be a helpful adjunct.
- Dynamic splints, which apply a constant tension to the soft tissues, may be helpful.
- Patient-adjusted static braces appear to be more effective. These braces use the principle of passive progressive stretch, allowing for stress relaxation of the soft tissues. They are applied for much shorter periods of time and are better tolerated by patients.

**SURGICAL MANAGEMENT**
- To improve elbow flexion, one must release any soft tissue structures posteriorly that might be tethering the joint. These include the posterior joint capsule and the triceps muscle and tendon, which can become adherent to the humerus.
  - Any bony or soft tissue impingement also must be removed anteriorly, including osteophytes off the coronoid process and any bony or soft tissue overgrowth in both the coronoid and radial fossae.
  - There must be a concavity above the humeral trochlea to accept both the coronoid centrally and the radial head laterally for full flexion to occur.
- Similarly, to improve elbow extension, posterior impingement must be removed between the olecranon tip and the olecranon fossa.
  - Anteriorly, any tethering soft tissues must be released, namely the anterior joint capsule and any adhesions between the brachialis and the humerus.

**Preoperative Planning**
- All radiographic studies should be reviewed.
- The presence and type of any retained implants is noted.
- Range-of-motion and pivot-shift testing is performed under anesthesia as well as under live fluoroscopy.

**Positioning**
- Patients are positioned supine with the arm on a hand table.
- The patient’s torso is brought to the edge of the operating table to ensure adequate elbow exposure for fluoroscopic imaging.
- A towel bump may be placed under the medial elbow.

**Approach**
- A direct posterior skin incision or a lateral incision is used.
- A direct posterior incision has been criticized for an increased propensity toward postoperative seroma formation.
- It has the advantage of being a utilitarian incision that allows access to the medial and lateral sides simultaneously.
- Advantages to the lateral exposure include its simplicity, less extensor and flexor–pronator disruption, and access to all three joint articulations.
- The main disadvantage of the lateral exposure is the inability to address the ulnar nerve when indicated.
- The deep interval for exposure of the anterior capsule lies between the extensor carpi radialis longus (ECRL) proximally and the extensor carpi radialis brevis (ECRB) distally. Posterior access is achieved between the triceps and the humerus.

**SURGICAL APPROACH**

- The procedure can be performed under general anesthesia or under regional anesthesia with a long-acting regional block.
- For the posterior incision, care is taken to avoid placing the line of incision directly over the prominence of the olecranon. Full-thickness fasciocutaneous flaps are elevated laterally to expose the extensor muscle mass.
- For a lateral incision, an extended Köcher approach is used, beginning along the lateral supracondylar ridge of the humerus and passing distally in the interval between the anconeus and the extensor carpi ulnaris (ECU).

**POSTERIOR RELEASE**

- The Köcher interval between the anconeus and ECU is developed.
- The anconeus is reflected posteriorly in continuity with the triceps. This exposes the posterior and posterolateral joint capsule (TECH FIG 1A,B).
- A triceps tenolysis is carried out with an elevator, releasing any adhesions between the muscle and the posterior humerus. The humeroulnar joint is identified posteriorly and the olecranon fossa is cleared of any fibrous tissue or scar that would restrict terminal extension. The tip of the olecranon is removed if there was evidence of overgrowth or impingement (TECH FIG 1C).
The posterior aspect of the radiocapitellar joint is inspected after excision of the elbow capsule just proximal to the conjoined lateral collateral and annular ligament complex through the “soft spot” on the lateral side of the elbow. The proximal edge of this complex lies along the proximal border of the radial head.

**ANTERIOR RELEASE**

- Once the posterior release is completed, dissection is carried anteriorly. The anterior interval proximally is between the lateral supracondylar column and the brachioradialis and ECRL. Distally the interval is between the ECRL and extensor digitorum communis (EDC) (TECH FIG 2A).
- The brachialis is then mobilized off the humerus and anterior capsule with an elevator, releasing any adhesions between the muscle and the anterior humerus (TECH FIG 2B).
- The brachioradialis and ECRL released from the lateral supracondylar ridge of the humerus (TECH FIG 2C).
- This dissection is continued distally between the ECRL and ECRB, allowing exposure of the anterior capsule with preservation of the lateral collateral ligament and the origins of the ECRB, the EDC and minimi, and the ECU from the lateral epicondyle.
- Dissection is then carried out beneath the elbow capsule between the joint and the brachialis. The capsule is excised as far as the medial side of the joint.
- The radial and coronoid fossae are cleared of fibrous tissue and the tip of the coronoid is removed if overgrowth or impingement was noted in flexion. Loose bodies are removed (TECH FIG 2D,E).
- After release of the anterior capsule, gentle extension of the elbow with applied pressure usually brings the joint out to nearly full extension.
- In longstanding cases of contracture, the brachialis muscle can be tight, inhibiting full terminal elbow extension. This myostatic contracture can be stretched for several minutes during the procedure and requires attention at subsequent physiotherapy (TECH FIG 2F).

**TECH FIG 2 • A.** The lateral view of a dissected elbow. Blue lines mark the fascial intervals for access to the anterior and posterior aspect of the joint, which leaves the extensor carpi ulnaris (ECU), extensor digitorum communis (EDC), and extensor carpi radialis longus (ECRL) origins intact as well as the underlying lateral collateral ligament complex. The anterior elbow capsule is exposed by releasing the extensor carpi radialis longus from the lateral supracondylar ridge. Distally the exposure continues between the ECRL and ECRB. T, triceps; BR, brachioradialis. B,C. The anterior exposure for release. The anterior capsule is exposed by detaching the humeral origin of the ECRL proximally and the interval between the ECRL and ECRB distally. The brachialis is released from the anterior capsule. The capsule should be visualized all the way over to the medial joint with all muscle reflected anteriorly. (continued)
Indications
- The importance of prolonged postoperative rehabilitation cannot be stressed enough. A program of active and passive range of motion, weighted elbow stretches with wrist weights, formal therapy, and patient-adjusted elbow bracing is common for 3 to 6 months after surgery.
- Postoperative gains may easily be lost in the patient who is not fully committed to rehabilitation or who does not have access to regular supervised therapy.

Ulnar nerve
- Patients with preoperative signs and symptoms of ulnar nerve irritability should undergo neurolysis and transposition of the ulnar nerve. Although no strict guidelines exist, patients with preoperative flexion less than 100 degrees generally undergo concurrent ulnar nerve release even in the absence of preoperative symptoms.

Median nerve and brachial artery
- These structures are generally well protected by the brachialis muscle. Their safety is increased if dissection proceeds in the interval between the elbow capsule and the brachialis.

Radial nerve injury
- The posterior interosseous nerve may be encountered as extracapsular dissection proceeds distal to the radiocapitellar joint. Care must be taken with more distal dissection, and a firm understanding of neural anatomy is mandatory before attempting capsular release. Except in cases of significant anterolateral heterotopic ossification, we do not routinely dissect and isolate the radial nerve from proximal to distal.

Iatrogenic posterolateral rotatory instability
- Instability may be induced with overly aggressive dissection about the lateral condyle. Care should be taken to stay anterior to the origin of the extensor carpi radialis brevis.

POSTOPERATIVE CARE
- Although several rehabilitation programs may be effective, we have found continuous passive motion, begun immediately in the recovery room and used continuously until the following morning, to be helpful in maintaining the motion gained at surgery (FIG 2A).
- Formal therapy is begun on postoperative day 1.
  - The dressing is removed and edema control modalities (eg, an edema sleeve or Ace wrap, ice) are used to limit swelling.
- Active and gentle passive elbow motion is combined with intermittent continuous passive motion.
- To help maintain extension, weighted passive stretches using a two-pound wrist weight with the arm extended over a bolster are performed several times daily for 10 to 15 minutes as tolerated.
- Because the collateral ligaments are not released at surgery, no restrictions are typically placed on therapy.
- Static progressive elbow bracing is begun early in the postoperative period. The brace is worn for about 30 minutes, two
or three times a day. Flexion and extension are alternated based on the preoperative deficit and the early progress of the elbow (FIG 2B).

- A nonsteroidal anti-inflammatory agent (Indocin) is commonly prescribed as a prophylaxis against heterotopic ossification for several weeks postoperatively. This also helps to limit inflammation of the joint and soft tissues during rehabilitation.
- Patients are typically discharged home on postoperative day 1. Home therapy is performed daily thereafter, including active and passive exercises, continuous passive motion, weighted stretches, and patient-adjusted bracing.
- Progress should be closely monitored by a therapist who is familiar with the protocol. The physician must also follow these patients closely.
- Although the bulk of ultimate elbow motion is gained during the first 6 to 8 weeks, patients can continue to make gains in terminal flexion and extension for several months postoperatively. This is especially true for elbow flexion.
- Continuous passive motion is typically discontinued at 3 to 4 weeks, but bracing is continued for several months as required. As long as the patient is able to obtain full elbow flexion and extension once per day (eg, in the brace), a favorable prognosis exists with respect to the ultimate outcome if vigilance is maintained.

OUTCOMES

- In appropriate patients, release of the contracted elbow can be a reliable and satisfying procedure with predictable results.
- We reviewed our results for 22 patents treated for posttraumatic elbow stiffness using a soft tissue release of the elbow through a lateral approach. The average length of follow-up was 29 months.

- Total elbow motion improved in all subjects. Extension increased from an average of 39 ± 10 degrees preoperatively to 8 ± 6 degrees at follow-up. Elbow flexion increased from 113 ± 18 degrees preoperatively to 137 ± 9 degrees at follow-up. Thus, total ulnohumeral joint motion increased an average of 55 degrees (P < 0.001).
- Elbow pain, as determined by visual analogue scales, decreased in all patients. Elbow function, as determined by standardized scales, also significantly improved.
- Radiographic analysis revealed no patients with regrowth of excised osteophytes or loose bodies at follow-up.

COMPLICATIONS

- Ulnar nerve
  - The most common complication after elbow release surgery involves the ulnar nerve. This may be related in part to improved elbow flexion after surgery, as ulnar nerve tension increases with flexion. This may precipitate symptoms in a nerve that is already subclinically compromised.
  - Patients with preoperative signs and symptoms of ulnar nerve irritability should undergo neurolysis and transposition of the ulnar nerve.
  - Although no strict guidelines exist, patients with preoperative flexion less than 100 degrees generally undergo concurrent ulnar nerve release even in the absence of preoperative symptoms.
- Median nerve and brachial artery
  - Although generally well protected by the brachialis muscle, these structures are at risk with anterior dissection. Their safety is increased if dissection proceeds in the interval between the elbow capsule and the brachialis.
  - In addition, transient median neuritis is known to occur in our practices after release. This is likely due to stretch of the median nerve with extension of the severely contracted elbow.
- Radial nerve injury
  - The posterior interosseous nerve may be encountered as extracapsular dissection proceeds distal to the radiocapitellar joint.
  - Except in cases of significant anterolateral heterotopic ossification, the radial nerve does not typically require identification.
- Persistent stiffness
  - The importance of prolonged postoperative rehabilitation cannot be stressed enough. A program of active and passive range of motion, weighted elbow stretches with wrist weights, formal therapy, and patient-adjusted elbow bracing is common for 3 to 6 months after surgery. All of our patients meet preoperatively both with the therapists at our home institutions as well as with their local therapists.

REFERENCES

DEFINITION

- Multiple techniques have been described for the release of elbow contractures. The medial approach has the advantages of direct access to both the anterior and posterior aspects of the ulnohumeral joint, and direct visualization of the ulnar nerve.
- Medial-based releases were initially proposed by Wilner, whose technique involved medial epicondylectomy and wide dissection.
- Weiss subsequently has described splitting the flexor pronator mass rather than complete release of the flexor pronator mass.
- Hotchkiss popularized this approach to deal with extrinsic contracture of the elbow and ulnar nerve involvement.
- Itoh et al and Wada et al underlined the importance of the posterior oblique band of the medial collateral ligament as a critical structure to identify and release if an extension contracture exists.

ANATOMY

- The medial compartment of the elbow includes the medial side of the ulnohumeral joint, the medial collateral ligament, the flexor–pronator mass, the ulnar nerve, and the median antebrachial cutaneous nerve (FIG 1A).
- The medial ulnohumeral joint is composed of the medial column, the medial epicondyle, the medial side of the proximal aspect of the ulna, and the coronoid process.
- The medial collateral ligament consists of three parts: anterior, posterior, and transverse segments (FIG 1B).
- The anterior bundle is the most discrete component, the posterior portion being a thickening of the posterior capsule, and is well defined only in about 90 degrees of flexion.
- The transverse component appears to contribute little or nothing to elbow stability.
- The medial collateral ligament originates from a broad anteroinferior surface of the epicondyle but not from the condylar elements of the trochlea just inferior to the axis of rotation. The ulnar nerve rests on the posterior aspect of the medial epicondyle, but it is not intimately related to the fibers of the anterior bundle of the medial collateral ligament itself.
- The flexor–pronator mass includes the pronator teres, the most proximal of the flexor pronator group; the flexor carpi radialis, which originates just inferior to the origin of the pronator teres at the anteroinferior aspect of the medial epicondyle; the palmaris longus muscle, which arises from the medial epicondyle and from the septa it shares with the flexor carpi radialis and flexor carpi ulnaris; the flexor carpi ulnaris, which is the most posterior of the common flexor tendons originating from the medial epicondyle and from the medial border of the coronoid and the proximal medial aspect of the ulna; and the flexor digitorum superficialis, which is the deepest from the common flexor tendon but superficial to the flexor digitorum profundus.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Diagnosis of the contracture is usually made by identifying a characteristic history and performing a physical examination.
- Joint involvement is confirmed by plain radiographs. The anteroposterior (AP) view gives good visualization of the joint line, but the lateral view demonstrates osteophytes on the coronoid and at the tip of the olecranon, even when the joint space is preserved.
- The details of the extent of the involvement are best observed on computed tomography.
- Transverse imaging by magnetic resonance imaging (MRI) has little utility in our practice.

NONOPERATIVE MANAGEMENT

- Several options have been proposed for the treatment of elbow contracture.
- Nonoperative treatment with mobilization of the elbow through the use of alternating flexion and extension splints sometimes provides a good result if it is begun soon after the contracture develops.
- Manipulation with the patient under anesthesia has also been recommended, but loss of motion and ulnar nerve injury have been reported.
- Recently, botulinum toxin has been used to release muscle contracture in order to improve elbow rehabilitation.
- Nonoperative treatment usually is successful only for extrinsic stiffness that has been present for 6 months or less, however, and the results are unpredictable. With failure of nonoperative treatment, surgical release may be indicated. Some reports of this being done through an arthroscopic procedure recently appeared. Most surgeons employ an open procedure, and several have been described.

SURGICAL MANAGEMENT

Indications

- Contracture release
- Stiff elbow
- Degenerative arthritis with anterior and posteromedial osteophytes
- Ulnar nerve symptoms

Advantages

- Allows exposure, protection, and transposition of the ulnar nerve
- Preserves the anterior band of the medial collateral ligament
- Affords access to the coronoid with intact radial head
Disadvantages
- Difficulty in removing heterotopic bone on the lateral side of the joint
- Affords poor access to radial head

Preoperative Planning
- Before surgery, the decision must be made to approach the capsule from the lateral or medial aspect.
- If the ulnar nerve is to be addressed or there is extensive medial or coronoid arthrosis, the medial approach is of value.
- If the radiohumeral joint is involved or if a simple release is all that is required, the lateral “column” procedure is carried out.

Positioning
- The patient is usually positioned supine, supported by an elbow or a hand table.
- Two folded towels should be placed under the scapula.
- A sterile tourniquet is positioned.
To expose the posterior joint, the patient’s shoulder should have fairly free external rotation; otherwise, the arm should be positioned over the chest.

**Approach**

- The skin incision may be a posterior skin incision or a midline medial one (FIG 2).
- The key to this exposure is identification of the medial supracondylar ridge of the humerus.
- At this level, the surgeon can locate the medial intermuscular septum, the origin of the flexor–pronator muscle mass, and the ulnar nerve.
- This site also serves as the starting point of the anterior and posterior subperiosteal extracapsular dissection of the joint.

---

**EXPOSING THE ULNAR NERVE AND THE MEDIAL FASCIA**

- Once the medial intermuscular septum is identified, the medial antebrachial cutaneous nerve is identified, traced distally, and protected.
  - The branching pattern varies, however, so it is occasionally necessary to divide the nerve to gain full exposure and to adequately mobilize the ulnar nerve, especially in revision surgery.
  - If this is necessary, the nerve is divided as proximally as the skin incision will allow, ensuring that the cut end lies in the subcutaneous fat (TECH FIG 1).
- If previously anterior transposition was performed, the ulnar nerve should be fully identified and mobilized before proceeding.
- The surgeon must be prepared to extend the previous incision proximally, as necessary.
- In this setting, the nerve is often flattened over the medial flexor–pronator muscle mass, or it can “subluxate” to a posterior position.
- This dissection requires patience and may take considerable time. Dissection of the nerve needs to be carried distally far enough to allow the nerve to sit in the anterior position without being kinked distal to the epicondyle.
- The septum is excised from the insertion on the supracondylar ridge to the proximal extent of the wound, usually about 5 to 8 cm.
- Many of the veins and perforating arteries at the most distal portion of the septum require cauterization.

**EXPOSING THE ANTERIOR CAPSULE FOR EXCISION AND INCISION**

- Once the septum has been excised, the flexor–pronator muscle mass should be divided parallel to the fibers, leaving roughly a 1.5-cm span of flexor carpi ulnaris tendon attached to the epicondyle (TECH FIG 2A,B).
- The surgeon then returns the supracondylar ridge and begins elevating the anterior muscle with a Cobb elevator.
Subperiosteally, the anterior structures of the distal humeral region proximal to the capsule are elevated to allow placement of a wide Bennett retractor. As the elevator moves from medial to lateral, the handle of the elevator is lifted carefully, keeping the blade of the elevator along the surface of the bone.

- When heterotopic ossification along the lateral distal humerus is profuse, the radial nerve is at risk if it is entrapped in the scar on the surface of the bone.
- A separate approach to the lateral side is sometimes needed.
- The median nerve, brachial vein, and artery are superficial to the brachialis muscle.

A small cuff of tissue of the flexor–pronator origin can be left on the supracondylar ridge as the muscle is elevated. This facilitates reattachment during closing.

- A proximal, transverse incision in the lacertus fibrosus may also be needed to adequately mobilize this layer of muscle.

Once the Bennett retractor is in place and the medial portion of the flexor–pronator has been incised, the plane between muscle and capsule should be carefully elevated.

As this plane is developed, the brachialis muscle is encountered from the underside. This muscle should be kept anterior and elevated from the capsule and anterior surface of the distal humerus.

TECH FIG 2 • A,B. Exposure of the anterior capsule. C–E. After excision of the anterior capsule, visualization of the ulnohumeral joint down to the radiocapitellar joint.
Chapter 44  EXTRINSIC CONTRACTURE RELEASE: MEDIAL OVER-THE-TOP APPROACH

TECHNIQUES

EXPOSING AND EXCISING THE POSTERIOR CAPSULE AND BONE SPURS

- The posterior capsule of the joint is exposed. The supracondylar ridge is again identified (TECH FIG 3).
- Using the Cobb elevator, the triceps is elevated from the posterior distal surface of the humerus.
- The exposure should extend far enough proximal to permit use of a Bennett retractor.
- The posterior capsule can be separated from the triceps as the elevator sweeps from proximal to distal. The posterior medial joint line should also be identified, as it is often involved by osteophytes or heterotopic bone.
- In contracture release, the posterior capsule and posterior band of the medial collateral ligament should be excised.
- Once this edge of the capsule is incised, it can be lifted and excised as far distally as is safe. From this vantage, and after capsule excision, the radial head and capitellum can be visualized and freed of scar, as needed.
- In cases of primary osteoarthritis of the elbow, removing the large spur from the coronoid is crucial.
- Using the Cobb elevator, the brachialis muscle can be elevated anteriorly for 2 cm from the coronoid process.
- With the elevator held in position, protecting the brachialis but anterior to the coronoid, the large osteophyte can be removed with an osteotome.
- The brachialis insertion is well distal to the tip of the coronoid.

ULNAR NERVE TRANSPOSITION

- After being reattached to the medial supracondylar region, the ulnar nerve should be transposed and secured with a fascial sling to prevent posterior subluxation.
- The sling can be fashioned by elevating two overlapping rectangular flaps of fascia or by using a medially based flap attached to the underlying subcutaneous tissue.
- Once this maneuver is completed, the nerve must not be compressed or kinked.
- The joint should be flexed and extended to ensure that the nerve is free to move.
**CLOSURE**

- The flexor–pronator mass should be reattached to the supracondylar ridge with nonabsorbable braided 1-0 or 0 suture.
  - If a large enough cuff of tissue was left on the medial epicondyle, no holes need be drilled in bone.
  - Otherwise, drill holes in the edge of the supracondylar ridge can be made to secure the flexor–pronator mass (TECH FIG 4).

**POSTOPERATIVE CARE**

- If the neurologic examination findings in the recovery room are normal, a brachial plexus block is established and maintained with a continuous pump through a percutaneous catheter.
  - The arm is elevated as much as possible, and mechanical continuous passive motion exercise is begun the day of surgery and adjusted to provide as much motion as pain or the machine itself allows.
  - After 2 days the plexus block is discontinued, and, at day 3, the continuous passive motion machine is stopped.
  - Physical therapy is not used, but a detailed program of splint therapy is prescribed.
  - Adjustable splints are prescribed, depending on the motion before and after the procedure. The splints include a hyperextension or a hyperflexion brace, or both.
  - A detailed discussion regarding heat, ice, and anti-inflammatory medication, along with a visual schedule for bracing, is provided.
  - During the first 3 months, the patient sleeps with the splint adjusted to maximize flexion or extension, whichever is more needed; it should not be so uncomfortable as to prevent sleeping for at least 6 hours.
  - Because the principal objective is to gain motion but to avoid pain, swelling, and inflammation, routine use of an anti-inflammatory medication is prescribed.
  - Therapy with splints is continued for about 3 months, during which time the patient is seen at 2- to 4-week intervals, if possible.
  - After 4 weeks, an arc of about 80 degrees of motion is obtained, and the amount of time that each splint is worn is gradually decreased.
  - Splinting at night is continued for as long as 6 months if flexion contracture tends to recur when the splint is not used.
  - Patients are advised that it may take a year to realize full correction.

**OUTCOMES**

- Recent reports on the results of surgical arthrolysis reveal an absolute gain in the flexion–extension arc between 30 and 60 degrees, \(1,3,5,7,9-11,14-16,19,21\)
  - A functional arc of motion between 30 and 130 degrees is obtained in more than 50% of cases, and some improvement in motion in more than 90% of the cases has been reported in the literature. \(1,3,5,7,9-11,14-16,19,21\)
  - In Europe, a combined lateral and medial approach has been used for many years, and gains in flexion arc have averaged between 40 and 72 degrees (in about 400 procedures). \(1,3,7,14\) Some preferred a posterior extensile approach if medial and lateral exposures are anticipated.
  - The importance of sequential release of tissues has been emphasized, based on an experience with 44 of 46 patients
Antuna et al.\(^\text{2}\) recommended that elbows with preoperative presence or absence of ulnar nerve symptoms. Patients who have stiff elbows must be evaluated for the preoperative period to decompress the ulnar nerve when ulnar nerve symptoms exist preoperatively.\(^\text{13}\)

Using a medial approach, Wada et al.\(^\text{12}\) obtained improvement of the mean arc of movement of 64 degrees. A functional arc of flexion–extension (30 to 130 degrees) was obtained in 7 of the 14 elbows. None of the patients developed symptoms related to the ulnar nerve. According to those authors, the medial approach has several advantages over both the anterior and lateral approaches:

- Pathologic changes in the posterior oblique bundle of the medial collateral ligament can be observed and excised under direct vision.
- Anterior and posterior exposure is possible through one medial incision, through which a complete soft tissue release and excision of part of the olecranon and coronoid process can be undertaken if necessary. Additional lateral exposure is indicated only if the medial approach has proved to be inadequate.
- In the medial approach, the ulnar nerve is routinely released and protected under direct vision, which decreases the risk of damage.

**COMPLICATIONS**

- A most important emerging consideration of the proper treatment of elbow stiffness is the vulnerability of the ulnar nerve.
- The most common cause of failure of treatment has been in patients whose preoperative ulnar nerve symptoms were not appreciated or addressed, or patients in whom ulnar nerve symptoms developed postoperatively without adequate treatment. This is attributable to traction neuritis caused by the abrupt increase in elbow flexion or extension during the operation.
- Even in the absence of preoperative neurologic symptoms, the nerve may be compromised subclinically and become symptomatic as elbow motion increases after surgery. Therefore, all patients who have stiff elbows must be evaluated for the presence or absence of ulnar nerve symptoms.
- Antuna et al.\(^\text{2}\) recommended that elbows with preoperative flexion limited to 90 to 100 degrees in which we expect to improve the motion by 30 or 40 degrees must be treated with inspection and often prophylactic decompression or translocation of the nerve, depending on the appearance of the nerve once the surgical procedure is finished.
- Furthermore, all patients with preoperative ulnar nerve symptoms, even if they are mild, are treated with mobilization of the nerve.
- These authors stated that manipulation of the elbow in the early postoperative period must be avoided if the nerve has not been decompressed or translocated.

**REFERENCES**

DEFINITION
- Rheumatoid arthritis (RA) is a chronic, systemic, inflammatory condition of unknown etiology affecting 1% to 2% of the population.
  - It affects females two to three times as frequently as males, and the incidence increases with age, typically peaking between 35 and 50 years of age.
  - Peripheral joints are often affected in a symmetric pattern.
  - The elbow is affected in about 20% to 70% of patients with RA, with a wide spectrum of severity.
- Ninety percent of these patients also have hand and wrist involvement, and 80% also have shoulder involvement.
- Juvenile rheumatoid arthritis (JRA) is diagnosed based on the presence of arthritis, synovitis, or both in at least one joint lasting for more than 6 weeks in an individual less than 16 years old.
  - Compared with adult-onset RA, JRA is complicated by severe osseous destruction, deformity, and soft tissue contractures.

PATHOGENESIS
- The cause of RA is unknown.
  - Infectious etiologies have been proposed, but no microorganism has been proven to be causative.
  - Genetic and twin studies have demonstrated that a genetic predisposition clearly exists, and the disease is also associated with autoimmune phenomena.
  - In patients with RA, numerous cell types, including B lymphocytes, CD4 T cells, mononuclear phagocytes, neutrophils, fibroblasts, and osteoclasts, have been shown to produce abnormally high levels of various cytokines, chemokines, and other inflammatory mediators.
  - The result is inflammatory-mediated proliferation of synovial tissue, leading to soft tissue and finally bony destruction.

NATURAL HISTORY
- Overall, the disease progresses from predominantly soft tissue (synovial) inflammation to articular cartilage damage and ultimately subchondral and periarticular bone destruction.
- Manifestations of RA are initiated by synovitis and synovial hyperplasia resulting in pannus formation. This correlates with a boggy, inflamed elbow that is painful and with limited range of motion.
- Synovial proliferation coupled with joint capsule distention may produce a compressive neuropathy with pain, paresthesias, or weakness in the ulnar or radial nerve distributions, or both.
- Degeneration may progress to ligamentous erosion or disruption, or both. Clinically, the patient experiences progressive instability as ligamentous integrity is compromised.
  - It may affect the annular ligament and produce radial head instability with anterior displacement.
  - Eventually the medial and lateral collateral ligament complexes may be disrupted, thus causing further instability.
  - Prolonged synovitis leads to erosion of the cartilage followed by subchondral cyst and marginal osteophyte formation; the result is end-stage arthritis.
  - End-stage disease is marked by severe damage to subchondral bone and gross joint instability. At this stage, patients typically have a painful, weak, and functionally unstable elbow.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients typically describe a history of a swollen, tender, and warm elbow with diminished and painful range of motion.
  - This may be accompanied by a report of progressively declining function, constitutional complaints, and often polylarticular involvement.
  - In early stages of the disease, the elbow may appear more boggy, with impressive soft tissue swelling and erythema about the elbow.
  - As the disease progresses to later stages, soft tissue swelling may become less prominent, and the elbow becomes more stiff and painful.

Differences in Examination Findings Between Rheumatoid Arthritis and Juvenile Rheumatoid Arthritis
- Elbows affected by JRA obviously occur in younger patients as compared with elbows affected by RA.
- Patients with JRA also have stiffer elbows and therefore typically do not have instability.
- Often JRA patients have more joints affected by the rheumatoid process, but they also demonstrate a greater tolerance for pain.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) and lateral radiographs of the elbow are obtained to assess the degree of rheumatoid involvement and for preoperative planning (FIG 1). No further studies are typically required.

Classification
- Although several classification systems have been proposed, the most commonly used is the Mayo Radiographic Classification System (Table 1). It allows monitoring of disease progression and often correlates well with clinical examination findings and patients’ functional limitations.
  - The grading system is based on bone quality, joint space, and bony architecture and delineates four grades of progression in order of increasing severity.
to optimize range of motion, as preoperative range of motion is often predictive of postoperative total arc of motion after arthroscopic synovectomy as well as total elbow arthroplasty.

**SURGICAL MANAGEMENT**

- Surgical management of the rheumatoid elbow primarily consists of synovectomy and total elbow arthroplasty.

**Surgical Management of the Elbow Before Total Elbow Arthroplasty**

- For early disease states, excellent clinical results may be achieved with synovectomy performed using open or arthroscopic techniques.
- The goal of synovectomy is to relieve pain and swelling. Although this procedure has not necessarily been shown to alter the natural history of the disease, it reliably produces symptomatic relief for 5 or more years in the majority of cases performed on elbows in the early stages of the disease process.³
- The arthroscopic approach is advantageous over the more traditional open approach in that it is less invasive, is associated with less perioperative morbidity, and also allows predictable access to the sacciform recess. When open synovectomy is performed, the radial head must be excised to access and completely débride the diseased synovial tissue that exists in this region.
- Open synovectomy has traditionally been accompanied by radial head excision due to (1) ubiquitous radiocapitellar and proximal radioulnar joint articular destruction and (2) the need to surgically expose the sacciform recess for the requisite complete synovectomy.
- It has been shown that routine radial head excision may predispose some patients with RA to increasing valgus elbow instability due to the loss of the stabilizing effect of the radial head (particularly if the medial collateral ligament is adversely affected by the rheumatoid process).⁷
- Now that the entire synovial proliferation around the radial neck can be accessed arthroscopically, a combined arthroscopic radial head excision is performed only in patients with stable elbows and preoperative elbow symptoms with forearm rotation. Otherwise, a complete arthroscopic synovectomy is performed without excising the radial head.
- In addition, the minimally invasive nature of an arthroscopic approach yields the potential advantages of less pain, faster recovery with earlier range of motion, and a lower rate of infection compared with an open procedure.
- An arthroscopic anterior capsular release may be performed at the time of the arthroscopic synovectomy to improve elbow extension. A posterior olecranon-plasty may also be performed to re-establish normal concavity of the olecranon fossa.
- Posteromedial capsule release should be avoided to prevent the risk of iatrogenic ulnar nerve injury. If an elbow requires a release of the posterior capsule to regain elbow flexion (typically those with 100 degrees or less of preoperative flexion), then the surgeon should consider performing an open ulnar nerve decompression and subcutaneous transposition followed by complete posterior capsule release (including the posteromedial band of the medial collateral ligament).

Total Elbow Arthroplasty

- This procedure is indicated primarily for advanced (grade III or IV) RA of the elbow in patients with significant pain and limitations in activities of daily living.
- Absolute contraindications include active infection, upper extremity paralysis, and a patient’s refusal or inability to abide by postoperative activity restrictions.
- Relative contraindications include presence of infection at a remote site and a history of infected elbow or elbow prosthesis.

Preoperative Planning

- AP and lateral radiographs of the elbow are reviewed to assess humeral bow and medullary canal diameter as well as angulation and diameter of the ulnar medullary canal.
- Preoperative radiographic templates may be helpful to assess preoperative radiographic magnification.
- In particular for JRA patients, the canal width may be very small, and therefore the surgeon must ensure that appropriately sized implants as well as intramedullary guidewires and reamers are available.
- If an ipsilateral total shoulder arthroplasty has been performed or is anticipated, use of a 4-inch humeral implant and a humeral cement restrictor should be considered.
- Preoperative limitations in forearm rotation may be due in part to ipsilateral distal radioulnar joint pathology. Thus, radiographs should also be obtained on the ipsilateral shoulder and wrist.

Implant Selection for Total Elbow Arthroplasty

- Implant options have traditionally been classified as linked (semiconstrained) or unlinked.
  - These terms are being used with decreasing frequency, however, as unlinked implant designs have been developed that have precisely contoured components that create a degree of constraint.
  - Linked, semiconstrained implants have about 7 degrees of varus–valgus “play” and 7 degrees of axial rotation, while unconstrained implants consist of unlinked, resurfacing components.
  - The stability of unconstrained implants depends on soft tissue and ligamentous integrity, while such tissues may be destroyed by the rheumatoid inflammatory process or surgically released with semiconstrained implants without compromising stability.
  - Although no prospective comparisons between linked (semiconstrained) and unlinked implants have yet been performed, both appear to have similar survivorship records.
  - The semiconstrained design is preferred because it is equally effective in pain relief and in improving range of motion and function, while preserving stability without an observed increase in aseptic loosening.
  - The Techniques section below focuses on implantation of a linked (semiconstrained) implant.

Sequence and Timing of Total Elbow Arthroplasty in the Patient with Polyarticular Involvement

- Because RA typically affects multiple joint articulations, the timing of elbow arthroplasty should be considered with regard to the need for arthroplasties of other joints.
- In general, the most disabling articulation should be addressed first. In the case of equivocal involvement in the elbow and a lower extremity joint in which arthroplasty is planned, the surgeon must consider the postoperative effects of surgery and plan accordingly.
- If total elbow arthroplasty is performed first, at least 3 to 6 months should pass before lower extremity reconstruction is performed to allow adequate healing in the elbow. If the lower extremity will be addressed first, total elbow arthroplasty should be delayed until assistive ambulatory devices, which may put strain on the elbow, are no longer required.
- Patients with total elbow arthroplasty should not weight bear with crutches. A walker may be used, provided it does not increase strain on the elbow. This may be achieved by raising the walker’s arm rests to an appropriate height such that when the forearms are placed on the arm rests, the elbow may not be extended beyond 90 degrees of flexion.

Assessment of the Cervical Spine

- Because nearly 90% of patients with RA have cervical spine involvement, about 30% of whom have significant subluxation, the cervical spine must be evaluated before any surgery in which intubation is likely.
- Cervical spine radiographs should be routinely obtained.
- If patients have neck pain, decreased range of motion, myelopathic symptoms, or radiographic evidence of instability, a magnetic resonance imaging (MRI) study should be ordered with concomitant referral to a spine surgeon to consider addressing the cervical spine pathology before elbow surgery.

Temporary Cessation of Medications Before Total Elbow Arthroplasty

- Tumor necrosis factor (TNF) inhibitors affect the immune system and have been found to increase the risk of developing a prosthetic joint infection.
  - In general, anti-TNF agents are typically stopped for a short period before surgery and for about 2 weeks after surgery to reduce the risk of perioperative morbidity.
  - Patients on chronic NSAIDs should stop taking those medications about 2 weeks before surgery to reduce the risk of increased bleeding.
  - For patients on chronic steroids, stress-dose steroids may be required perioperatively.
  - Communications with the patient’s rheumatologist and the anesthesiologist are imperative to coordinate these efforts.

Positioning

- Intravenous antibiotics are administered 30 to 60 minutes before the incision.
  - The patient is placed in a supine position on the operating table with a rolled towel under the ipsilateral scapula.
  - The entire operative extremity and shoulder girdle is prepared and draped; a sterile tourniquet is placed.
  - The arm is exsanguinated and the tourniquet inflated.

Approach

- Although multiple approaches may be used, the Bryan-Morrey approach (triceps–anconeus “slide”) is preferred.
INCISION AND EXPOSURE

- A straight incision, measuring about 15 cm, is made centered between the lateral epicondyle and the tip of the olecranon.
- The ulnar nerve is carefully identified and isolated along the medial aspect of the triceps.
- Proximal neurolysis of the nerve is achieved by incising the fascia from the medial head of the triceps to the medial intermuscular septum and then mobilized to beyond its first motor branch distally by splitting the cubital tunnel retinaculum, which includes the band of Osborne (the fascia between the two heads of the flexor carpi ulnaris [FCU]) and the FCU fascia (TECH FIG 1A,B).
- The intermuscular septum is excised and a deep pocket of subcutaneous tissue over the flexor pronator group distally and anterior to the triceps proximally is created.
  - The nerve is then anteriorly transposed into this subcutaneous tissue pocket; it must be protected throughout the operation.
- An incision is then made over the medial aspect of the ulna between the anconeus and FCU. The anconeus is subperiosteally elevated off the ulna.
- The medial aspect of the triceps is then retracted along with the fibers of the posterior capsule to tension the Sharpey fibers at their ulnar insertion (TECH FIG 1C,D).

These fibers are then sharply dissected, and the triceps in continuity with the anconeus is reflected from medial to lateral (TECH FIG 1E).
- The lateral ulnar collateral ligament complex is released from its humeral attachment, thus allowing the extensor mechanism to be completely reflected to the lateral aspect of the humerus (TECH FIG 1F).
- If ulnohumeral ankylosis is present, as is sometimes the case in JRA patients, a saw or osteotome may be necessary to re-establish the joint line and to create the osteotomy at the appropriate center of rotation of the ulnohumeral joint.
- The elbow is then progressively flexed, exposing the medial collateral ligament, which is then released subperiosteally from its humeral attachment (TECH FIG 1G).
- The tip of the olecranon is removed with a rongeur or oscillating saw, depending on the quality of the bone, and the humerus is then externally rotated and the elbow fully flexed to adequately expose the articulating surfaces of the humerus, ulna, and radial head.
The midportion of the trochlea is then removed, with an oscillating saw if the bone is dense or with a rongeur if the bone is soft, up to the roof of the olecranon fossa. The removed bone should be preserved for the anterior, distal humeral bone graft needed later in the procedure (TECH FIG 2A). The roof of the olecranon is entered with a rongeur or burr, and a small twist reamer is then used to identify the humeral medullary canal (TECH FIG 2B,C). For patients with severe stiffness, the effect of humeral shortening should be considered. Hughes et al developed a biomechanical model that demonstrated that resecting 1 cm or less of humeral bone has little effect on triceps strength. With the elbow in 30 degrees of flexion, resecting 1 to 2 cm reduced triceps strength by 17% to 40%, while shortening of 3 cm reduced extension strength by 63%. Therefore, the humerus should not be shortened by greater than 2 cm.

An alignment stem is then placed down the canal. The handle of the alignment stem is then replaced by the humeral cutting jig (TECH FIG 2D,E). An oscillating saw is used to make oblique cuts along the edges of the jig, with the tip of the saw pointing away from the midline of the humerus to avoid cross-hatching at the junction of the column and the olecranon fossa (TECH FIG 2F). Care must be taken as this area may be very thin in patients with RA, and thus susceptible to fracture. With the midportion of the trochlea removed, a thin rasp or intramedullary guide is used to again identify the humeral canal. Progressive 6-inch rasps are typically used unless an ipsilateral shoulder arthroplasty has been performed or is planned (TECH FIG 2G). In these cases, consider using a 4-inch humeral component. The anterior capsule is completely subperiosteally released from the anterior aspect of the humerus to accommodate the flange of the humeral component and to allow unencumbered postoperative elbow extension.
TECH FIG 2 • A. For soft bone, a rongeur is used to remove the midportion of the trochlea. B. A burr is used to enter the roof of the olecranon. C. Then a twist reamer is used to identify the medullary canal. D,E. The humeral cutting jig is aligned as a template for removal of the distal humeral articulation. F. An oscillating saw is placed at an oblique angle to the jig to accurately remove the articulating surface of the distal humerus while avoiding cross-hatching of the supracondylar columns. G. An appropriately sized rasp is used for the humeral canal.
ULNAR PREPARATION

- It is important to fully expose the greater sigmoid notch.
- A high-speed burr is angled 45 degrees relative to the axis of the ulnar shaft at the junction of the sigmoid fossa and coronoid to identify the ulnar medullary canal (TECH FIG 3A,B).
- Again, a twist reamer is used to further identify the canal, and an appropriately sized ulnar rasp is then inserted.
- The ulnar bow should be acknowledged and palpated while inserting the ulnar rasps to avoid ulnar perforation.
  - During advancement of the rasp, it is important to maintain proper rotation of the rasp so that the handle is perpendicular to the flat, dorsal aspect of the proximal ulna (TECH FIG 3C,D).
- Alternatively, reaming should be considered if the canal is very small, as may be the case in JRA patients.
- The ulnar canal is thus prepared, and the ulnar component is inserted to the depth such that the center of the ulnar component is midway between the tips of the olecranon and coronoid to reproduce the elbow’s axis of rotation (TECH FIG 3E).
- A rongeur is then used to remove the tip of the coronoid.
- Because proximal radioulnar arthritis is ubiquitous in patients with RA and JRA, and the Conrad-Morrey total elbow arthroplasty does not require proximal radioulnar and radiocapitellar reconstruction, a radial head excision is performed.
  - This may be performed by rotating the forearm and using a rongeur to progressively excise the radial head from an axial orientation, while holding the elbow in full flexion.

TECH FIG 3 • A,B. A high-speed burr is used to identify the ulnar medullary canal. C,D. A small twist reamer is used to identify the ulnar canal (C), which is then rasped to the appropriate size while maintaining proper rotation (D). E. The ulnar component is seated to ensure the proper depth and axis of rotation.
TRIAL REDUCTION

- The humeral component is then inserted and a trial reduction is performed.
- Range of motion is tested and should be full without limitation in the flexion–extension plane.
  - If range of motion is limited owing to inadequate soft tissue release, this should be addressed at this time.
- The components should also be evaluated for bony impingement, which may commonly occur posteriorly (olecranon impingement on the humerus) or anteriorly (coronoid tip on the anterior flange of the humeral component; TECH FIG 4).
  - Any impinging bone should be removed with a rongeur.
- After satisfactory trial reduction, the provisional components are removed.

CEMENTING

- Both medullary canals are then pulse lavaged and dried.
- Based on the trial components used, the length of the cement applicator is measured to equal that of the humeral component.
  - The tip of the applicator is cut at this level to ensure appropriate depth of the cement down the humeral canal (TECH FIG 5).
- It is recommended that cementing of the components be performed simultaneously.
  - Two packs of cement with antibiotics are mixed and injected with a runny consistency.
  - The humeral cement is placed first, followed by the ulnar cement and then the ulnar component.
  - Remove excess cement.
HUMERAL COMPONENT AND BONE GRAFT

- A small (about 2 cm × 2 cm and 2- to 4-mm thick) piece of the removed trochlea is used for the anterior bone graft.
- This bone graft is wedged between the anterior aspect of the humerus and the flange as the humeral component is placed (TECH FIG 6).
- This provides the humeral component with rotational stability as well as additional stability in the AP plane.
- Once again, excess cement is removed at this time.

ASSEMBLY AND IMPACTION

- The components are then linked with the use of two interlocking cross-pins, which are placed from opposite directions (TECH FIG 7A).
- If humeral bowing or a small canal exists, a slight bow can be placed in the proximal aspect of the humeral component to ensure proper fit (TECH FIG 7B, C).
- After coupling the prosthesis, the components must be seated; the elbow is flexed to 90 degrees and the humeral component is then impacted such that the distal aspect of the humeral component is roughly at or slightly proximal to the contour of the distal capitellum (TECH FIG 7D, E).
- Range of motion is checked and a full arc of motion is confirmed.
- The elbow is taken through several arcs of flexion—extension to “normalize” the rotational version of components to one another.
- Hold the elbow in full extension until the cement cures.

(continued)
TRICEPS REATTACHMENT

- Small cruciate and transverse drill holes are placed through the olecranon at the site of triceps reattachment, and a heavy, nonabsorbable suture is placed on a Keith needle and then brought through the distal medial cruciate drill hole and out the proximal lateral hole (TECH FIG 8A–C).
- The elbow is flexed to about 60 degrees and the extensor mechanism is reduced over the tip of the olecranon; consider slightly overreducing the extensor mechanism medially to minimize the potential for postoperative lateral subluxation.
- The suture is woven through the triceps tendon in a locking, crisscross pattern such that the suture emerges at the proximal medial hole (TECH FIG 8D).
- The suture is then passed through this hole and out the distal medial hole such that it is located directly across from the initial suture end.
- These suture ends are then passed again through the forearm extensor fascia and tied together.
- Two reinforcing sutures are then passed through the transverse holes and extensor fascia before being tied together.
- Avoid knots directly over the subcutaneous border of the proximal ulna.
- The tourniquet is then deflated and hemostasis is achieved.
- The medial soft tissue extensor mechanism is then reaproximated.

TECH FIG 7 • (continued) D,E. The elbow is flexed to 90 degrees and the humeral component is then impacted.

TECH FIG 8 • Cruciate (A,B) and transverse (C) drill holes are placed in the ulna for triceps reattachment. (continued)
TECH FIG 8 • (continued) **D.** Suture is passed through the proximal ulna and then woven through the triceps tendon before being tied together.

**ULNAR NERVE TRANSPOSITION AND WOUND CLOSURE**

- The protected nerve is in the subcutaneous tissue pocket previously created, and dermal sutures are placed to protect and secure the nerve (TECH FIG 9).
- Wounds are closed in layers, and a drain is placed. Staples are used to close the skin.
- A volar splint is placed with the elbow in full extension, making sure to adequately pad the anterior aspect of the splint both proximally and distally to prevent skin breakdown.

TECH FIG 9 • The ulnar nerve is transposed into the subcutaneous tissue of the medial epicondylar region and secured with sutures in the dermal layer.

POSTOPERATIVE CARE
- Postoperatively, the anteriorly placed splint maintains the elbow in full extension for about 24 to 36 hours.
- The elbow is elevated overnight and on postoperative day 1.
- The drain is removed on postoperative day 1 or when output is less than 30 mL in an 8-hour period.
- After splint removal, open-chain active-assisted range of motion is allowed. A formal physical therapy consultation is not usually required.
- The patient is restricted to no pushing and no overhead activities for 3 months to protect the triceps. In addition, no repetitive lifting of objects heavier than 5 pounds and no lifting greater than 10 pounds in a single event is allowed for life.
- A collar and cuff are provided for comfort.

OUTCOMES
- Successful outcomes for total elbow arthroplasty are judged based on relief of pain and improved range of motion, stability, and function.
  - The Mayo Elbow Performance Score assigns numeric values to each of these categories to produce scores for each of these criteria as well as an overall score. Outcomes are often compared using this system.
- Total elbow arthroplasty for RA
  - In the largest study with the longest follow-up in the literature, Gill and Morrey reported 86% good or excellent results with a 13% reoperation rate on 69 patients with RA treated with a semiconstrained total elbow arthroplasty. Forty-four of these patients were followed for more than 10 years.
  - The prosthetic survival rate was 92.4% at 10 years of follow-up, thus approaching the success of lower extremity arthroplasty.
- Total elbow arthroplasty for JRA
  - Connor and Morrey reported 87% good or excellent results on 19 patients (24 elbows) followed for a mean of 7.4 years.
  - The mean improvement in the Mayo Elbow Performance Score was 59 points, 96% had little or no pain, and there was no evidence of loosening in any prostheses at the latest follow-up.
- The mean flexion-extension arc of motion improved by only 27 degrees (from 67 to 90 degrees) in this study, but these outcomes were reported before shortening of the humerus for severely contracted elbows was routinely performed.

COMPLICATIONS
- Infection
- Aseptic loosening
- Mechanical failure
- Short term
- Long term
- Ulnar nerve injury
- Triceps weakness or avulsion
- Ulnar component fracture
- Ulnar fracture
- Wound healing problems

REFERENCES
DEFINITION
- Most comminuted elbow fractures have significant associated soft tissue injuries, which are often of equal or greater importance to the bony element.
- The key point in determining how to treat acute elbow fractures is to assume that all fractures will be anatomically reduced and fixed.
- An acute elbow replacement should be considered only if it is felt that open reduction and internal fixation is unlikely to achieve a predictably good functional outcome.
- In the vast majority of cases, elbow replacements for the treatment of acute fractures should be limited to the physiologically elderly patient with low demands and osteoporotic bone stock.

ANATOMY
- The bony anatomy of the elbow consists of the distal humerus, proximal ulna, and proximal radius.
- Important soft tissue stabilizers include the medial and lateral ligamentous complexes and surrounding musculature, especially the brachialis, common flexor and common extensor masses, and triceps.
- The ulnar nerve is tethered to the medial condylar–epicondylar fragment by the cubital tunnel retinaculum distally and the arcade of Struthers proximally.

PATHOGENESIS
- Elbow injuries are often the result of direct impact—for example, a direct blow on the elbow during a fall.
- Knowing the energy of the fracture is important to gauge the likelihood of associated injuries.
- Less energy is required to create a comminuted fracture in elderly and osteoporotic individuals, but muscular injuries of the triceps and brachialis are common, with a subsequent influence on the functional outcome.
- The ulnar nerve displaces with the medial fragment. As a consequence, the nerve may kink, leading to a local nerve injury. Nerve lacerations are an uncommon consequence of comminuted distal humeral fractures.

NATURAL HISTORY
- Most distal humeral fractures are treatable with either open reduction and internal fixation (ORIF) or nonoperative management. The challenging fracture subgroups are those that involve the articular surfaces and are comminuted.
- Many direct and indirect soft tissue complications may ensue, including neurovascular entrapment, muscle tears leading to myositis ossificans and soft tissue contracture with joint stiffness.
- There is some evidence to suggest that congruently reducing and fixing a comminuted intra-articular distal humeral fracture does not eliminate the risk of posttraumatic arthritis, although, where possible, ORIF should remain the primary goal.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The physical examination (FIG 1) should be performed gently in the presence of fractures, especially when comminution suggests the possibility of neurovascular injury if the examination is too vigorous.
- A complete examination of the elbow should also include evaluation of associated injuries. It should begin away from the elbow, progressing toward it.
- The following associated injuries should be ruled out:
  - Distal radial and scaphoid fractures: Since the most common mechanism of injury is a fall onto an outstretched hand, the energy transfer of the fall begins in the extended wrist, through the distal radius and scaphoid. Direct palpation of the distal radius should be done and anatomic snuff-box tenderness should be elicited. Palpation of the scaphoid tubercle and ulnar and radial deviation of the wrist may also identify a scaphoid injury.
  - Distal radioulnar joint disruption: Ballottement of the ulnar head should be done in the volar and dorsal directions, in pronation and supination. A disrupted joint is often painful with such ballottement, and the ulnar head may be prominent with the forearm in pronation.
  - Fracture extension beyond the elbow: The examiner should palpate the ulna shaft, along its subcutaneous border, from the wrist to the olecranon.
  - Interosseous membrane injury: Palpating the interval between the bones of the forearm is not a sensitive examination but can raise suspicion for an Essex-Lopresti injury.

FIG 1 • Typical appearance of an elbow with an underlying fracture with extensive swelling and bruising.
leading to further imaging. If an interosseous membrane disruption is present, this will influence the type of implant used for elbow replacement (one with a radial head replacement), but the pathology is not commonly described.

**IMAGING AND DIAGNOSTIC STUDIES**
- Plain radiographs, including anteroposterior (AP) and lateral views (FIG 2) of the elbow and both wrists, should be obtained. The elbow view may have to be taken in a protective splint or plaster back-slab for patient comfort.
- Elbow radiographs will allow initial assessment of the degree of commination and may indicate the presence of decreased bone mineral density.
- Bilateral wrist views will indicate the presence of an axial (interosseous membrane) injury if the ulnar head is in positive variance compared to the contralateral uninjured wrist.
- Plain tomograms are of use in improving the understanding of the fracture configuration, but an alternative would be a computed tomography (CT) scan. With the latter the surgeon can view a three-dimensional reconstruction, which is a useful surgical planning tool.
- If there is evidence on physical examination of a neurologic injury, it is prudent to document its extent with a carefully performed neurologic examination.

**DIFFERENTIAL DIAGNOSIS**
- Nonunion
- Ligamentous disruption
- Fracture-dislocation

**NONOPERATIVE MANAGEMENT**
- The “bag-of-bones” technique is a nonoperative method of treatment described by Eastwood that encourages the compressive molding of the comminuted distal humeral fracture fragments.
- Subsequent rehabilitation with collar and cuff support achieves substandard but acceptable results only in the elderly and debilitated group of patients who have almost no demand on elbow function.
- This type of treatment does not achieve acceptable results with respect to stability and strength in younger patients.

**SURGICAL MANAGEMENT**

**Open Reduction and Internal Fixation**
- ORIF has been widely documented for comminuted fractures of the distal humerus.
- Some reported series demonstrate good results with fixation of such challenging fractures, with better results predominantly in the younger age groups. Rarely are good results achieved in the elderly, osteoporotic group. Many series report less-than-satisfactory outcomes in the elderly treated by operative fixation. A direct comparison of internal fixation to primary total elbow replacement in the elderly osteoporotic group revealed that replacement produced no poor results and no need for revision surgery at 2 years of follow-up. The internal fixation group produced three poor results requiring revision to a total elbow replacement.

**Elbow Arthroplasty**
- When a distal humerus fracture is not reconstructable, arthroplasty becomes a valid treatment option.
- Elbow replacement following a failed attempt at fixation has proven to have a significantly worse outcome than if the arthroplasty was performed initially. There are a number of studies that support the concept of an acute total elbow arthroplasty in select patients with comminuted fractures of the distal humerus.
- The more traditional form of replacement for the elderly and low-demand population with an unreconstructable distal humerus fracture is the total elbow arthroplasty.
- A more recent innovation has been the replacement of the distal humerus (hemiarthroplasty) to preserve an intact ulna and radial head. This procedure is not FDA approved and so should be considered experimental and not for general consideration, especially since the elbow joint is variable and highly congruent in its topography, which differs from many of the standard implants used for acute fractures.

**Indications and Contraindications**
- Indications for acute total elbow arthroplasty
  - Comminuted, unreconstructable distal humerus fracture
  - Physiologically elderly patient
  - Low-demand patient
- Indications for acute elbow hemiarthroplasty
  - Unreconstructable distal humeral fracture (C3)
  - Unreconstructable combined fractures of capitellum and trochlea
  - Very low bicondylar T fracture of distal humerus
    - Young patient
    - Active patient
  - Repairable or intact collateral ligaments (may require reconstruction of the medial and lateral supracondylar columns)
    - Repairable or intact radial head
  - Absolute contraindications for acute joint replacement
    - Infection (overt)
    - Lack of soft tissue coverage (skin, muscle)
  - Relative contraindications for acute joint replacement
    - Infection in distant body part
    - Contaminated wound
    - Neurologic injury involving the elbow flexors
Preoperative Planning

- Standard radiographs should be obtained (AP and lateral).
- If doubt exists regarding the ability to anatomically repair the fracture, then a CT scan should be requested to assess the degree of comminution and the fracture line orientation.
- An assessment of humeral shaft bone loss is important in planning the implant design that might be considered. If the degree of loss is greater than the articular condylar fragments, an implant that has the ability to restore humeral length will be more appropriate. If an unreconstructable fracture of the humeral articular surfaces without humeral shaft bone loss is encountered, an implant with the ability to resurface the articular surfaces as a hemiarthroplasty or a resurfacing ulnotrochlear replacement can be considered, but the former implantation technique should be regarded as an off-label and experimental procedure.
- Humeral shaft length loss of 2 cm can be tolerated and standard implants used.
- Humeral shaft length loss of greater than 2 cm can be restored with implant designs with anterior flanges, especially those with extended flanges that allow restoration of humeral length.
- The surgeon should assess the intramedullary canal dimensions of the humerus and ulna. This will help to plan the requirement of extra-small diameter.
- Neurovascular status of the limb should be fully assessed and documented in the clinical notes.

Patient Positioning

- Two methods of patient positioning can be used, depending on surgeon comfort and the access required:
  - Supine: The arm is draped for maximum maneuverability. During the procedure the arm is supported on a large rolled towel placed on the patient’s upper thorax, carefully avoiding the endotracheal tube, stabilized by an assistant. In this position the surgeon stands on the side of the patient’s injured limb (FIG 3A).
  - Lateral decubitus: The arm is positioned on an arm support, thereby minimizing the need for an assistant, but this set-up is less maneuverable. In this position the surgeon stands on the opposite side of the patient’s injured limb (FIG 3B).

Surgical Approach

- Two main surgical approaches are useful for acute total elbow arthroplasty:
  - Triceps-splitting approach
  - Bryan-Morrey approach
- The triceps should be carefully managed in either approach, and it often has a thin tendon, especially in older patients and those with rheumatoid arthritis. The triceps tendon should be dissected from the olecranon with a small curved scalpel blade, maintained perpendicular to the interface between the tendon and bone.

INCISION AND DISSECTION

- Make a midline longitudinal skin incision (TECH FIG 1A), with a gentle curve to avoid the olecranon weight-bearing prominence. Extend the incision 5 cm distal to and proximal to the prominence of the olecranon tip.
- Develop the full-thickness medial and lateral skin flaps (TECH FIG 1B) and define the medial and lateral borders of the triceps (TECH FIG 1C,D).
- At the medial border, define and partially neurolyse the ulnar nerve, and mark and handle it with a tied vessel loop (without an attached hemostat, since its constant weight may cause inadvertent nerve injury) (TECH FIG 1E).
- With the nerve visualized and handled to safety, remain in the medial gutter to extend the dissection distally to define the medial fracture fragment. Transect the medial collateral ligament in its entirety, and remove all soft tissue from this bony fragment and remove the latter (TECH FIG 1F).
TECH FIG 1 • A. Skin incision is posterior longitudinal, with or without a small diversion to avoid the “point” of the olecranon. B. Raising the skin should aim to maintain the full thickness of the flaps by using the “flat knife” technique. C. The medial and lateral borders of the triceps are defined (arrows). D. This patient had an anconeus epitrochlearis (star) in relation to the ulna nerve (UN). E. A vessel loop is used to maneuver the nerve without an attached clip. F. The medial fragment of the fracture is removed once all the soft tissues are released from it, and the nerve is gently retracted to ensure tension-free removal.

TRICEPS MANAGEMENT

Triceps Preserving

- With the ulnar nerve gently medially retracted, use a periosteal elevator to define the plane between the triceps and the posterior humerus, from the medial to the lateral border, exiting posterior to the lateral intermuscular septum. Use this elevator to lift the triceps, with blunt dissection, by sliding the shaft of the elevator proximal and distal in the interface (TECH FIG 2A).
- Develop the lateral triceps–lateral intermuscular septum margin and resect the lateral fracture fragments, having firstly cleared them of soft tissue attachments (TECH FIG 2B).
  - While in the lateral corridor, visualize the radial head and resect sufficient head to prevent abutment on the prosthesis.
  - From the lateral margin of the humeral shaft, raise the brachialis from 2 to 3 cm of the anterior surface.

Modified Bryan-Morrey Approach

- Preserving the integrity of the triceps insertion makes component insertion more difficult. An alternative approach for managing the triceps is to reflect it from the tip of the olecranon from medial to lateral, thereby improving exposure (TECH FIG 3).
- Define the medial triceps border and dissect the ulna nerve free from its connections, while protecting it in a vessel loop. The nerve is transposed into a subcutaneous pocket.
- The medial triceps is dissected to its ulna attachment. Release the triceps from the medial condylar fragments and transect the medial collateral ligament. Free the medial fragments from soft tissue attachments and remove the medial fragments between the triceps and a gently anteriorly retracted ulnar nerve.
TECH FIG 2 • A. A periosteal elevator is introduced between the triceps and the humeral shaft and the two structures are separated by sliding the elevator proximally and then distally to the level of the triceps insertion. B. The lateral corridor is defined and lateral fragments are removed.

- Develop the interval between the anconeus and flexor carpi ulnaris along the subcutaneous border of the ulna.
- The triceps tendon is sharply elevated from the olecranon, in continuity with the anconeus, and subluxed laterally. Take care to release the Sharpey fibers adjacent to the bone in order to retain the flap thickness. Further access is afforded by raising the anconeus from its ulnar attachment while maintaining its attachment distally.
- As the triceps is reflected laterally, the lateral condylar fragments are identified and removed by releasing the lateral collateral ligament and common extensor tendon.

TECH FIG 3 • A. The triceps is split through its central tendon, in line with the fibers. The tendinous portion is dissected from the olecranon to gain access to the ulna. B,C. To dissect the Sharpey fibers off the ulna, the surgeon uses the scalpel parallel to the ulna surface and maintains the release directly adjacent to the bone. D. Comminuted distal humeral fracture in an osteoporotic elderly woman, with CT imaging confirming significant articular comminution. This is the view through the triceps split.
BONE PREPARATION

- Identify the olecranon fossa (if any part of it still exists). This landmark is the seating point for the base of the anterior flange of the Coonrad-Morrey humeral component (TECH FIG 4A). If the olecranon fossa is not present owing to a greater degree of comminution, an extended-flange humeral component can be used.
- Release the anterior capsule and any soft tissue from the anterior surface of the distal humerus. This provides a site for the anterior humeral bone graft.
- The posterior flat surface of the humerus is identified since this plane approximates the axis of rotation of the distal humerus (TECH FIG 4B). Humeral canal preparation is completed with the canal broaches provided with the implant system being used.
- The ulnar canal preparation commences with removal of the tip of the olecranon. The intramedullary canal is entered at the base of the coronoid (TECH FIG 4C,D).
- The entry point is enlarged up toward the coronoid with a burr to allow easier component insertion without cortical abutment, which leads to malalignment (TECH FIG 4E).

TECH FIG 4 • A. The humeral component entry point, the apex of the olecranon fossa, is identified and humeral canal preparation is commenced by opening the canal with a bone nibbler or burr. B. The posterior flat surface of the humeral shaft is identified and the component is aligned. C,D. Ulnar canal preparation is commenced by opening the canal at the base of the coronoid process with a drill or burr. (continued)
During intramedullary preparation, the broaches must parallel the subcutaneous border of the ulna. This ensures that the track of insertion of the ulna parallels the intramedullary canal.

The tip of the coronoid is removed to avoid impingement during terminal flexion (TECH FIG 4F,G).

The radial head does not need to be resected if there is no disease of the proximal radioulnar joint (TECH FIG 4H).

### IMPLANT INSERTION AND TENSIONING

- With the canal preparation completed (TECH FIG 5A), including pulse lavage of the medullary canals and cement restrictor placement, implant insertion can commence (TECH FIG 5B,C).
- Humeral insertion
  - When bone loss is at or below the level of the olecranon fossa, standard humeral insertion can occur. If bone loss occurs above the olecranon fossa (greater than 2 cm), then humeral length must be restored.
  - Prepare a wedge-shaped bone “cookie” for placement behind the humeral flange.
  - Inject antibiotic cement into the humerus.
  - When inserting the humeral component, place the bone graft behind the anterior flange. Because the humeral condyles have been resected, the implant can

TECH FIG 4 • (continued) E. The trajectory of the ulnar component (black ring) is prepared by rasping the entry track posteriorly into the ulna with a rasp or bone nibbler (gray crescent). F,G. The tip of the coronoid should be resected sufficiently to prevent abutment on the humeral flange during full flexion. Also shown are the resections of the olecranon and the entry point for the ulnar stem insertion. H. The partially resected radial head is used as a bone graft for incorporation behind the humeral flange.
be completely seated and coupled once the cement has hardened.
- Maintain the component orientation relative to the posterior flat surface of the distal humerus.
- Seat the component and flange until the flange is completely engaged with the anterior cortex.
- Ulnar component insertion
  - Inject antibiotic cement into the ulnar canal.
  - The ulnar component is inserted such that the axis of rotation is recreated and the implant is perpendicular to the dorsal flat surface of the olecranon.

**TRICEPS REATTACHMENT**

- The triceps is reattached using a nonabsorbable suture in a running locking mode (eg, running Krakow stitch) to achieve predictable purchase (**TECH FIG 6A,B**).
- Avoid capturing large amounts of triceps muscle fibers within the locking loops.
- The triceps tendon should be reattached to the flat of the olecranon process, not to the tip (**TECH FIG 6C,D**). Pass the sutures through bone tunnels (oblique crossing) that begin on the periphery of the flat reattachment area of the olecranon (**TECH FIG 6E**).
- Avoid tying the sutures directly over the midline of the proximal ulna, which is a source of painful symptoms and may require knot removal. Place the knot under the anconeus.
- When tensioning the triceps at reattachment, place the elbow at 30 to 45 degrees of flexion while tying the knot.
- Use a separate absorbable suture to “cinch” the triceps footprint onto the reattachment area (**TECH FIG 6F**).

**TECH FIG 6 • A,B.** A running locking stitch is used to improve triceps purchase when reattaching the muscle to the ulna. A. An example of a running locking stitch on either side of the split tendon. B. A locking stitch that locks both sides of the split together with one continuous locking suture. It is then reinforced with a reversed across-split locking suture. (continued)
TECH FIG 6 • (continued) C,D. The triceps footprint to which reattachment should be attempted is predominantly on the flat part of the ulna or olecranon process, and not the tip, which is resected to prevent posterior abutment. E. Drill holes (1.5 to 2 mm) are oriented in a crossing fashion to secure the triceps to the footprint area. F. A separate “cinch” suture is used to increase the security and the area of contact between the triceps and the ulna, thereby improving healing potential.

WOUND CLOSURE

- The ulnar nerve is transposed into an anterior subcutaneous location.
- Reapproximate the triceps to the flexor and extensor masses with absorbable suture. Do not overtighten this repair, as it will restrict motion.
- The use of a subcutaneous drain is a matter of surgeon preference. However, there is no literature demonstrating the efficacy of a postoperative drain in preventing hematoma.
PEARLS AND PITFALLS

| Indications | ■ A complete history and physical examination should be performed, with specific questions about any bone mineral density problems and healing tendency.  
■ Care must be taken to address associated pathology at the elbow, wrist, and shoulder. |
| Planning | ■ The surgeon should attempt fracture osteosynthesis when physiologically the patient has adequate bone stock and demand on the elbow.  
■ Arthroplasty should be available in the physiologically older and lower-demand patient, with a view to converting the decision to an acute arthroplasty if the osteosynthesis potential is tenuous. |
| Exposure | ■ Initial definition and protection of the ulnar nerve are important. Careful dissection of the nerve from the cubital tunnel restraints will allow freedom to move the nerve without risking traction injury during the remainder of the procedure.  
■ If the exposure involves removing the triceps from its ulnar attachment (Bryan-Morrey or TRAP approach), the site of Sharpey fiber attachment should be marked and reattached anatomically.  
■ During a tendon-splitting approach, the distal triceps tendon should be split within the structure of the tendon and should not involve the muscular belly. |
| Inspection | ■ A thorough inspection of the ulna and radial articular surface should be performed to investigate the possibility of a hemiarthroplasty replacement in the appropriately selected younger patient.  
■ The surgeon should observe the state of the ulnar nerve and muscles around the elbow (especially triceps and brachialis); this will help to explain altered nerve function in the former, and weakness and possible myositis ossificans and stiffness in the latter. |
| Bone preparation | ■ If the humeral columns are intact, then an attempt at preservation should be made, with their extensor and flexor mass attachments, during a total elbow replacement. |
| Implantation | ■ When planning length and implantation, the surgeon should pay careful attention to the tension and lever arms of the main motor drivers; the brachialis and triceps need some tension to function well, but if over-tensioned the elbow will be stiff and if under-tensioned the elbow will be weak. |
| Wound closure | ■ Drains should not be used because of the superficial nature of the elbow and the risk of deep infection. However, the surgeon should pay close attention to hemostasis, and for the first 12 hours a moderately tight bandage should be used to avoid hematoma formation. The dressing is reduced the next day. |
| Rehabilitation | ■ With triceps reattachment, the surgeon should be cautious to avoid overzealous rehabilitation for fear of compromising triceps healing, with subsequent avulsions or extension weakness. |

### POSTOPERATIVE CARE

■ A volar plaster or thermoplastic splint is used to maintain the elbow in full extension for the first several days. This avoids tension on the incision and on the triceps reattachment.  
■ The arm is elevated on pillows or with a Bradford sling overnight to prevent edema.  
■ Nonsteroidal anti-inflammatories are avoided because of their detrimental effects on tissue healing (bone to tendon and bone to bone).  
■ On the second day after surgery the dressing is removed and the compliant patient should commence gentle active antigravity flexion, with passive gravity-assisted extension.  
■ Graduated and targeted motion is prescribed, with greater than 90 degrees of elbow flexion attempted after 5 weeks. This allows sufficient time for the triceps to adhere and heal (incompletely) to the ulna. Aggressive flexion too early may result in triceps avulsion or pull-out. Triceps antigravity exercises can commence after 5 weeks.  
■ Always, at each patient interaction, the surgeon should reiterate the restrictions of use with an elbow arthroplasty: limited internal (varus) and external (valgus) rotatory torques, 2-pound repetitive and 10-pound single-event lifting.

### COMPLICATIONS

■ Triceps avulsion  
■ Stiffness  
■ Overlengthened implantation  
■ Overtensioned triceps reattachment  
■ Overzealous closure of triceps to flexor–extensor compartments  
■ Inadequate soft tissue release  
■ Impingement  
■ Radial head on humeral component (distal yolk)  
■ Coronoid on humeral component (anterior yolk)  
■ Olecranon process on posterior humerus  
■ Deep venous thrombosis  
■ Infection  
■ Periprosthetic fracture  
■ Osteoporotic bone  
■ Stem–canal mismatched sizes  
■ Stem–canal mismatched curvature  
■ Inadequate opening for ulna component at coronoid base  
■ Ulna nerve neuropathy or injury

### OUTCOMES

■ Cobb and Morrey\(^1\) reported 15 excellent and 5 good results, with one patient with inadequate data, in a cohort of patients with acute distal humeral fractures (average age 72 years) at 3.3 years of follow-up.  
■ Ray et al\(^3\) reported 5 excellent and 2 good functional results in a group of patients with an average age of 81 years at 2 to 4 years of follow-up.  
■ Gambirasio et al\(^5\) reported excellent functional results in a cohort of 10 elderly patients with osteoporotic intra-articular fractures.
Frankle et al. compared the outcomes of patients over age 65 with comminuted intra-articular distal humeral fractures treated with ORIF versus total elbow replacements. The ORIF group had 8 excellent results, 12 good results, 1 fair result, and 3 poor results, with 3 patients requiring conversion to elbow replacement. All 12 acute primary elbow replacements achieved excellent (n = 11) or good (n = 1) results.

Kamineni and Morrey reported an average Mayo Elbow Performance Score (MEPS) of 93/100 in a series of 49 acute distal humeral fractures (average patient age 67 years) at 7 years of follow-up. The average arc of motion was 107 degrees.

Lee et al. reported seven acute elbow replacements for distal humeral fractures in patients with an average age of 73 years. The average arc of motion was 89 degrees and the average MEPS was 94/100 at an average follow-up of 25 months.

REFERENCES

DEFINITION

- Primary degenerative arthritis of the elbow is an uncommon problem.\(^1\)
- It occurs in less than 2% of the population\(^29\) and principally affects the dominant extremity in middle-aged manual laborers.\(^1,3,17,23,29\)
- The disorder predominates in men and is rarely seen in women, with an incidence of 4 to 5:1.\(^8\)
- The dominant extremity is involved in 80% to 90% of symptomatic patients. Bilateral involvement of the elbow is noted in 25% to 60% of patients.\(^6\)
- It has also been reported in people who require continuous use of a wheelchair or crutches, in athletes, and in patients with a history of osteochondritis dissecans of the elbow.\(^21,25\)
- The pattern of pathologic changes in primary degenerative arthritis is different than the age-related changes of the distal humerus and the radiohumeral joint.\(^6,26\)
- The current understanding of the disease process in primary degenerative arthritis has led to treatment algorithms designed to address the pathologic process short of joint replacement.
- The role of total elbow arthroplasty (TEA) for patients with primary degenerative arthritis of the elbow is limited, in large part because of the younger age and increased activity levels of patients with this condition.

PATHOGENESIS

- The exact pathogenesis of primary osteoarthritis of the elbow is still unknown. It is generally believed that overuse plays a key role in the onset of the disease process. However, younger patients with this disease often have predisposing conditions such as osteochondritis dissecans.\(^11\)
- The degenerative changes of the elbow joint are usually more advanced in the radiohumeral joint, where bare bone is often in wide contact, and the capitellum appears to have been shaved obliquely (FIG 1).\(^6\)
- This is due to the high axial, shearing, and rotational stresses at this articulation, which result in marked erosion of the capitellum and hypertrophic callus formation in a skirt-like pattern on the radial neck.\(^32\)
- The ulnohumeral joint is usually less involved in the beginning of the disease process, but involvement becomes more pronounced with more advanced disease.\(^21\)
- The central aspect of the ulnohumeral joint is characteristically spared. The anterior and posterior involvement of this joint is usually manifested by fibrosis of the anterior capsule in the form of a cord-like band and hypertrophy of the olecranon.
- Osteophytes are seen over the olecranon, especially medially, the coronoid process, and the coronoid fossa.
- These changes in the radiohumeral and ulnohumeral joints lead to the loss and fragmentation of the cartilaginous joint surfaces with distortion, cyst formation, and bone sclerosis.\(^2\)
- Kashiwagi\(^9\) noted that the early stage of the disease is characterized by small, round bony protuberances; the early stage progresses into various shapes of osteophytes and bony sclerosis with more advanced cases.
- Suvarna and Stanley\(^30\) reported on the progressive fibrosis of the local marrow, increased thickness of all the bony components of the olecranon fossa, and increases in anterior and posterior fibrous tissues.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Despite considerable radiographic severity, many patients with osteoarthritis of the elbow report minimal symptoms.\(^11\)
- Trauma rarely underlies the onset of degenerative arthritis. However, trivial injury often brings the problem to the patient’s attention.
- Characteristic manifestations of primary degenerative arthritis of the elbow are well described.\(^22,24\) These include:
  - Progressive loss of motion
Mechanical symptoms of locking and catching caused by intra-articular loose bodies (occurs in about 10% of patients)9
- Pain at the extremes of motion due to mechanical impingement of osteophytes (pain occurs most frequently at terminal extension, although about 50% of patients also have pain during terminal flexion)
- Pain throughout the arc of motion indicates significant involvement of the ulnohumeral joint; this typically occurs late in the disease process.
- Ulnar neuropathy
  - Medial joint pain in patients with advanced osteoarthritis of the elbow might be the first manifestation of ulnar neuropathy.
  - Up to 20% of patients with primary osteoarthritis of the elbow have some degree of ulnar neuropathy.1
  - The proximity of the ulnar nerve to the arthritic posteromedial aspect of the ulnohumeral joint makes it susceptible to impingement.
  - The expansion of the capsule as a result of synovitis and the presence of osteophytes in that area of the joint result in direct compression and ischemia of the ulnar nerve.
  - Acute onset of cubital tunnel syndrome in patients with osteoarthritis of the elbow might be also the first manifestation of a medial elbow ganglion.10
- Radiocapitellar symptoms: With more progressive disease, the patients may have pain with forearm rotation and throughout the range of elbow motion. This could lead to disability in this patient population as well in the older laborers who extensively use their upper extremity.6,16,33

PHYSICAL FINDINGS
- Physical examination findings depend on the extent of the patient’s disease.
- Range of motion
  - The flexion-extension arc will demonstrate loss of extension greater than flexion and will average about 30 to 120 degrees.
  - The midrange of the flexion–extension arc is typically pain-free in the early stages of the disease.
- A painful midrange of motion and crepitus indicate more extensive involvement of the ulnohumeral joint.
- The arc of pronation–supination is rarely affected early in the disease process. Involvement of the proximal radioulnar and radiohumeral joint later in the disease process may limit forearm rotation.
- Forced motion at the extremes of flexion and extension will often cause pain, particularly in extension.
- Ulnar nerve symptoms need to be thoroughly evaluated. Symptoms of ulnar neuropathy associated with primary degenerative arthritis of the elbow include:
  - Decreased sensation and weakness
  - Positive Tinel sign at the cubital tunnel
  - Positive elbow hyperflexion test

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Some characteristic radiographic features are seen on the anteroposterior and lateral radiographs of the elbow:
  - Radiocapitellar narrowing (noted in 25% to 50% of patients)
  - Ossification and osteophyte formation in the olecranon fossa in almost all patients with osteoarthritis of the elbow15,21
  - Osteophyte formation of the coronoid and olecranon processes
  - Loose bodies and fluffy densities might be observed filling the coronoid and olecranon fossae (FIG 2A,B).
- Radiographs do not allow for accurate visualization of all osteophytes.
- A cubital tunnel view is obtained if there is ulnar nerve irritation to look for impinging osteophytes or loose bodies.4,6,7
- Computed tomography (CT) helps in delineating the detailed structural anatomy of the articular surface of the elbow with an accurate determination of the locations of the osteophytes and loose bodies (FIG 2C).
- When contemplating surgical treatment of the osteoarthritic elbow, a CT is quite helpful for determining which osteophytes need to be removed.

FIG 2 • A,B. Anteroposterior and lateral views of a right osteoarthritic elbow show narrowing of the joint line and subchondral sclerosis, with formation of osteophytes in the coronoid, capitellar, and olecranon fossae. (continued)
Three-dimensional reconstructions provide additional detail on osteophytic deformity and facilitate preoperative planning of removal.

MRI does not provide any useful information in primary osteoarthritis of the elbow and is rarely indicated.

NONOPERATIVE MANAGEMENT

Because of their young age, most patients with primary osteoarthritis of the elbow tend to be active and involved in manual labor, which will place a great demand on any kind of prosthetic replacement.

Early in the course of the disease, treatment by nonsurgical measures should be followed.21 This consists of activity modification, physical therapy, anti-inflammatory medications, and possibly steroid injection or visco-supplementation.13

SURGICAL MANAGEMENT

Indications

If nonoperative treatment fails to improve symptoms, surgery may be indicated.

Several surgical options exist for the management of primary degenerative arthritis of the elbow. Surgery is directed toward addressing the pathology contributing to the predominant complaints of the patient.

The surgical techniques depend on:

- Degree of osteophyte formation
- Degree and direction of motion loss
- Associated loose bodies
- Associated ulnar nerve symptoms
- Degree of ulnohumeral involvement resulting in pain through the midrange of motion

Arthroscopic Débridement

Arthroscopic management of degenerative arthritis of the elbow is discussed in detail in Chapter SM-22.

In general, arthroscopic débridement for degenerative arthritis of the elbow can be performed for moderate to severe disease when there are no midrange symptoms, indicating limited involvement of the ulnohumeral joint.

Advantages of arthroscopy include the ability to visualize the entire joint and limited morbidity from surgery.

Savoie et al reported good results with extensive arthroscopic débridement involving capsular release, fenestration of the distal part of the humerus, and removal of osteophytes.28

Disadvantages of arthroscopy include potential neurovascular injury and difficulty assessing the normal anatomic relationships, resulting in inadequate débridement, compared with open débridement and release.

Contraindications to arthroscopic treatment include altered neurovascular anatomy, limited surgical expertise, and advanced involvement of the ulnohumeral joint.

Open Débridement

- Open débridement can be performed for all patients with primary degenerative arthritis of the elbow.
- Open joint débridement should be considered in patients with advanced disease or when the treating surgeon has limited experience with arthroscopic techniques.
- Options for open débridement of the elbow include:
  - Outerbridge-Kashiwagi arthroplasty (see Chap. SE-42)
  - Lateral column approach for débridement (see Chap. SE-43)
  - Medial over-the-top approach for débridement (see Chap. SE-44)

Total Elbow Arthroplasty

- TEA for the treatment of primary osteoarthritis of the elbow is performed sparingly in carefully selected patients. In general, the patient population with primary degenerative arthritis of the elbow includes relatively young men who are physically active in their occupation and want to remain so. TEA is contraindicated in high-demand patients.
- The indications for TEA for primary degenerative arthritis of the elbow include patients older than 65 years with low physical demands and a painful arc of motion. These patients should have attempted and failed all other appropriate treatment options.

Implant Choices

- Unlinked (resurfacing) and linked (semiconstrained) designs may be appropriate in patients with primary degenerative arthritis of the elbow.
- The current literature supports the use of linked implant designs for primary degenerative arthritis. However, osteoarthritis may be the best indication for the use of an unlinked implant.
- Linked implants
  - Current linked designs with a semiconstrained, loose-hinged articulation allow varying degrees of varus–valgus motion and rotational laxity (FIG 3A).
  - Muscle activation about the elbow protects against excessive loading, thereby reducing aseptic loosening.

![Computed tomography of the elbow demonstrating marginal osteophytes on the ulna and olecranon fossa.](FIG 2 • (continued) C)
Unlinked implants
- Anatomic requirements for the use of unlinked implants include:
  - Competence of the medial and lateral collateral ligaments
  - Minimal deformity of the subchondral architecture
  - Integrity of the medial and lateral supracondylar columns
- Maintenance of the collateral ligaments and surrounding muscles helps absorb forces across the elbow, thereby reducing stress on the bone–cement interface. This has the theoretical, but unproven, advantage of offloading stresses on the implant.
- Some authors believe that this potential advantage may allow this implant type to be used in a higher-demand patient population. However, this potential advantage is yet unproven. Therefore, the indications for total elbow replacement are still limited in this patient population to patients willing to adopt low physical demands.
- The major complication of unlinked implants is instability.
- If an unlinked implant is considered in this patient population, the ability to convert to a linked replacement (linkable) has obvious advantages.

Linkable implants
- These devices permit implantation in an unlinked fashion, taking advantage of the benefits of an unlinked design (FIG 3B).
- The ulnohumeral articulation can be captured, thereby converting the unlinked implant to a linked implant by placing an ulnar cap on the ulnar component (FIG 3C). This can be performed at the time of implantation of the unlinked implant if stability cannot be established or at a point distant to the initial implantation if instability becomes an issue.

Patient Positioning
- The patient is positioned supine on the operating room table with a bump under the ipsilateral scapula. The arm is positioned across the chest and supported on a bolster (FIG 4).
- A tourniquet is applied to the arm. The use of a sterile tourniquet increases the “zone of sterility” and allows removal for more proximal exposure if needed.

Approach
- The surgical technique for linked arthroplasty is discussed in other chapters. Please refer to these chapters for the specific technical details of implantation of a linked, semiconstrained implant. This chapter will discuss an unlinked total elbow system, which can be converted to a linked implant if required for stability.
SURGICAL EXPOSURE

- A straight posterior, midline incision placed just off the medial tip of the olecranon is used (TECH FIG 1).
- Full-thickness flaps are elevated. The extent of flap elevation is based on how the triceps is to be managed surgically.
- The ulnar nerve is identified, protected with help of a Penrose drain, and transposed anteriorly.

TECH FIG 1 • Straight posterior midline skin incision is placed off the medial aspect of the olecranon. (Courtesy of Tornier, Inc., Edina, MN.)

TRICEPS MANAGEMENT

- Surgical management of the triceps is a matter of surgeon preference. The general methods of triceps management are triceps-sparing, triceps-reflecting, and triceps-splitting approaches.
  - Triceps-sparing approaches leave the triceps attached to the tip of the olecranon. The advantage of this type of approach is that it prevents triceps weakness postoperatively, but it sacrifices surgical exposure.
  - Triceps-reflecting approaches subperiosteally elevate the triceps from its attachment on the ulna; it must be carefully reattached and protected postoperatively. However, surgical exposure is facilitated with these approaches.
  - Triceps-splitting approaches violate the attachment of the triceps to the ulna yet provide the advantages of improved visualization of the joint.

A triceps-splitting approach is performed by completing a midline split in the triceps muscle and tendon, which is carried distally onto the ulna along the subcutaneous border of the ulna between the anconeus and the flexor carpi ulnaris (TECH FIG 2A).

- The medial triceps is elevated in continuity with the flexor carpi ulnaris while the lateral triceps is elevated in continuity with the anconeus. Care must be taken when elevating the medial triceps flap. The medial triceps attachment to the triceps is tenuous in comparison to the lateral triceps flap, which is much more robust.
- The medial collateral ligament (anterior bundle) and lateral collateral ligament complex are tagged and released from their humeral attachment (TECH FIG 2B).
- The shoulder is externally rotated and the elbow is flexed, allowing the ulna to separate from the humerus (TECH FIG 2C).

TECH FIG 2 • A. Triceps-splitting approach carried from the subcutaneous border of the ulna proximally into the triceps tendon. The medial and lateral triceps are subperiosteally elevated from the olecranon. B. The medial and lateral collateral ligaments are released from their humeral attachment and tagged for later repair. C. The elbow is dislocated with flexion of the joint, allowing the ulna to separate from the humerus. This separation provides exposure for component insertion. (Courtesy of Tornier, Inc., Edina, MN.)
IMPLANTATION

Humeral Preparation
- Sizing of the implant to the patient’s native anatomy is critical. Trial spools should be compared to the distal humerus and the proximal radioulnar joint for appropriate sizing (TECH FIG 3A,B). If the native joint size is between spool sizes, the smaller spool is selected.
- The medial and lateral points of the axis of rotation through the distal humerus are determined and an axis pin is placed through these two points, thereby replicating the axis. A drill guide aids in reproducing these points (TECH FIG 3C).
- The central portion of the distal humerus articulation is removed, the intramedullary canal is opened, and a rod is placed in the intramedullary canal. The axis pin is replaced to determine the offset of the intramedullary canal relative to the flexion–extension axis (TECH FIG 3D,E).
- A distal humeral cutting block is used to precisely prepare the distal humerus relative to the intramedullary canal and the flexion–extension axis (TECH FIG 3F,G).
- The humeral canal is sequentially broached to the size selected for the articular spool.

Ulnar Preparation
- Preparation of the ulna is based on the flexion–extension axis of the proximal radius and ulna. The selected size spool is attached to the cutting guide, and the guide is tightened with set screws (TECH FIG 4A). Care must be taken to maintain the relationship of the trochlea and capitellar portions of the spool with the native greater sigmoid notch and radial head.
- A bell saw is used to resect a small portion of the articular surface and subchondral bone of the ulna (TECH FIG 4B).
- If the radial head is going to be replaced, a sagittal saw is used to resect the radial head through the cutting guide. The canal is broached and a trial radial head component is inserted.
- The ulnar canal is opened and sequentially broached to the same size as the selected humeral component.

Component Placement
- If the replacement is going to be unlinked, a short ulnar component can be used. If the implant is going to be linked, a standard (longer) stem is selected. If a standard ulnar component is going to be used, flexible reamers may be required to prepare the ulna.
- Trial reduction is performed to assess the alignment, stability, and tracking of the components.
- If the components are going to be inserted unlinked, the collateral ligaments are reattached to the anatomic origin through the humeral implant. An accessory box stitch could be placed through the ulna and humeral component to support the collateral ligament repair.
- The canals are lavaged and cement restrictors are placed in the humerus and ulna.
- Antibiotic-impregnated cement is injected into the canals. Methylene blue is added to the cement to facilitate cement removal if required in the future.
A locking stitch is used to repair the collateral ligaments through the cannulated humeral bolt (TECH FIG 5A).

Further support is achieved using a cerclage stitch passed through the humeral bolt and a transverse drill hole in the ulna (TECH FIG 5B).

The selected anatomic spool is attached to the ulnar cutting jig. The set screws are tightened, taking care to ensure the anatomic spool stays firmly opposed to the native radius and ulna. With the ulnar cutting guide properly aligned, a bell saw is used to prepare the proximal ulna. The radial head can also be removed using the same cutting jig. (Courtesy of Tornier, Inc., Edina, MN.)

The medial and lateral collateral ligaments are reattached to the epicondyles using a locking stitch that is passed through the cannulated humeral screw. The collateral ligament repair is reinforced with a box stitch passed through the cannulated humeral screw and a transverse hole placed through the proximal ulna. (Courtesy of Tornier, Inc., Edina, MN.)
TRICEPS REPAIR

- Triceps repair is crucial for the stability of unlinked devices.
- The triceps is reattached through two crossing drill holes and one transverse drill hole in the olecranon.
- A grasping suture (Krackow stitch) is used and passed through the crossing drill holes.
- A cerclage stitch is passed through the transverse drill hole around the triceps attachment (TECH FIG 6).

TECH FIG 6 • The triceps is repaired to the ulna through drill holes. The split in the triceps and between the anconeus and flexor carpi ulnaris is closed side to side with interrupted or running suture. (Courtesy of Tornier, Inc., Edina, MN.)

WOUND CLOSURE

- The ulnar nerve is transposed into an anterior subcutaneous pouch.
- The wound is closed over a drain placed in the subcutaneous position.

POSTOPERATIVE CARE

- The arm is placed in a well-padded postoperative dressing and the arm is immobilized in about 90 degrees of flexion for the first several days.
- A resting elbow splint at 90 degrees with the wrist included is fabricated before discharge to protect the soft tissue repair while it heals.

OUTCOMES

- Most studies in the literature reporting on TEA involve large numbers of patients, mostly with rheumatoid arthritis or other inflammatory pathologies but very few patients with primary osteoarthritis.
- This makes it difficult to make accurate conclusions on the value of this treatment option for this population of patients.\(^{5,14,20,27}\)
- There are few studies in the English literature reporting specifically on the outcome and complications of TEA as a treatment option for patients with primary osteoarthritis of the elbow.\(^{4,13}\)
- Kozak\(^{13}\) reported on the Mayo clinic experience.
- Over a 13-year period, only 5 of 493 patients (<1%) who underwent TEA had the procedure performed for primary osteoarthritis of the elbow.
- A linked Coonrad-Morrey implant (Zimmer, Warsaw, IN) was used in three patients and an unlinked Pritchard elbow resurfacing system (ERS) (DePuy, Warsaw, IN) was used in the other two patients.
  - The average age of the patients was 67 and follow-up ranged from 37 to 121 months.
  - Two minor and four major complications were reported in four elbows, two of which required revision.

- This rate of complications, according to the authors, is much higher than the rate of complications reported in TEA performed for other reasons in the same institution during the same period of time, including revision TEA, posttraumatic arthritis, nonunion of distal humerus, and rheumatoid arthritis.\(^{12,18,19}\)
- Espag et al\(^{4}\) reported on 11 Souter-Strathclyde cemented unlinked primary TEAs in 10 patients with osteoarthritis of the elbow.
  - The diagnosis was primary osteoarthritis of the elbow in nine patients and posttraumatic osteoarthritis in two patients.
  - The average age of the patients was 66 years; mean follow-up was 68 months.
  - Only one patient required revision after 97 months for ulnar component loosening.
  - All patients reported good symptomatic relief of pain and a significant increase in range of motion, and all patients considered the procedure to be successful.
  - The authors compared these results with the result of Souter-Strathclyde TEA used in patients with rheumatoid arthritis.\(^{27,31}\)
  - The revision rate in their series (9%) performed for ulnar component loosening compares favorably with the revision rate with the rheumatoid patients (5% to 21%), in which the main indications for revision included dislocation, and perioperative fracture.
  - The authors attributed the decrease in the incidence of peri- and postoperative fracture to the good amount of bone stock in patients with primary osteoarthritis of the elbow, which makes the risk of fracture very minimal.
  - As evident from this review, the outcome studies of TEA in patients with primary osteoarthritis of the elbow are very limited. The above-mentioned studies included a
small number of patients, and no final recommendation could be drawn at this time.

- It is hoped that a greater understanding of elbow anatomy and kinematics will lead to advances in prosthetic design and surgical technique.
- The newer anatomic unlinked implants may improve the outcome of elbow replacement in younger patients.  
- More outcome studies are needed on these implants or any other modern implants before openly recommending elbow replacement in younger active patients with primary osteoarthritis of the elbow.

REFERENCES

DEFINITION AND PATHOGENESIS

- Posttraumatic conditions of the elbow represent a variety of disorders involving the elbow as a result of previous injury. Included among the posttraumatic conditions are:
  - Posttraumatic arthritis
    - Primary pathology involves posttraumatic degeneration of the articular surface.
    - Secondary pathologies can include contracture, loose bodies, and heterotopic bone.
  - Nonunion of the distal humerus
    - Total elbow arthroplasty (TEA) is considered when reconstruction of the nonunion is deemed impossible or undesirable.
  - Dysfunctional instability of the elbow
    - This is a special clinical situation where the fulcrum for stable elbow function is lost. The forearm may be dissociated from the brachium (FIG 1).
  - Chronic instability (dislocation)
    - Chronic ligamentous instability of the elbow can lead to articular degeneration, particularly in the elderly, osteopenic patient.
- Treatment for posttraumatic conditions is individualized depending on the underlying pathology as well as the functional demands and age of the patient.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient history is directed at gaining information about the initial injury, treatments undertaken, complications of treatment, presenting complaints, and patient expectations.
- Detailed investigation of the patient’s symptoms should include questions regarding the degree of pain, presence of instability or stiffness, and mechanical symptoms of catching, or locking.
- The physical examination of the elbow should follow a systematic approach:
  - Inspection of the elbow
    - Presence and location of previous skin incisions or persistent wounds
    - Alignment of the extremity at rest
    - Prominent hardware
  - Range of motion (ROM)
    - Active ROM is assessed and compared to the opposite side. The degree of motion, smoothness of motion, and feel of the endpoint are established.
    - Normal active ROM varies, but it should be symmetrical with the opposite unaffected side. Range of motion should be from near full extension (may have hyperextension) to 130 to 140 degrees of flexion. Normal forearm rotation is an arc of 170 degrees, with slightly more supination than pronation.
    - Functional ROM has been defined as a flexion–extension arc from 30 degrees to 130 degrees and a pronation–supination arc from 50 degrees of pronation and 50 degrees of supination.10
    - Passive range of motion (PROM) is then assessed and compared to the active motion arc.
    - Palpation of the elbow should systematically review all of the bony and soft tissue structures of the elbow.
    - The ulnar nerve needs to be carefully assessed. If previously surgically manipulated, its location should be identified if possible.
    - Motor function of the elbow should be assessed, in particular the flexor (biceps and brachialis) and extensor (triceps) function.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Orthogonal radiographic views of the elbow are mandatory (FIG 2).
  - A good lateral radiograph can typically be obtained.
  - A useful anteroposterior (AP) radiograph can be difficult, particularly if the patient has significant flexion contracture. A poor AP radiograph can make assessment of the joint space difficult, typically resulting in overestimating the amount of joint destruction.
  - Oblique radiographs can be helpful in obtaining more detail.
  - CT scans are particularly helpful in assessing the integrity of the bone and establishing whether the joint space is reasonably preserved.
  - Three-dimensional reconstructions provide a better understanding of any deformity.
  - Magnetic resonance imaging is rarely needed in the assessment of a posttraumatic joint and is therefore used sparingly.

FIG 1 Radiograph demonstrating dissociation of the forearm from the brachium in a patient with an inadequately treated fracture of the distal humerus with resultant nonunion.
DIFFERENTIAL DIAGNOSIS
- Nonunion or malunion of the distal humerus
- Posttraumatic stiffness of the elbow
- Chronic dislocation of the elbow

NONOPERATIVE MANAGEMENT
- The success of nonoperative management depends on specific features of the pathology and the motivation and goals of the patient.
- Activity modification is used to reduce the forces across the elbow.
- Range of motion of the elbow should be maintained. Aggressive efforts to regain lost motion can aggravate the joint.
- External bracing is occasionally used to support an unstable extremity. However, in general, bracing is poorly tolerated and functionally limiting.

SURGICAL MANAGEMENT
- Surgical management of traumatic conditions of the elbow is directed at addressing the underlying cause of disability and should take into consideration the patient’s age, physical requirements, and expectations.

Surgical Options
**Interposition Arthroplasty**
- **Indications**
  - Patients with pain or loss of range of motion who have failed to respond to nonoperative management
  - Posttraumatic arthritis in patients who are either too young for TEA or who are unwilling to accept the functional restrictions with TEA
  - The patients who do best following interposition are those with painful loss of motion when there is no requirement for aggressive, heavy use of the extremity.
- **Contraindications**
  - Active infection (septic arthritis with persistent infection)
  - Grossly unstable elbow
  - Marked angular deformity
  - Pain without associated functional loss

- **Total Elbow Replacement**
  - Patients with posttraumatic conditions of the elbow tend to be younger than other patients undergoing TEA.
  - In this group of patients, TEA should be considered in patients who:
    - Have failed to respond to appropriate nonoperative management
    - Are not appropriate candidates for other surgical options
    - Are willing to adopt a more sedentary lifestyle
    - Have no absolute contraindications to the procedure

Preoperative Planning
**Interposition Arthroplasty**
- **Graft options**
  - Achilles tendon allograft has the advantage of no donor site morbidity. It can also be used to reconstruct the collateral ligaments if necessary.
  - Dermal or fascia lata autogenous graft
  - Dermal tissue allograft
- **Revision**
  - The salvage for a failed interposition arthroplasty is a TEA.¹
  - Interposition arthroplasty should not be undertaken unless the surgeon is comfortable performing a total elbow replacement in the face of failure.

**Total Elbow Replacement**
- Implants are described in terms of their physical linkage (linked, unlinked, or linkable) and based on their constraint (constrained, semiconstrained, minimally constrained).
- **Linkage** is determined by whether the components are physically linked.
- **Constraint** is a more poorly defined quality of the implant. It depends on the geometry of the implant and its interaction with stabilizing soft tissues about the elbow.⁶
- **Implant selection in posttraumatic arthritis**
  - Linked (semiconstrained) designs: Linked implants have the advantage of being universally applicable to all posttraumatic conditions of the elbow.
  - Unlinked designs: The requirement for the use of unlinked designs in posttraumatic conditions of the elbow is integrity of the collateral ligaments and limited deformity such that normal anatomic relationships can be re-established.
  - **Linkable designs**: Linkable designs have been developed to take advantage of the features of an unlinked implant while capturing the universal applicability of the linked implants. They can be converted from unlinked to linked either at the time of an initial surgery if stability cannot be conferred or remotely if instability becomes an issue postoperatively.

Positioning
- **Interposition arthroplasty**
  - Supine with the arm across the chest and a bump under the ipsilateral shoulder
  - Alternatively, the lateral decubitus position with the arm over an arm holder
  - Total elbow replacement

**FIG 2** • AP and lateral radiographs of the elbow in a patient with posttraumatic arthritis of the elbow.
Patients are placed supine on the operating table with a bump under the ipsilateral shoulder. The arm should be freely mobile through the shoulder to allow manipulation of the joint throughout surgery. The arm can then be placed across the body on a bump or externally rotated through the shoulder and flexed at the elbow (FIG 3).

**FIG 3** • Patient positioning for total elbow arthroplasty with the arm across the body supported on a bolster.

**INTERPOSITION ARTHROPLASTY**

- Posterior skin incision: Develop medial and lateral subcutaneous flaps.
- Isolate and transpose the ulnar nerve.
- Perform deep exposure to the elbow through an extensile Köcher approach. The triceps can be partially released from the ulna to allow the triceps–anconeus composite to be mobilized (TECH FIG 1A).
- Mobilize the common extensor group from the anterior capsule and release it proximally with the extensor carpi radialis longus.
- Isolate the lateral ulnar collateral ligament and release it from its humeral origin (TECH FIG 1B). Perform an anterior and posterior capsular release. Supination of the forearm allows the ulna to be rotated away from the humerus. Attempt to leave the medial collateral ligament intact as it will improve postoperative stability.
- Inspect the cartilage surfaces. If more than 50% of the articular surface is involved, surgery proceeds to interposition.
- If extensile exposure is required, the extensile Köcher approach can be expanded to a triceps-reflecting anconeus pedicle (TRAP) approach (TECH FIG 1C,D). Reshape the distal humerus to conform to the olecranon. Remove the cartilage from the distal humerus and smooth the bone, but avoid aggressive resection of bone (TECH FIG 1E).
- Prepare the interposition tissue. The graft of choice is up to the surgeon, but there is a growing experience with allograft Achilles tendon. In addition to being a robust graft source, it allows for reconstruction of one or both collateral ligaments (TECH FIG 2A).
- Place drill holes across the supracondylar region from anterior to posterior (TECH FIG 2B). These drill holes are placed at the medial aspect of the trochlea, above the trochlear sulcus, at the lateral margin of the trochlea, and at the lateral aspect of the capitellum.
- Drape the interposition tissue over the distal humerus and secure it with sutures placed through the graft from front to back. If there is collateral ligament insufficiency, the tails of the graft (especially when using Achilles tendon) can be fashioned to reconstruct the collateral ligaments (TECH FIG 2C).
- Leave the radial head intact, especially if medial collateral ligament reconstruction is performed, to contribute to the valgus stability of the elbow.
- Repair the lateral collateral ligament through drill holes at the center of rotation laterally. Do not tie the ligament until the external fixator is securely applied.

**TECH FIG 1** • A. Extensile Köcher approach to the lateral elbow. The anconeus and triceps are elevated off the posterolateral capsule while the common extensor group is elevated off the anterior capsule. Exposure can be extended posteriorly with partial release of the triceps from the lateral aspect of the olecranon. B. Deep extensile exposure requires release of the lateral collateral ligament and anterior and posterior capsule. (continued)
TECH FIG 1 • (continued) C,D. The triceps-reflecting anconeus pedicle (TRAP) approach is an alternative approach that allows extensile exposure. C. The medial interval is along the medial triceps proximally and between the anconeus and flexor carpi ulnaris. The triceps is reflected from medial to lateral (Bryan-Morrey approach) off the olecranon in continuity with the anconeus. D. The lateral interval is an extensile Köcher approach between the anconeus and the extensor carpi ulnaris, which is extended proximally along the lateral supracondylar column. The triceps–anconeus composite maintains the neurovascular pedicle to the anconeus from above while allowing extensile exposure to the joint. E. The remaining cartilage on the distal humerus is removed and the subchondral bone is reshaped. Care should be taken to retain as much subchondral bone as possible for structural support of the interposition membrane.

**Hinged Elbow External Fixator**

- Apply a hinged external fixator to protect the interposed graft and to stabilize the joint while soft tissue healing occurs.
- The axis of rotation of the elbow is defined by bony landmarks about the lateral and medial joint (TECH FIG 3A).
  - The center of rotation at the lateral elbow is the center point of an arc defined by the articular surface of the capitellum.
  - The center of rotation at the medial elbow is defined by tightly distributed instantaneous centers of rotation approximated by a point at the anterior inferior aspect of the medial epicondyle.
- Establish an axis pin coincident with the lateral and medial centers of rotation. This is the foundation for construction of the fixator.
- The type of fixator used dictates the method of pin insertion relative to the axis pin. Fixator systems that allow the humeral and ulnar pins to be placed independently and then assembled to the axis pin are easiest for the surgeon with limited experience (TECH FIG 3B).
- When placing the humeral pin, take care to avoid injury to the neurovascular structures.
  - Pins in the proximal humerus are placed through the anterolateral aspect of the deltid distal to the axillary nerve.
  - Pins in the midshaft of the humerus are placed in the anterolateral humerus to avoid the radial nerve, which lies posteriorly.
- Ulnar pins are placed along the posterolateral aspect of the ulna.
TECH FIG 2 • A. The interposition membrane is prepared with mattress sutures placed distally. The Achilles tendon allograft also permits reconstruction of the collateral ligaments if necessary. B. Drill holes are placed from posterior to anterior across the supracondylar region to secure the interposition graft. C. The interposition membrane is secured to the distal humerus. If necessary, the graft can be fashioned to reconstruct the collateral ligaments. (From Morrey BF, Larson AN. Interposition arthroplasty of the elbow. In: Morrey BF, Sanchez-Sotelo J, eds. The Elbow and Its Disorders, 4th ed. Philadelphia: Elsevier; 2009: Figure 69–6.)

TECH FIG 3 • A. Drawing demonstrating the center of rotation on the lateral and medial side of the elbow. B. Photograph demonstrating a hinged external fixator. The humeral and ulnar pins are independently attached to the hinge.
A bar is fixed to the humeral and another bar is fixed to the ulnar pins.

The hinge is loosely attached to the humeral and ulnar bars.

The joint is reduced and ligament reconstruction, if necessary, is completed.

With the joint reduced, the fixator is tightened. If desired, distraction can be applied.

### TOTAL ELBOW REPLACEMENT

#### Surgical Approach

- A straight posterior skin incision placed off the medial aspect of the olecranon is preferred. Previous incisions may modify the location of the incision. Regardless of the incision used, deep access to the medial and lateral aspect of the joint is essential.

- Identify the ulnar nerve. If not previously handled surgically, the nerve is transposed anteriorly. If the nerve was previously transposed, it only needs to be identified, but not formally dissected unless the position of the nerve places it at risk during surgery.

#### Triceps Management

- Triceps-reflecting approaches are preferred over triceps-sparing approaches for posttraumatic conditions. Posttraumatic scarring and deformity can make a triceps-sparing approach difficult unless a nonunited distal humeral segment is to be resected.

- A Bryan-Morrey approach is typically performed (**TECH FIG 4A,B**). The medial aspect of the triceps is developed proximally while the interval between the anconeus and flexor carpi ulnaris (FCU) is developed distal to the olecranon. The triceps is reflected from medially to laterally in continuity with the anconeus. Release of the lateral and medial collateral ligaments completes the exposure and allows separation of the ulna from the humerus.

- A modification of the Bryan-Morrey approach involves release of the triceps insertion onto the ulna through an extra-articular osteotomy of the dorsal tip of the ulna (**TECH FIG 4C,D**). The rationale for this modification relates to the recognized complication of triceps insufficiency that occurs with soft tissue release of the triceps. The osteotomy affords several advantages:
  - Bone-to-bone healing of the osteotomy is more reliable than soft tissue healing of the triceps to the ulna.
  - Failure of the osteotomy to heal can be identified radiographically and addressed early.

#### Deep Dissection

- Release the collateral ligaments and capsule (**TECH FIG 5**). This permits the ulna to be separated from the humerus. If ligamentous integrity is necessary (ie, unlinked arthroplasty) then the lateral ulnar collateral ligament and medial collateral should be tagged with plans at reattachment via bone tunnels in the humerus during closure.

- Release contracted muscles (flexor–pronator and common extensor) to correct deformity, which can result in maltracking of the TEA. Release the scarring about the elbow sufficiently to gain unencumbered access to the humerus and ulna for component implantation.

- The tip of the olecranon can be removed to better visualize the trochlea.
Component Insertion and Completion

- Insertion of total elbow implants is performed in standard fashion and is described in Chapter SE-45.
- After component insertion, the triceps mechanism is repaired through bone tunnels in the ulna. When a sliver of bone is taken with the triceps insertion, transverse tunnels are made. Each limb of nonabsorbable suture is tied over the top of the triceps and bone fragment. An additional cerclage suture is brought through one of the two transverse tunnels and is brought around the tip of the olecranon, incorporating the triceps insertion. This suture counters the pull of the triceps.
- The anconeus is repaired to the flexor carpi ulnaris fascia. Similarly, the medial triceps is repaired to the flexor–pronator group.
- Subcutaneous ulnar nerve transposition is routinely performed.
- A subcutaneous drain is placed and wound closure is performed.
PEAKS AND PITFALLS

**Indications**
- Interposition arthroplasty is considered in patients with a stable elbow and limited, painful ROM.
- TEA is considered in carefully selected patients if other nonoperative and operative measures have been exhausted.

**Goals of treatment**
- Regardless of the treatment undertaken, the goal of treatment is a pain-free, functional arc of motion.

**Interposition arthroplasty**
- Predictors of poor outcome:
  - Painful, mobile elbow
  - Preoperative instability
  - Need to reconstruct both the medial and lateral ulnar collateral ligaments at the time of interposition
  - Maintain the fixator for at least 4 weeks (preferably 6 weeks).
  - Meticulous pin care is required.

**TEA**
- Ulnar nerve transposition in all cases
- Triceps-reflecting approach, especially when the joint is very stiff
- Release both the medial and lateral collateral ligaments.
- Release the flexor-pronator and common extensor, particularly if there is significant preoperative deformity.

**POSTOPERATIVE MANAGEMENT**

**Interposition Arthroplasty**
- ROM is started as quickly as allowed by the condition of the soft tissues. In general, immediate motion is preferred. However, the prerequisite is a quiet soft tissue envelope. ROM may be assisted with a continuous passive motion machine if desired.
- Patients are taught pin care, which is performed daily at home.
- Patients are seen at 10 to 14 days postoperatively for staple removal and wound check and every 2 weeks thereafter until pin removal.
- The external fixator is left in place for about 4 to 6 weeks and then removed in the operating room with assessment of elbow stability and motion under anesthesia.
- I prefer to wait 6 weeks to allow collateral ligament healing since instability is the most common complication after fixator removal.
- Rehabilitation is continued, focusing on obtaining a functional ROM.

**Total Elbow Replacement**
- The elbow is immobilized in full extension in a well-padded anterior splint.
- The arm is elevated on pillows or suspended from an IV pole to reduce swelling.
- The splint is removed 24 to 48 hours after surgery.
- Gentle active ROM is begun in flexion, pronation, and supination. Active extension is avoided for 6 weeks to protect the triceps repair. However, gravity-assisted extension or passive extension is permitted.
- In general, formal physical therapy is rarely required to regain ROM. However, it may be beneficial in patients who struggle to regain their ROM. The general timeline of therapy is:
  - Phase I (0 to 6 weeks): Protect the soft tissue and begin protected active-assistive ROM.
  - Phase II (6 to 12 weeks): Continue to improve ROM. Begin strengthening exercises and encourage functional use of the arm.
  - Phase III (12 to 16 weeks): Return to normal functional activities within the restrictions for TEA.
  - Postoperative stiffness may be helped with splinting. Static splinting is preferred over dynamic splinting.
  - Restrictions: Lifetime limitations of the operated extremity include 2- to 5-pound repetitive lifting and 10-lb single-event restriction.

**OUTCOMES**

**Interposition Arthroplasty**
- The most predictable results for interposition occur in patients presenting with:
  - Stiffness and pain preoperatively
  - Stable elbow
  - One or no ligament reconstruction required at surgery
- Poor results are noted when:
  - Pain is the only presenting complaint
  - Elbow is unstable
  - Reconstruction of both the medial and lateral collateral ligaments is needed at the time of interposition
- Most studies report a 70% satisfaction rate among patients with respect to pain relief; 80% of patients regain a functional ROM.
- Cheng and Morrey 2 found that 67% of patients treated for rheumatoid arthritis had satisfactory relief of pain, and 75% of patients treated for osteoarthritis were satisfied at 5-year follow-up.

**Total Elbow Arthroplasty**
- Patients undergoing TEA for posttraumatic conditions of the elbow tend to be younger and have higher demand.
- TEA for posttraumatic conditions of the elbow is associated with improved clinical outcomes.
- A higher complication rate is noted for posttraumatic conditions compared to other indications for TEA.
- Mechanical complications such as component fracture and increased polyethylene bushing wear are more common.
Causes of increased complications include:

- Multiple previous surgeries
- Deformity of the elbow requiring realignment of the extremity through the implant

**COMPLICATIONS**

**Interposition Arthroplasty**

- Complications of interposition arthroplasty include:
  - Instability
  - Infection
  - Ulnar neuropathy
  - Resorptive bone loss
  - Heterotopic bone formation
- Complications related to the external fixator include:
  - Superficial pin tract infections
  - Deep infection (osteomyelitis)
  - Pin breakage
- In the literature, complications have been reported to occur in up to 25% of patients.

**Total Elbow Replacement**

- TEA for traumatic conditions is associated with a high complication rate. Major complications include:
  - Infection
    - Current reports indicate an infection rate of 2% to 5% for primary TEA.
    - Higher infection rates are noted with posttraumatic arthritis and a history of prior surgery.
  - Loosening
  - Triceps insufficiency (an underrecognized problem)
  - Neurologic injury (incidence of transient ulnar neuropathy as high as 26% and permanent nerve injury up to 10%)
  - Wound complications
    - Associated with prior surgery
    - Manage wound by immobilizing in extension postoperatively; use a subcutaneous drain to avoid hematoma formation. A significant postoperative hematoma should be evacuated.
    - Periprosthetic fracture (can occur intraoperatively or postoperatively; incidence ranges from 1% to 23%)

**REFERENCES**

Elbow arthrodesis is a rarely performed orthopaedic procedure. It is mainly performed for severe joint destruction due to:
- Posttraumatic arthrosis
- Instability
- Infection
Historically, it is performed for a tuberculous infection of the elbow.1
- Early fusion rates are about 50%.1
- With modern techniques, fusion rates approach 50% to 100%.3,9
- Arthrodesis of the elbow results in greater functional disability than arthrodesis of the ankle, hip, or knee joints.
- Satisfactory shoulder function is a prerequisite, even though it does not compensate for loss of motion in the elbow.2
- Compensatory motion is seen more in the spinal column and wrist.
- A functional hand is also desirable when performing arthrodesis of the elbow.
- No optimal position for arthrodesis exists.
- The position of fusion is dictated by the needs of the patient.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Skin and soft tissue defects are evaluated.
- The surgeon should evaluate the need for bone graft or soft tissue coverage before arthrodesis.
- If soft tissue coverage is necessary, a plastic surgery consultation is recommended.
- Shoulder, wrist, and spinal column motion is evaluated.
- Neurologic and motor deficits are documented.
- Blood flow to the hand is determined.
- The quality and quantity of bone available for fusion are assessed.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard radiographs of the elbow are obtained.
- Computed tomography (CT) scans of the elbow are obtained for more detailed bony anatomy.
- If infection is suspected:
  - Blood work is obtained for complete blood count, sedimentation rate, and C-reactive protein.
  - The joint is aspirated or an indium scan is performed.

SURGICAL MANAGEMENT
- The elbow is one of the most difficult joints to fuse because of the long lever arm and strong bending forces across the fusion site.
- Arthrodesis should be considered a salvage procedure when no other satisfactory surgical option exists.

Indications
- Septic and tuberculous arthritis
- Sequela of septic arthritis
- Complex war injuries (with large bone and soft tissue defects)
- Young healthy laborers with posttraumatic arthritis who are too young for total elbow arthroplasty
- Posttraumatic arthrosis or severe instability
- Pseudarthrosis
- Severely comminuted intra-articular fractures of the distal humerus with joint destruction
- Chronic osteomyelitis
- Failed elbow arthroplasty
- Failed internal fixation for nonunions

Contraindications
- Massive bone loss preventing successful arthrodesis
- Massive soft tissue loss not amenable to flap reconstruction
- Compromised function of the ipsilateral shoulder, wrist, and spinal column

Preoperative Planning
- The best elbow position is controversial, although the literature suggests between 45 and 110 degrees.
- Historically, 90 degrees is accepted as the best position.
- Factors for choosing the best position include:
  - Gender
  - Occupation
  - Hand dominance
  - Functional requirements
  - Associated joint involvement
  - Unilateral versus bilateral arthrodesis
  - Patient preference
- One to 3 weeks before surgery, the elbow to be fused is braced or casted in various angles.
- Generally acceptable angles include:
  - Male: dominant arm at 90 degrees
  - Females seem to prefer lower angles of 40 to 70 degrees.
  - Ninety to 110 degrees is better for personal hygiene.
  - Forty to 70 degrees is better for extrapersonal needs and activities.
  - Bilateral elbow arthrodesis: dominant arm at 110 degrees, nondominant arm at 65 degrees
- Soft tissue coverage is evaluated.
- Flap coverage or skin grafts are performed before arthrodesis.
- If soft tissue coverage is required, the joint is stabilized with an external fixator.
- The surgeon should consider bulk graft with demineralized bone matrix and cancellous allograft or autograft.
For large bone defects, autograft cancellous bone is preferable.
Antibiotics are given 30 minutes before the incision.
General anesthesia is used.
An axillary or interscalene block can be used.

Special Instruments
- Large fragment locking set (4.5-mm locked narrow plate)
- A 3.5-mm locked plate may be substituted in smaller patients.
- Sterile goniometer
- Plate press
- High-speed burr
- Power drill
- Osteotomes
- Oscillating saw
- Kirschner wire set

Patient Positioning
- A tourniquet is placed as high on the arm as possible. A sterile tourniquet is required to increase the zone of sterility.
- The patient is placed in the lateral decubitus position with the operative arm resting on a padded arm rest.

SURGICAL APPROACH
- Mark existing surgical scars and use prior incisions.
- Use a direct posterior approach for the elbow.
  - An anterior approach may be needed if the tissue is compromised posteriorly.
- If flap coverage is present, a plastic surgeon may be required for exposure.
  - Flaps with vascular pedicles can be located with Doppler.
- Create full-thickness flaps right down to the bone.
- Split the triceps tendon longitudinally.
- Carry the triceps split distally in the interval between the flexor carpi ulnaris (FCU) and the anconeus.
- Identify the ulnar nerve and make sure it remains protected.
- Identify neurovascular structures in known areas before following structures through areas of heavy scar tissue.

ARTHRODESIS

Osteotomy and Fracture Reduction
- Expose the dorsal surface of the distal humerus and proximal ulna.
- Use osteotomes to “fish-scale” the exposed bone.
- Open the medullary canal of the humerus and ulna.
- Perform a step-cut osteotomy of the proximal ulna and distal humerus to increase the surface area for fusion (TECH FIG 1A).
- Contour the bone so that it can be reduced at the appropriate angle chosen for arthrodesis.
  - It is often necessary to excise the radial head to allow for adequate reduction of the humerus and ulna.
- Reduce the distal humerus to the proximal ulna.
  - Confirm the fusion angle with a sterile goniometer (TECH FIG 1B).
  - Provisionally hold the reduction at the desired angle with 1.6-mm Kirschner wires.
- Apply the 4.5-mm locking plate posteriorly, prebent at the chosen angle of arthrodesis (TECH FIG 2B).
  - A long plate should be selected with a minimum of 10 to 14 holes.
  - A plate press is easier to use than bending irons.
- The plate functions as a neutralization device.
- All compression is achieved with the lag technique employed for screw placement.
- The plate is pulled down to the bone and secured with cortical screws before adding locked screws.
- Use at least one locked screw proximal and distal to the fusion site to increase the torsional strength of the construct (TECH FIG 2C).

Screw and Plate Fixation
- Drill from distal to proximal for lag screw insertion (TECH FIG 2A).
  - Use two or three lag screws whenever possible.
- Check the position and fixation of the construct intraoperatively with fluoroscopy.
- The final construct should compress well at the fracture site.
- The plate should conform securely to the bone at the desired angle of fusion (TECH FIG 3A).
- Irrigate and close the wound.
- Place one or two deep flat drains.
- Final radiographs should be taken intraoperatively (TECH FIG 3B,C).
TECH FIG 1 • A. Step-cut in distal humerus and proximal ulna. This is a multiplanar cut and should accommodate for the elbow position in both the coronal and sagittal planes. The step-cut provides a larger surface area for primary bone healing. B. Intraoperative use of a goniometer to confirm the fusion angle before definitive fixation.

TECH FIG 2 • A. Placement of lag screw. Screws are placed from distal to proximal in a crossed configuration. Two or three lag screws are placed before plate application. Provisional fixation is obtained with Kirschner wires and the fusion position is measured with a goniometer. B. Plate placement after the fusion angle has been confirmed. (continued)
PEARLS AND PITFALLS

- Step-cut bone to increase the surface area for healing.
- Place lag screws in both vertical and horizontal planes to increase compression.
- Keep dorsal tissue flaps at full thickness, including the periosteum.
- Use lag technique to compress the bone ends.
- Never identify neurovascular structures in areas of extensive surgical scarring. Work from known to unknown surgical fields.
- Open the medullary canal to facilitate blood flow.
- Select a plate of sufficient length to span the fusion site. Longer plates are desirable.
- Never place locking screws before reduction and compression of the bone ends.
- Keep patients in a cast for at least 4 months, until fusion occurs, depending on radiographs.

TECH FIG 2 • (continued) C. A guide for locking the screw through the plate and across the step-cut osteotomy. Compression must be achieved before locking screws are placed. A, distal humerus; B, proximal ulna.

TECH FIG 3 • A. Completed elbow arthrodesis using step-cut osteotomy and 3.5-mm locking plate and lag screw technique. A, distal humerus; B, proximal ulna. B,C. AP and lateral postoperative radiographs of left elbow fusion using step-cut osteotomy and locked plating technique.
POSTOPERATIVE CARE

- Drains are removed before hospital discharge.
- Intravenous antibiotics are continued for 48 hours or longer, depending on intraoperative cultures.
- Sutures or staples are removed at 2 weeks.
- The arm is placed in a long-arm cast at the 2-week visit.
- The patient is placed in serial casts for at least 4 months.
- Cast application is continued until there is radiographic evidence of union.

DEFINITION

The first reports of a distal metatarsal osteotomy date back to Reverdin, who described in 1881 a subcapital closing-wedge osteotomy for the correction of hallux valgus deformity.

The chevron osteotomy has become widely accepted for correction of mild and moderate hallux valgus deformities. In the initial reports by Austin and Leventen and Miller and Croce, no fixation was mentioned. They suggested that the shape of the osteotomy and impaction of the cancellous capital fragment upon the shaft of the first metatarsal provided sufficient stability to forego fixation.

To increase the indication for this technically simple osteotomy, internal fixation and a lateral soft tissue release have been added.

ANATOMY

The special situation distinguishing the first metatarsophalangeal (MTP) joint from the lesser MTP joints is the sesamoid mechanism.

On the plantar surface of the metatarsal head are two longitudinal cartilage-covered grooves separated by a rounded ridge. The sesamoids run in these grooves.

The sesamoid bone is contained in each tendon of the flexor hallucis brevis; they are distally attached by the fibrous plantar plate to the base of the proximal phalanx.

The head of the first metatarsal is rounded and cartilage-covered and articulates with the smaller concave elliptic base of the proximal phalanx.

Fan-shaped ligamentous bands originate from the medial and lateral condyles of the metatarsal head and run to the base of the proximal phalanx and the margins of the sesamoids and the plantar plate.

Tendons and muscles that move the great toe are arranged in four groups:

- Long and short extensor tendons
- Long and short flexor tendons
- Abductor hallucis
- Adductor hallucis

Blood supply to the metatarsal head

- First dorsal metatarsal artery
- Branches from the first plantar metatarsal artery

PATHOGENESIS

Extrinsic causes

- Hallux valgus occurs predominantly in shoe-wearing populations and only occasionally in the unshod individual.

Although shoes are an essential factor in the cause of hallux valgus, not all individuals wearing fashionable shoes develop this deformity.

Intrinsic causes

- Hardy and Clapham found in a series of 91 patients a positive family history in 63%.
- Coughlin reported that a bunion was identified in 94% of 31 mothers whose children inherited a hallux valgus deformity.
- Association of pes planus with the development of a hallux valgus deformity has been controversial.
- Hohmann was the most definitive that hallux valgus is always combined with pes planus.
- Coughlin and Kilmartin noted no incidence of pes planus in the juvenile patient.
- Pronation of the foot imposes a longitudinal rotation of the first ray, which places the axis of the MTP joint in an oblique plane relative to the floor. In this position the foot appears to be less able to withstand the deformity pressures exerted on it by either shoes or weight bearing.

The simultaneous occurrence of hallux valgus and metatarsus primus varus has been frequently described. The question of cause and effect continues to be debated.

PATIENT HISTORY AND PHYSICAL FINDINGS

Patient history often includes:

- Pain in narrow shoes
- Symptomatic intractable keratoses beneath the second metatarsal head (in 40% of patients)
- Lateral deviation of the great toe
- Pronation of the great toe
- Keratosis medial plantar underneath the interphalangeal joint
- Bursitis over the medial aspect of the medial condyle of the first metatarsal head
- Hypermobility of the first metatarsal-cuneiform joint

Physical examination for hallux valgus deformity includes the following:

- Hallux valgus angle: Normal is 15 degrees or less.
- Intermetatarsal angle: Normal is 9 degrees or less.
- Measurement of the position of the medial sesamoid relative to a longitudinal line bisecting the first metatarsal shaft
  - Grade 0: no displacement of sesamoid relative to the reference line
  - Grade I: overlap of less than 50% of sesamoid relative to the reference line
  - Grade II: overlap of greater than 50% of sesamoid relative to the reference line
  - Grade III: sesamoid completely displaced beyond the reference line
- Joint congruency: measuring the lateral displacement of the articular surface of the proximal phalanx with respect to the corresponding articular surface of the metatarsal head, as seen on a dorsoplantar roentgenogram
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs of the foot should always be obtained with the patient in the weight-bearing position with AP, lateral, and oblique views. The following criteria are examined:
  - Hallux valgus angle
  - Intermetatarsal angle
  - Sesamoid position
  - Joint congruency
  - Distal metatarsal articular angle: the relationship between the articular surface of the first metatarsal head and a line bisecting the first metatarsal shaft (normal is 10 degrees or less)
  - Arthrosis of the first MTP joint

DIFFERENTIAL DIAGNOSIS
- Ganglion
- Hallux rigidus

NONOPERATIVE MANAGEMENT
- Comfortable wider shoes
- Orthotics?
- Spiral dynamics physiotherapy in adolescents

SURGICAL MANAGEMENT
Indications
- Symptomatic hallux valgus deformity with a first intermetatarsal angle of up to 16 degrees
- Stable first metatarso-cuneiform joint

Contraindications
- Narrow metatarsal head so that adequate translation is not possible
- Intermetatarsal angle of more than 16 degrees
- Impaired vascular status
- Skeletally immature patient
- Severe osteoarthritic changes

Preoperative Planning
- Standard weight-bearing AP and lateral radiographs are mandatory.
- The hallux valgus and intermetatarsal angles and tibial sesamoid position are measured.
- A preoperative drawing is helpful.
- Clinical examination includes measurement of active and passive range of motion of the first MTP joint as well as inspection of the foot for plantar callus formation indicative of transfer metatarsalgia and stability of the first tarsometatarsal joint.

Positioning
- The foot is prepared in the standard manner.
- The patient is positioned supine.
- An ankle tourniquet is optional.

Approach
- The lateral soft tissue release is performed through a dorsal approach.
- The chevron osteotomy is performed through a straight midline incision.

LATERAL SOFT TISSUE RELEASE
- The procedure is typically performed under a peripheral nerve block.
- Make a dorsal 3-cm longitudinal incision over the first web space (TECH FIG 1A).
- Continue deep dissection bluntly.
- Insert a lamina spreader and a Langenbeck retractor to expose the first web space.
- Divide the lateral joint capsule (metatarso-sesamoid... (continued)
Chapter 1 DISTAL CHEVRON OSTEOTOMY: PERSPECTIVE

### TECHNIQUES

- Externally rotate the leg. Make a second skin incision at the medial aspect of the first MTP joint (TECH FIG 2A). Perform careful dissection to avoid any damage to the dorsomedial nerve. Open the medial MTP joint capsule with an inverted L-type incision (TECH FIG 2B,C). Inspect the joint for degenerative changes.
- Minimally shave the medial eminence to achieve a plane surface but also to preserve as much metatarsal head width as possible (TECH FIG 2D). This is one of the most important principles if a chevron osteotomy is carried out in a moderate to severe deformity.

### CHEVRON OSTEOTOMY

- Externally rotate the leg. Make a second skin incision at the medial aspect of the first MTP joint (TECH FIG 2A).
- Perform careful dissection to avoid any damage to the dorsomedial nerve. Open the medial MTP joint capsule with an inverted L-type incision (TECH FIG 2B,C). Inspect the joint for degenerative changes.
- Expose the metatarsal head and place Hohmann retractors dorsal and plantar just extra-articular of the first MTP joint. The plantar Hohmann retractor protects the plantar artery to the metatarsal head, and the dorsal retractor protects the dorsal intra-articular blood supply originating from the capsule.

**TECH FIG 1** • (continued) D. The great toe is brought into 20 degrees varus to demonstrate the release of the lateral structures.

**TECH FIG 2** • A. Medial skin incision for the osteotomy. B, C. Inverted L-type capsular incision. D. The medial eminence is minimally resected.
Drill a 1.0-mm Kirschner wire slightly dorsal to the center of the exposed medial eminence. This wire is generally inclined 20 degrees from medial to lateral, aiming at the head of the fourth metatarsal (TECH FIG 3A–C). In the situation of an elevated position of the first metatarsal, the inclination may be increased. If shortening or lengthening of the first metatarsal is needed, the wire may be aimed to the fifth or third metatarsal head.

Using a saw guide (TECH FIG 3D), make two cuts with an oscillating power saw so that they form an angle of 60 degrees proximal to the drill hole.

Once the capital fragment is freely mobile, pull the metatarsal shaft medially by using a towel clip while pushing the metatarsal head laterally with the help of the thumb of the other hand (TECH FIG 4A,B).

If the distal metatarsal articular angle is increased, a wedge from the distal dorsal cut may be excised to place the metatarsal head in a more varus position. If there is only a minor increase of the distal metatarsal articular angle, this may also be achieved by impacting the metatarsal head onto the shaft.

Insert a guidewire for a cannulated Charlotte multiuse compression screw (Wright Medical Technology) from the distal dorsal metatarsal shaft obliquely to lateral plantar of the metatarsal head (TECH FIG 4C,D).
Check the position of the osteotomy and the guidewire with a C-arm or a FluoroScan.
Measure the length of the screw with the cannulated depth gauge (TECH FIG 5A). The multiuse compression screws are designed to be totally self-tapping and self-drilling. However, to avoid dislocation of the head, use the cannulated drill (TECH FIG 5B) and cannulated head drill (TECH FIG 5C).

Insert the screw (TECH FIG 5D).
Excise the medial eminence in line with the metatarsal shaft, taking care not to excise too much bone off the metatarsal head (TECH FIG 5E).
While an assistant holds the great toe in a slightly overcorrected position, repair the medial joint capsule with U-type sutures, and tighten the first web space sutures (TECH FIG 5F).

**TECH FIG 5** • A. Length determination using the depth gauge. B. Predrilling with the Charlotte cannulated drill. C. Preparing a countersunk area with the Charlotte cannulated head drill. D. The screw is inserted until the head is completely countersunk within the bone. E. The medial eminence is resected. F. Closing of the medial capsule with U-type sutures.

POSTOPERATIVE CARE

- Starting immediately postoperatively, ice application to the foot is helpful to reduce swelling.
- Provided that the bone quality was intraoperatively sufficient, patients are allowed to walk with a postsurgical type shoe (OFA Rathgeber) (FIG 1) on the same day (limited for 4 weeks).
- Weekly changes of the tape dressing are necessary.
- An alternative to weekly dressing changes is the postoperative hallux valgus sock, which also reduces postoperative edema (FIG 2).
- Radiographs are taken intraoperatively and at 4 weeks of follow-up.
- After radiographic union is achieved, normal dress shoes with a more rigid sole are allowed.
- After 4 weeks physiotherapy to achieve normal forefoot function is recommended (FIG 3).

OUTCOMES

- In the early years of this technique it was limited to patients 50 years and younger. This was represented by the study of Johnson et al, which established a contraindication for using a chevron osteotomy in patients older than 50 years. However, Trnka and Schneider have proven that age is not a limiting factor for the chevron osteotomy.
- Another important issue that was stretched out over the years was the combination of a lateral soft tissue release and a distal chevron osteotomy. Earlier reports have expressed concern about an increased risk of avascular necrosis if a lateral release is performed in addition to a chevron osteotomy. Jahss, Mann, and Meier and Kenzora have all suggested that avascular necrosis frequently accompanies distal Chevron with lateral soft tissue release, citing an incidence of up to 40%. Pochatko and Trnka could not support this in their publications and found no increased risk of avascular necrosis.
- Chevron osteotomy was for many years limited to mild hallux valgus deformities. Designed primarily without fixation, the concern was stability and loss of fixation. As it became more obvious that a lateral soft tissue release is important for correction of more severe deformities, this concern gained weight. According to papers by Harper and Sarrafian, lateral displacement is limited to 50% of metatarsal width.
- Over a period of 14 years we have modified and developed the chevron osteotomy. By reviewing each step of the development with clinical studies, we now perform a chevron osteotomy with lateral soft tissue release and single screw fixation.
■ Trnka et al22 reported in 2000 a series of 43 patients (57 feet) with 2-year and 5-year follow-up. Radiographic evaluation revealed a preoperative average hallux valgus angle of 29 degrees and a preoperative average intermetatarsal angle of 13 degrees. At the 2-year follow-up, those angles averaged 15 and 8 degrees, respectively, and at the 5-year follow-up, they averaged 16 and 9 degrees. The results at these two follow-up periods proved that the chevron osteotomy is a reliable procedure for mild and moderate hallux valgus deformity and that there are no differences in outcome based on age.

■ Schneider et al19 reported in 2004 a series of 112 feet (73 patients) with a minimum follow-up of 10 years. For 47 feet (30 patients), the results were compared with those from an interim follow-up of 5.6 years. The AOFAS score improved from a preoperative mean of 46.5 points to a mean of 88.8 points after a mean of 12.7 years. The first MTP angle showed a mean preoperative value of 27.6 degrees and was improved to 14.0 degrees. The first intermetatarsal angle improved from a preoperative mean of 13.8 degrees to 8.7 degrees. The mean preoperative grade of sesamoid subluxation was 1.7 on a scale of 0 to 3 and improved to 1.2. Measured on a scale of 0 to 3, arthritis of the first MTP joint progressed from a mean of 0.8 to 1.7. The progression of arthritis of the first MTP joint between 5.6 and 12.7 years postoperatively was statistically significant. Excellent clinical results after chevron osteotomy not only proved to be consistent but also showed further improvement over a longer follow-up period. The mean radiographic angles were constant, without recurrence of the deformity. So far, the statistically significant progression of first MTP joint arthritis has not affected the clinical result, but this needs further observation.

■ Sanhudo17 retrospectively reviewed 50 feet with moderate to severe hallux valgus deformity in 34 patients with a mean follow-up of 30 months. There was a mean AOFAS score improvement of 39.6 (44.5 to 84.1) points. The hallux valgus angle and intermetatarsal angle improved a mean of 22.7 degrees and 10.4 degrees, respectively. He concluded that the chevron osteotomy is also indicated for moderate to severe hallux valgus deformity.

COMPLICATIONS

- Avascular necrosis of the metatarsal head
- A lateral release does not increase the incidence.16
- Hallux valgus
- Malpositioning
- Loss of fixation

REFERENCES

SURGICAL MANAGEMENT
- The primary indication for a chevron osteotomy is symptomatic hallux valgus deformity with a moderate deformity with an intermetatarsal angle of less than 15 degrees. The first metatarsocuneiform joint should be stable. The osteotomy can also be used to correct an abnormal distal metatarsal articular angle. It is used as a sole procedure in those presenting with minimal transfer symptoms.

Preoperative Planning
- AP and lateral weight-bearing radiographs of the foot are evaluated for metatarsal length, intermetatarsal angle, hallux valgus angle, distal metatarsal articular angle, and interphalangeal angle for cases that may require a proximal phalangeal osteotomy to obtain complete correction. Congruency of the joint, presence of osteophytes, the size of the bony medial eminence, and the position and condition of the sesamoids are noted.

Positioning
- Surgery is performed on an outpatient basis.
- Prophylactic antibiotics are administered.
- A thigh tourniquet is applied.
- The patient is positioned supine with a sandbag under the ipsilateral buttock so the big toe points to the ceiling.

CHEVRON OSTEOTOMY
- Perform the distal soft tissue release through a first web space incision. Take care to avoid stripping the lateral metatarsal head soft tissues. We then perform the osteotomy in a step manner as described below.
- Approach the metatarsal through a medial longitudinal incision extending from a point 1 cm proximal to the medial eminence to the medial flare of the proximal phalanx. This can be extended distally if a phalangeal osteotomy is required. Identify the dorsal medial cutaneous nerve and incise the medial capsule sharply in a single longitudinal direction (TECH FIG 1A). Expose the medial eminence and resect it 1 mm medial to the sagittal sulcus (TECH FIG 1B). The most important part of the exposure is the identification of the plantar vascular supply (TECH FIG 1C). The osteotomy must be extracapsular. This plantar vascular supply must remain attached to the capital fragment to minimize any risk of avascular necrosis (AVN).
- The apex of the osteotomy is defined as the center of an imaginary ellipse or circle started by the articular surface of the metatarsal. Mark the apex with ink (TECH FIG 2A).
- Create the transverse limb of the osteotomy from the apex to the plantar surface of the metatarsal. The obliquity of this cut varies, the most important factor being that the osteotomy must remain extra-articular and the plantar vascular supply must be maintained to the metatarsal head (TECH FIG 2B). Complete the osteotomy through to the lateral side.
- Perform the vertical osteotomy by measuring a 90-degree angle to the plantar cut and then angling the saw blade to reduce this angle by 10 to 20 degrees. The exact angle is not crucial; we find aiming for the angle to be between 60 and 80 degrees produces a stable osteotomy (TECH FIG 2C). Complete this osteotomy to the lateral side to allow displacement of the head fragment. Take care to protect the extensor hallucis longus tendon while performing the vertical osteotomy.
- Use a sharp towel clip to grasp the proximal fragment and use the thumb to apply lateral displacement to the capital fragment (TECH FIG 3A). We allow a maximum of 50% displacement. A McDonald dissector can be used to tease the capital fragment over if required.
• Use in-line force to compress the head fragment onto the shaft, allowing cancellous impaction (TECH FIG 3B). This aids in the immediate stability of the osteotomy while fixation is achieved.

• We prefer fixation using a 1.6-mm Kirschner wire, although a compression screw can also be used. We pass the Kirschner wire in a retrograde fashion under direct vision from the plantar head obliquely across to the proximal fragment and through an appropriately placed small skin incision (TECH FIG 3C). Back the wire out to leave it a few millimeters deep to cartilage, thus maintaining excellent fixation without penetrating the joint.

Shave the redundant neck cortex, approximating to 50% of the protruding portion.

• Imbricate the medial capsule with a strong absorbable suture while holding the hallux in a neutral or slightly abducted position with the aid of a swab.

• Confirm the reduction in the intermetatarsal angle, screws, and relocation of the sesamoids with image intensification with the foot flat on the image intensifier. Assess the need for a proximal phalangeal osteotomy.

• Close the wound in layers with continuous Monocryl to the skin and apply a forefoot bandage to maintain the correction.

**TECH FIG 2**

A. An imaginary ellipse based on the articular surface is made and the center is marked with ink. This is used as the apex of the osteotomy.  
B. The longitudinal cut is performed, ensuring that the proximal limb is extra-articular and the vascular bundle is maintained to the head.  
C. The saw blade is placed at 90 degrees to the longitudinal cut and then angled to produce a chevron osteotomy of between 60 and 80 degrees.

**TECH FIG 3**

A. The osteotomy is displaced and held with a clip.  
B. In-line compression is performed to impact the cancellous fragments together to increase stability.  
C. A 1.6-mm Kirschner wire is passed in a retrograde fashion across the osteotomy site.
PEARLS AND PITFALLS

**Exposure**
- The most important part of the exposure is that of the plantar vascular bundle. Failure to do so may compromise the blood supply to the metatarsal head.

**Osteotomy**
- If displacement of the osteotomy is difficult, check that all cuts have been completed. A limited lateral capsulotomy may be performed if needed, restricting the knife cuts to the lateral soft tissues distal to the metatarsal head.

**Distal metatarsal articular angle correction**
- To correct an abnormal distal metatarsal articular angle, a small medial wedge from the vertical limb of the osteotomy can be performed. This will make the osteotomy more unstable, and care must be taken to achieve good fixation.

POSTOPERATIVE CARE
- If safe, patients are discharged home on the day of surgery with strict advice to elevate the foot whenever resting for the first 2 weeks.
- In most cases they are allowed to bear weight on their heel and lateral forefoot in a hard-soled postoperative shoe.
- Cast immobilization is not required.
- The wound is inspected at 2 weeks, at which time the hallux is restrapped and patients are taught simple passive and active toe flexion–extension exercises.
- At 4 weeks postoperatively the osteotomy is assessed. The Kirschner wire is removed in the outpatient setting.
- At 6 weeks the osteotomy is checked radiologically, and if there is consolidation at the line of the osteotomy, the patient is instructed to wear a wide shoe or sneaker and to progress to full weight bearing as tolerated. Strapping of the hallux is discontinued at this time.

OUTCOMES
- The chevron osteotomy is the most commonly performed distal chevron osteotomy for mild hallux valgus in the United States, and outcomes are excellent. AVN with the use of a lateral release remains a concern. Recent reports suggest very low rates of AVN when correcting moderate deformities with the chevron osteotomy with a lateral release. The improved correction that we see with a lateral release means that we perform it in every case.
- Evidence also now suggests that concern that the osteotomy should be reserved for patients under 50 years old may not be true, with equivalent results in differing age groups.

COMPLICATIONS
- Complications include AVN, stiffness, wound problems, infection, undertreatment, overtreatment, fractures, chronic regional pain disorder, and deep vein thrombosis. Delayed union and nonunion are rare complications with the use of fixation.

REFERENCES
DEFINITION
- Hallux valgus is a common condition that can affect both adults and adolescents. Patients complain of pain and restriction with activities of daily living because of the lateral deviation of the great toe, the medial deviation of the first metatarsal, and the onset of inflammation at the progressively worsening medial eminence of the first metatarsal head.

ANATOMY
- The first metatarsophalangeal (MTP) joint’s complex anatomy is directly related to its complex physiology. The concave articular surface of the great toe’s proximal phalanx articulates with the convex first metatarsal head. Its physiologic relationship is maintained by the surrounding articular capsule and collateral ligaments. At the plantar aspect of the first MTP joint, the sesamoid complex acts as a rail on which the first metatarsal head glides congruently with the intrinsic and extrinsic tendons, providing power and stability to the joint.

PATHOGENESIS
- Congruent first MTP joint (physiologic distal metatarsal articular angle [DMAA])
  - The literature suggests that that lateral deviation of the great toe is the primary event leading to hallux valgus deformity. This primary deforming force has a reciprocal relationship with metatarsus primus varus; the first and second intermetatarsal angle (IMA) worsens with an increase in the hallux valgus angle (HVA), and vice versa. The valgus of the proximal phalanx produces forces whose vectors determine the lateral deviation of the head of the first metatarsal.
  - Congruent first MTP joint (increased DMAA)
    - With an increased DMAA, hallux valgus is present despite congruency of the first MTP joint. The articular surface of the first metatarsal head is in a valgus position relative to the first metatarsal shaft axis; therefore, hallux valgus is present even without an imbalance of the muscle forces on the first MTP joint. However, this imbalance leads to a worsening of the deformity. Hallux valgus with an increased DMAA is less common than the incongruent type and typically occurs in men and younger patients.

NATURAL HISTORY
- Shoe wear may contribute to the development of hallux valgus deformity. A narrow and triangular toe box combined with high heels may force lateral deviation of the great toe, leading to a mechanical disadvantage of the abductor hallucis muscle. Persistence of these deforming forces may create a relative lateral displacement of the extensor hallucis longus and flexor hallucis longus tendons, which in turn may increase valgus deviation of the great toe. Eventually, the first MTP joint’s medial capsule and collateral ligament become attenuated, while its lateral soft tissues become contracted.
- The laterally deviated hallux proximal phalanx exerts a varus-producing force to the first metatarsal head, thereby worsening the metatarsus primus varus deformity. Since the sesamoid complex is attached to the proximal phalanx, the sesamoid position typically remains anatomic as the first metatarsal head subluxates medially. Progression of this displacement often produces the functional deficits and pronation of the great toe.
- Because the first MTP joint is stable and congruent but malaligned with respect to the first metatarsal axis (increased DMAA), juvenile and adolescent hallux valgus deformity should prompt evaluation for potential associated pathology, such as metatarsus adductus, hypermobility, or ligamentous laxity.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients typically complain of pain over the first metatarsal head’s medial eminence, especially while standing and walking in a narrow toe box shoe. Occasionally, patients develop a symptomatic bursitis over the medial eminence.
- Pain plantar to the first metatarsal head suggests a symptomatic and incongruent articulation of the sesamoids with the first metatarsal head. Compensation for this discomfort may lead to transfer metatarsalgia.
- An imbalance of forefoot pressures created by the malalignment of the first ray secondary to hallux valgus may also lead to transfer metatarsalgia.
- We routinely review the patient’s general health, activity level, and family history of hallux valgus. We always check for comorbidities that may have a direct impact on the success of corrective bunion surgery, particularly diabetes, arthritis, and neurovascular diseases.
- To fully appreciate the degree of hallux valgus deformity, the involved foot must be examined with the patient standing.
- We evaluate the range of motion and alignment of the ankle, hindfoot, midfoot, and forefoot with the patient standing.
- Pronation of the hallux is also best assessed with the patient standing.
- The lesser toes are carefully examined for deformities, which can be rigid or supple, requiring different types of treatment.
- Pronation of the great toe must be assessed as well as the presence of callosities under the toes and forefoot associated with metatarsalgia.
- Passive correction of hallux valgus is attempted. With the patient standing, pressure is applied over the lateral face of the great toe, trying to correct its valgus deviation. Patients with passive correctable lateral deviation of the great toe will need less invasive or hazardous procedures for the treatment of their hallux valgus deformity, particularly the adductor hallucis release.
Hypermobility of the first ray can have an influence on the onset of the hallux valgus deformity as well as on its treatment.

It is easy to differentiate the flexible and rigid forms of hammer or claw toes by applying thumb pressure in the forefoot sole and elevating the metatarsal heads; in the flexible forms, the deformities reduces or disappears completely; in the rigid forms, the maneuver does not change the hammer or claw toes.

A positive MTP joint drawer sign indicates the presence of a capsulitis and instability of the joint due to the lesion of the plantar capsule or collateral ligaments, more commonly the lateral portion of the plantar plate.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Hallux valgus must be assessed with a minimum of AP and lateral weight-bearing radiographs of the foot.

  - The HVA is determined by the intersection of the diaphyseal axes of the first metatarsal and the proximal phalanx. Arbitrarily, a normal HVA does not exceed 15 degrees (Fig. 1A).

  - The IMA is the angle between the diaphyseal axes of the first and second metatarsals. Arbitrarily, a normal IMA does not exceed 9 degrees (Fig. 1B).

  - The sesamoid position is determined by its relationship with the first metatarsal diaphyseal axis. Typically the sesamoids remain in their anatomic position; with progressive hallux valgus deformity, the first metatarsal head progressively subluxates medially in relation to the sesamoids.

- Normal (grade 0) sesamoid position: The tibial and fibular sesamoids are equidistant from the bisecting line of the first metatarsal.

- Sesamoid position grades 1 to 3: Grades 1 through 3 signify an increasingly greater lateral position of the tibial sesamoid relative to the bisecting line of the first metatarsal shaft axis, with grade 3 indicating that the tibial sesamoid is positioned completely laterally relative to the reference line (Fig. 1C and 2).

- The interphalangeal angle (IPA) is measured between the articular edges of the head and the line bisecting the first metatarsal. The IPA normal value is up to 10 degrees.

- The proximal phalanx articular angle is measured between the tangent to the proximal articular surface of the proximal phalanx of the great toe and the line bisecting the diaphyseal axis of the same phalanx. It is considered normal up to 8 degrees (Fig. 3). Inter-and intra-observer reliability for measuring the DMAA is poor.

- The DMAA is obtained by the intersection of the line that connects the articular edges of the head and the line bisecting the first metatarsal shaft. The DMAA normal value is up to 8 degrees (Fig. 3). Inter-and intra-observer reliability for measuring the DMAA is poor.

- Relative length of the first and second rays is measured pre- and postoperatively. Most osteotomies lead to shortening of the first metatarsal. In our experience, greater than 5 mm of first metatarsal shortening frequently results in transfer metatarsalgia (Fig. 1D).

**DIFFERENTIAL DIAGNOSIS**

- Hallux valgus interphalangeus
- Hallux rigidus
- Sesamoiditis

**NONOPERATIVE MANAGEMENT**

- Patient education

  - While there is no concrete evidence that shoe wear causes hallux valgus, we believe that wearing shoes with tight toe boxes and high heels contributes to the worsening of deformity.

  - Patients with intrinsic factors contributing to hallux valgus, such as an increased DMAA, should be educated that they are particularly prone to external forces worsening their hallux valgus deformity.

- Orthotic devices and insoles may relieve symptoms but generally do not correct deformity. Moreover, patients already in need of wider toe boxes may need to find shoes with extra depth to accommodate both their foot deformity and the orthotic device. In juvenile hallux valgus (skeletally immature patients), the use of a custom-made night splint could limit the progression but cannot reverse the deformity.

**FIG 1** AP radiograph of a patient with hallux valgus. **Left,** Hallux valgus angle (**HVA**; up to 15 degrees). **Second from left,** First intermetatarsal angle (**IMA**; up to 9 degrees). **Second from right,** Sesamoid position. In this patient, the tibial sesamoid is divided into two halves by the diaphyseal axis of the first metatarsal, which means the beginning of a grade 2 sesamoid subluxation (normal is grade 0). **Right,** Relative length of the first and second metatarsals; normal is up to 5 mm.

**FIG 2** Evaluation of hallucal sesamoid position. Grade 0, no displacement of sesamoids relative to the middle diaphyseal axis of the first metatarsal (normal). Grade 1, overlap of less than 50% of the tibial (medial) sesamoid to the reference line. Grade 2, overlap of more than 50% of the tibial sesamoid to the reference line. Grade 3, tibial sesamoid completely displaced beyond the reference line.

**FIG 3** G0, G1, G2, G3.
In skeletally mature patients, intermittent use of a corrective splint does not adequately counterbalance many hours of shoe wear with a narrow toe box and a high heel.

SURGICAL MANAGEMENT

- The primary indication for the biplanar distal chevron osteotomy is moderate hallux valgus deformity with a 1–2 IMA of 14 degrees or less associated with a DMAA greater than 8 degrees.15
- Reports of the traditional distal chevron technique over the past two decades suggest that comparable outcomes are achieved for younger and older patients.9
- In our hands, contraindications to any distal first metatarsal osteotomy for hallux valgus correction include asymptomatic deformity; a 1–2 IMA exceeding 15 degrees; first MTP joint stiffness or degenerative arthritis; and osteoporosis or osteopenia.

Preoperative Planning

- Satisfactory neurovascular status
- Is the hallux valgus passively correctible? The surgeon should assess associated lesser toes deformities, including fixed versus flexible deformity, impingement or overlap on the first toe, and presence of plantar calluses.
- Using radiographic measurements from preoperative weight-bearing radiographs of the foot, we always have a preoperative estimation of the required lateral translation of the first metatarsal head and wedge resection to correct the increased DMAA.

Positioning

- The patient is positioned supine, with the plantar aspect of the operated foot in line with the end of the operating table.
- We stand on the side of the table immediately adjacent to the operated foot; our assistant stands at the end of the table.
- We routinely use a tourniquet.

Approach

- A 5-cm longitudinal midaxial medial incision is made, centered over the medial eminence (FIG 4).
- Careful subcutaneous dissection is performed to protect the dorsal and plantar medial sensory nerves to the hallux.
- While the distal metatarsal metaphysis must be exposed, periosteal stripping is kept to a minimum and the lateral vascular supply to the first metatarsal head remains protected.
- In our experience, with the proper indications outlined above, we rarely need to perform a risky lateral dissection of the adductor hallucis tendon at the joint line.
- A routine portion of the exposure, lateral dislocation of the metatarsal head, serves as a physiologic release of the adductor hallucis by bringing its phalangeal insertion closer to its origin.9,10,15

CAPSULOTOMY

- I use a Y-shaped incision over the medial face of the MTP joint capsule, creating three distinct flaps that I reapproximate at the completion of the procedure to achieve optimal tensioning (TECH FIG 1A,B).
- A short V capsular flap attached to the base of the hallux proximal phalanx may be used as an anchor to correct the deformity. I always preserve the relatively thin dorsal capsular flap continuous with the lateral capsule to maintain the blood supply to the first metatarsal head. The stout plantar capsular flap attached to the sesamoids serves to re-establish the optimal first metatarsal head-sesamoid position when tensioned after completion of the osteotomy.
MEDIAL AND DORSAL METATARSAL HEAD EXPOSURE

- After capsulotomy the first metatarsal head’s medial eminence and sagittal groove are exposed.
- Starting at the medial aspect of the sagittal groove, I resect the medial eminence with a small oscillating saw from dorsal to plantar, in line with the medial edge of the foot (TECH FIG 2A,B).
- I make sure to preserve the integrity of the metatarsal head and medial cortex of the metatarsal shaft (TECH FIG 2C,D).

- Occasionally, a “dorsal bunion” is present in the absence of degenerative change. I routinely resect this dorsal eminence in line with the dorsal cortex of the metatarsal shaft to eliminate any chance for impingement and potentially improve cosmesis (TECH FIG 2E).
OSTEOTOMY

As a point of reference, I mark the geometric center of the first metatarsal head with a sharp instrument on the prepared medial surface (TECH FIG 3A). From this point I draw the segments (arms) of the planned osteotomy.

I cut the plantar arm of the osteotomy parallel to the inferior surface of the foot (TECH FIG 3B), thereby creating a broad and stable surface area to promote healing between the two osteotomy fragments.

According to the preoperative radiographic DMAA estimate, I plan a medially based wedge resection as part of the dorsal limb osteotomy to rotate the capital fragment into a more physiologic relationship with the first metatarsal shaft. Three methods exist to determine the correct size for the medial wedge to be removed:

- A trigonometric formula (wedge width = tan DMAA × first metatarsal head width [in millimeters])
- Drawing the wedge corresponding to the measured DMAA over the AP radiographic image of the first metatarsal
- By direct vision during the operation, make the distal cut parallel to the distal metatarsal articular surface and the proximal cut perpendicular to the long axis of the first metatarsal (TECH FIG 3C-E).

The saw blade must not violate the inferior portion of the metatarsal head fragment.

In my experience, each millimeter of lateral metatarsal head translation corresponds to one degree of 1–2 IMA correction. Using average physiologic dimensions, the metatarsal head may be translated laterally up to 6 mm to create a 9-degree 1–2 IMA without forfeiting osteotomy stability.

After dorsal wedge resection and simultaneous to lateral translation, rotate the metatarsal head to create a physiologic DMAA and achieve optimal bony apposition at the dorsal aspect of the osteotomy.9,12

Gentle longitudinal traction on the hallux and concomitant pressure with the thumb over the medial capital fragment facilitates lateral displacement (TECH FIG 3F).

By driving the great toe as a joystick, the capital fragment is rotated under direct vision to correct the DMAA.
Once the proper positioning of the fragments is obtained, apply gentle pressure on the great toe to coapt the osteotomy site (TECH FIG 3G).

In our experience, it is not necessary to check the position of the fragments and the amount of correction with fluoroscopy but, for those who think that it is advisable, this is the right moment to do that. You can use a 1.2-mm Kirschner wire to maintain the fragments temporarily during the fluoroscopic checking.

I routinely secure the osteotomy with a single screw, either a solid screw placed in lag fashion or a headless cannulated or noncannulated dual-pitch compression screw, while maintaining manual reduction of the osteotomy.

- Screw position: 5 mm proximal to the dorsal arm of the biplanar chevron osteotomy, on the first metatarsal shaft (TECH FIG 3H)

- Screw trajectory: I aim the screw 10 degrees distally and 15 degrees laterally to target the optimal portion of the laterally translated distal fragment, compress the fragments, and limit the risk of penetrating the plantar articular surface.

- Using a 2.7-mm solid screw
- Initial 2.0-mm drill hole, followed by overdrill of the near cortex with a 2.7-mm drill to create a lag effect
- Because of the screw trajectory and relatively thin overlying capsule and skin, consider using a countersink.
- Insertion of the 2.7-mm screw to carefully compress the osteotomy and maintain reduction (TECH FIG 3I)
- Using a headless cannulated or noncannulated dual-pitch screw
- Guide pin (if cannulated)
I judiciously resect redundant medial capsule. Holding the proximal phalanx in optimal alignment relative to the long axis of the first metatarsal in both the sagittal and transverse planes facilitates determining the overlap of residual medial capsule.

In anticipation of some tendency toward recurrence of deformity, I typically hold the hallux in a slight varus and plantarflexion position.

In my experience, this optimal position is best maintained by the assistant holding the first metatarsal, the MTP joint, and hallux between the thumb and the second finger of the assistant’s hand so that the hallux rests in the space between the assistant’s first and second metacarpals (TECH FIG 4A,B).

With the assistant maintaining the optimal position, I resect the redundant capsular flaps. Next, I check the relationship of the medial sesamoid and first metatarsal head, applying greater tension to the plantar flap to reduce the head on the sesamoids if necessary. I place a 2-0 nonabsorbable buried suture at the central corners of both the dorsal and plantar capsular flaps and systematically close the capsulotomy from distal to proximal (TECH FIG 4C).

I appose the residual V-shaped flap attached to the medial aspect of the proximal phalanx to the previously sutured dorsal and plantar flaps. In my experience, removing greater capsular redundancy from the dorsal portion of the phalangeal flap facilitates correction of hallux pronation (TECH FIG 4D-F).

I use a single suture, which is placed at the center of the Y, where the capsular flaps meet (TECH FIG 4G).

Once the medial capsulorrhaphy is complete, the assistant releases the toe. Ideally, the hallux should maintain its corrected alignment without external support.

Occasionally I augment the capsulorrhaphy with complementary tensioning sutures to obtain the desired position. Again the hallux must be held in the corrected position, or even slight varus as noted above (TECH FIG 4H).

Carefully resect the residual medial prominence of the proximal fragment with an oscillating saw, directing the saw blade from dorsal to plantar while avoiding any violation of the first metatarsal diaphysis (TECH FIG 3K).

I routinely irrigate the first MTP joint with saline solution to remove undesirable detritus.

CAPSULORRHAPHY

I judiciously resect redundant medial capsule. Holding the proximal phalanx in optimal alignment relative to the long axis of the first metatarsal in both the sagittal and transverse planes facilitates determining the overlap of residual medial capsule.

In anticipation of some tendency toward recurrence of deformity, I typically hold the hallux in a slight varus and plantarflexion position.

In my experience, this optimal position is best maintained by the assistant holding the first metatarsal, the MTP joint, and hallux between the thumb and the second finger of the assistant’s hand so that the hallux rests in the space between the assistant’s first and second metacarpals (TECH FIG 4A,B).

With the assistant maintaining the optimal position, I resect the redundant capsular flaps. Next, I check the relationship of the medial sesamoid and first metatarsal head, applying greater tension to the plantar flap to reduce the head on the sesamoids if necessary. I place a 2-0 nonabsorbable buried suture at the central corners of both the dorsal and plantar capsular flaps and systematically close the capsulotomy from distal to proximal (TECH FIG 4C).

I appose the residual V-shaped flap attached to the medial aspect of the proximal phalanx to the previously sutured dorsal and plantar flaps. In my experience, removing greater capsular redundancy from the dorsal portion of the phalangeal flap facilitates correction of hallux pronation (TECH FIG 4D-F).

I use a single suture, which is placed at the center of the Y, where the capsular flaps meet (TECH FIG 4G).

Once the medial capsulorrhaphy is complete, the assistant releases the toe. Ideally, the hallux should maintain its corrected alignment without external support.

Occasionally I augment the capsulorrhaphy with complementary tensioning sutures to obtain the desired position. Again the hallux must be held in the corrected position, or even slight varus as noted above (TECH FIG 4H).

Carefully resect the residual medial prominence of the proximal fragment with an oscillating saw, directing the saw blade from dorsal to plantar while avoiding any violation of the first metatarsal diaphysis (TECH FIG 3K).

I routinely irrigate the first MTP joint with saline solution to remove undesirable detritus.

Dual-diameter drill corresponding to the particular screw system

Insertion of the screw after proper screw length has been determined, with compression of the fragments and stability created at the osteotomy (TECH FIG 3J)

Carefully resect the residual medial prominence of the proximal fragment with an oscillating saw, directing the saw blade from dorsal to plantar while avoiding any violation of the first metatarsal diaphysis (TECH FIG 3K).

I routinely irrigate the first MTP joint with saline solution to remove undesirable detritus.

CAPSULORRHAPHY

I judiciously resect redundant medial capsule. Holding the proximal phalanx in optimal alignment relative to the long axis of the first metatarsal in both the sagittal and transverse planes facilitates determining the overlap of residual medial capsule.

In anticipation of some tendency toward recurrence of deformity, I typically hold the hallux in a slight varus and plantarflexion position.

In my experience, this optimal position is best maintained by the assistant holding the first metatarsal, the MTP joint, and hallux between the thumb and the second finger of the assistant’s hand so that the hallux rests in the space between the assistant’s first and second metacarpals (TECH FIG 4A,B).

With the assistant maintaining the optimal position, I resect the redundant capsular flaps. Next, I check the relationship of the medial sesamoid and first metatarsal head, applying greater tension to the plantar flap to reduce the head on the sesamoids if necessary. I place a 2-0 nonabsorbable buried suture at the central corners of both the dorsal and plantar capsular flaps and systematically close the capsulotomy from distal to proximal (TECH FIG 4C).

I appose the residual V-shaped flap attached to the medial aspect of the proximal phalanx to the previously sutured dorsal and plantar flaps. In my experience, removing greater capsular redundancy from the dorsal portion of the phalangeal flap facilitates correction of hallux pronation (TECH FIG 4D-F).

I use a single suture, which is placed at the center of the Y, where the capsular flaps meet (TECH FIG 4G).

Once the medial capsulorrhaphy is complete, the assistant releases the toe. Ideally, the hallux should maintain its corrected alignment without external support.

Occasionally I augment the capsulorrhaphy with complementary tensioning sutures to obtain the desired position. Again the hallux must be held in the corrected position, or even slight varus as noted above (TECH FIG 4H).

Carefully resect the residual medial prominence of the proximal fragment with an oscillating saw, directing the saw blade from dorsal to plantar while avoiding any violation of the first metatarsal diaphysis (TECH FIG 3K).

I routinely irrigate the first MTP joint with saline solution to remove undesirable detritus.

Dual-diameter drill corresponding to the particular screw system

Insertion of the screw after proper screw length has been determined, with compression of the fragments and stability created at the osteotomy (TECH FIG 3J)
Close the subcutaneous tissue with interrupted absorbable sutures.
- I favor using absorbable subcuticular sutures and interrupted fine nylon suture in young patients (more favorable skin) and older patients (less favorable skin), respectively.

I routinely use a bunion dressing, or H dressing, in the first web space to relieve tension on the medial capsulorrhaphy. I wrap the forefoot with a sterile cotton bandage followed by an adhesive bandage that maintains slight compression on the first metatarsal.

**PEARLS AND PITFALLS**

Indications
- I favor a proximal first metatarsal osteotomy with a 1–2 IMA greater than 15 degrees.
- In my experience, the power of 1–2 IMA correction is limited by the width of the metatarsal head.
- In general, 1 mm of lateral translation equals 1 degree of 1–2 IMA correction.
- A biplanar osteotomy is not required unless the DMAA exceeds 8 degrees.

Approach
- I routinely perform the skin incision 2 mm dorsal to the medial midaxial line to identify and protect the dorsomedial sensory nerve to the hallux.

Capsular flaps
- Develop the capsular flaps carefully to allow optimal soft tissue balancing during capsulorrhaphy.

Medial eminence resection
- Perform the medial eminence resection in line with the medial foot, not the medial aspect of the first metatarsal.
- Less resection is better (limits potential for varus)!

Osteotomy
- The plantar arm should be parallel to the plantar plane of the foot.
- The apex of the wedge to be resected dorsally should coincide with the lateral cortex of the head to avoid shortening of the metatarsal.

Screw fixation
- Direct the drill and screw laterally to capture the plantar “tongue” of the distal fragment.
- Avoid placing a screw that penetrates the plantar cortex at the metatarsal head-sesamoid complex.
- Remember to countersink the dorsal metaphyseal cortex when using a 2.7-mm screw.

Capsulorrhaphy
- Be sure that your assistant maintains the great toe at the right position during capsulorrhaphy.

Dressing
- Should maintain the great toe in the optimal position for 3 weeks.
the fragment fixation. In a general view, we can see the size and position of the screw used in its fixation, and the alignment of the cephalic fragment with the metatarsal diaphysis resulting from the dorsal fragment resection.

**POSTOPERATIVE CARE**

- Anticipated dried blood may harden the bandage and create pressure-related symptoms postoperatively. This occurs often enough that we routinely change the patient’s bandage on postoperative day 3 or 4. We allow my patients to bear weight in a Barouk postoperative shoe after the first dressing change. This orthosis concentrates the patient’s weight on the rear of the foot while protecting the forefoot. Our patients do not routinely require crutches or assistive devices, but the occasional elderly patient with comorbidities may benefit from temporary use of a walker.

- We routinely change the bandage for my bunion patients at 10-day intervals to confirm that proper great toe alignment is maintained. To confirm that the alignment and reduction are maintained, we obtain a radiograph of the operated foot at 3 weeks after surgery. In our experience, at 1 month postoperatively patients may transfer to a pair of soft and wide lace-up shoes and initiate hallux range-of-motion exercises.

- In our practice, it takes an average of 3 to 4 months for patients to reach the maximum range of motion and return to regular shoe wear and full activity.

**OUTCOMES**

- Patient satisfaction rates after distal biplanar chevron osteotomy for moderate hallux valgus deformity approach 90%, depending on appropriate patient expectations and selection.

- In our experience, the procedure reliably and reproducibly corrects the 1–2 IMA, HVA, and increased DMAA (**FIG 5**).

**COMPLICATIONS**

- Complications are similar to other distal first metatarsal osteotomies for correction of hallux valgus.

- Recurrence or undercorrection

- Inappropriate preoperative planning

- Stretching the indications

- Usually due to inadequate:
  - Lateral translation
  - Rotation of the first metatarsal head
  - Soft tissue balancing during the capsulorrhaphy
  - Lack of proper postoperative bunion dressing

- Avascular necrosis of the head of the first metatarsal

- Overzealous lateral soft tissue stripping

- Overpenetration of the saw blade into the lateral capsule

- Although radiographic first metatarsal head changes are frequently observed after distal metatarsal osteotomies, they rarely progress to symptomatic necrosis and collapse of the metatarsal head.

- First MTP joint stiffness

- In our experience, joint stiffness responds to physical therapy and advancing the weight-bearing status. We maintain that slight overcorrection and some MTP joint stiffness is preferable to undercorrection and full MTP joint motion.

- Hallux varus

- Overresection of the medial capsule

- Unnecessary overrelease of the lateral capsule and adductor hallucis tendon

**REFERENCES**

DEFINITION
- The distal chevron osteotomy has proven to be a reliable, reproducible method of bunion repair for mild to moderate deformity. By altering the location and displacement of the osteotomy, the indications can be expanded to more complex deformities while preserving the straightforward surgical exercise.
- The apex of the chevron osteotomy can be modified to a more proximal location along with a reduced angle to provide a stable healing surface that facilitates maximal lateral translation.
- The proximal location of the osteotomy also reduces the risk of avascular necrosis and permits safe lateral capsule release needed for larger corrections.
- This technique facilitates treatment for moderate to severe bunion deformity with a straightforward surgical method using limited, readily available internal fixation.

ANATOMY
- Factors contributing to a bunion deformity vary among individuals. The diverse anatomic features require scrutiny during surgical planning.
- Pertinent to the corrective factors of a translational osteotomy is the width of the distal metatarsal. The amount of correction may be limited in a small, narrow, or “hourglass” shaped bone.
- The distal metatarsal articular angle (DMAA) may be altered by varus or valgus rotation during a distal osteotomy. This additional corrective factor should be addressed during the surgical planning.
- The position of the sesamoids needs to be assessed for optimal correction. Station III subluxation usually requires a lateral capsule release to restore normal joint mechanics.
- Hypermobility of the first ray should be evaluated. Correction by lateral translation of the distal metatarsal may be compromised if the cuneiform–metatarsal joint is unstable.

IMAGING AND DIAGNOSTIC STUDIES
- Weight-bearing AP and lateral radiographs are used to determine bone morphology, associated disease, and deformity parameters used in decision making.

SOFT TISSUE PREPARATION
- When significant sesamoid subluxation is present (grade II or III), use a dorsal first web incision to expose the lateral capsule.
- A Freer elevator is helpful to probe and identify the dorsal margin of the subluxed lateral sesamoid. Then incise the capsule longitudinally from the phalanx to well proximal to the lateral sesamoid. The adductor tendon is plantar to this incision and is preserved. Leave the intermetatarsal ligament intact. The purpose of this longitudinal cut is to allow medialization of the plantar sesamoid complex at the time of capsule repair from the medial side.
- Expose the joint through a medial longitudinal incision. Identify and protect the superficial peroneal nerve. Mobilize the tissues to expose the capsule from the medial sesamoid inferiorly to the extensor hallucis longus tendon superiorly. The medial plantar digital nerve is also at risk and needs to be protected as the dissection nears the medial sesamoid.

SURGICAL MANAGEMENT
Positioning
- The patient is positioned supine. When regional ankle block anesthesia is used, an ankle tourniquet is applied. Otherwise, a thigh tourniquet can be used for general or spinal anesthesia.
Cut the capsule longitudinally and slightly plantar to the center of the metatarsal. Reflect the capsule to expose the medial metatarsal eminence and the joint, but pre-
serve it on the dorsal or plantar aspect to minimize risk of vascular insult.

**BONE PREPARATION**

- Remove the medial eminence with a power saw. The amount of bone is based on radiographic interpretation. Avoid excessive removal to prevent hallux varus. Usually the cut is 1 to 2 mm medial to the articular margin or the sagittal groove.
- Determine the apex of the osteotomy and mark it with a surgical pen (TECH FIG 1). It is typically 15 to 20 mm from the articular surface. Outline the proximal limbs at an angle of about 35 to 45 degrees. If the limbs are too short, there may be instability; if they are too long, there may be difficulty translating or rotating the distal head portion.

Next, use a Freer elevator to gently strip the periosteum and soft tissue over the area where the osteotomy is anticipated to cut the dorsal and plantar aspects of the metatarsal. Again, leave the tissues distal to the bone cut in place to minimize vascular compromise.
- The osteotomy can be affected by saw position with a dorsal, plantar, proximal, or distal angulation. Generally, a straight or neutral cut is best.
- After completing the osteotomy, the distal head fragment should be readily mobilized. Translation is facilitated by applying traction to the toe with one hand and using the other hand to pull with a towel clip on the apex of the proximal metatarsal. Thumb pressure against the head while maintaining traction will allow repositioning of the metatarsal with minimum force (TECH FIG 2A). If the head fragment is not readily mobilized, the osteotomy needs to be rechecked and cut.
- Since the osteotomy is usually proximal to the metaphyseal bone, the lateral cortex often appears as a spike. The distal head is then perched on this lateral process to maintain length (TECH FIG 2B). Up to 90% translation is possible and satisfactorily stabilized with Kirschner wires. Slight varus or valgus tilt can be applied as indicated by the DMAA.
- Using 0.054 smooth Kirschner wires, direct a pin from the proximal third of the metatarsal, medially exiting the lateral cortex and then entering the distal head fragment. These three points of fixation help maximize stability.

**TECH FIG 1 •** Usual location for the osteotomy.

**TECH FIG 2 •** A. The osteotomy is translated laterally with traction and thumb pressure on the distal end while counterpressure is applied with a towel clip to the medial spike of the proximal end. B. The lateral cortex of the proximal metatarsal provides a stable spike to perch the distal head fragment.
with large corrections (TECH FIG 3). Place a second similar pin and check the position with radiographic control. Pins are typically bent and left out percutaneously but can be cut adjacent to the bone and removed electively.

- Cut the large prominence of bone from the proximal, medial metatarsal and contour it in line with the distal head’s medial margin. It is important to cut this back proximal enough to avoid a residual bump at the mid-metatarsal area (TECH FIG 4).

TECH FIG 3 • Optimal pin placement. Note contact with the medial and lateral aspect of the proximal metatarsal before entering the distal head fragment.

TECH FIG 4 • The saw is used to remove the remaining medial “bump” of the first metatarsal. This needs to be contoured in line with the medial metatarsal head to avoid symptoms at this area postoperatively.

**SOFT TISSUE CLOSURE**

- Tighten the medial capsule by removing a U-shaped wedge of tissue from the plantar aspect near the medial sesamoid. The amount of tissue removed is judged to allow adequate correction of the hallux valgus. Next, repair the capsule defect in the plantar limb. Then perform a “pants-over-vest” closure between the plantar and dorsal capsule to improve sesamoid position. The goal is to bring the medial sesamoid to the medial margin of the metatarsal head (TECH FIG 5). Skin closure and bunion dressings are then applied.

TECH FIG 5 • A. The longitudinal capsule incision. B. A U-shaped wedge of capsule is removed and sutured to tighten the plantar limb of the capsule and correct the hallux valgus. C. Suture is placed in a “pants-over-vest” technique to advance the plantar limb of the capsule medial and dorsal. D. The remaining capsule is closed.
POSTOPERATIVE CARE

- Patients are instructed to keep the limb elevated the majority of the first 2 weeks postoperatively. They are allowed to “heel walk” in a postoperative shoe with crutches provided for longer distance or pain management.
- At 2 weeks, sutures are removed and another bunion dressing is applied. The patient is instructed to passively dorsiflex and plantarflex the toe.
- At 5 weeks the pins are removed and the patient is taught to use a compression wrap and toe spacer. Aggressive range-of-motion exercises are initiated.
- Patients are followed on a 3- to 4-week basis to monitor healing and alignment (FIG 2).
- With larger osteotomy translation and correction, radiographic healing can take 3 months or more. However, the osteotomy is usually stable for activities of daily living within 2 months. Sports and strenuous activities may require 3 to 5 months of healing.

OUTCOMES

- We assessed 72 procedures in 62 patients operated on between Jan. 1, 2002, and Dec. 30, 2003. AOFAS scores and radiographic assessments were obtained from 39 at an average of 27.6 months after surgery.5
- AOFAS scores averaged 93.3, with complete radiographic healing in all patients.
- Hallux valgus angle correction averaged 22.3 degrees and intermetatarsal angle correction averaged 7.7 degrees.

COMPLICATIONS

- Complications included three symptomatic hallux varus deformities that were felt to be due to routine adductor release. This has been revised to a limited lateral capsule release as described here with preservation of the adductor tendon in most cases.
- There were three symptomatic medial diaphyseal “bumps” due to inadequate resection of the medial metatarsal after translation. This is now being addressed with more aggressive medial contouring.
- There was one symptomatic dorsal malunion and one case of surgical neuritis of the peroneal nerve branches.
- Only three cases of new or increased transfer lesions were identified.
- No cases of avascular necrosis were identified.

REFERENCES

PEARLS AND PITFALLS

- Avoid routine lateral adductor release to reduce the risk of hallux varus unless specifically indicated by the clinical situation. The increased lateral translation of the osteotomy usually decompresses the lateral structures. The main focus is to realign the sesamoids under the metatarsal head.
- An aggressive contouring of the proximal portion of the metatarsal is necessary to reduce the risk of a residual bony bump near the osteotomy site. This often goes into the medullary canal. The Kirschner wires need to be placed proximal enough to avoid being cut out during this maneuver.
- Two Kirschner wires are recommended to reduce the risk of head migration until healing callus has developed.

FIG 2 • A. Intraoperative radiographic appearance of the osteotomy. The “medial bump” still needs removal from the metatarsal. Office radiographs at 2 weeks (B), 8 weeks (C), and 12 months (D).
DEFINITION

- Hallux valgus is a deformity of the forefoot characterized by progressive lateral subluxation of the proximal phalanx of the first toe on the first metatarsal head. It is considered pathologic when the patient experiences symptoms associated with a valgus deviation (hallux valgus angle [HVA]) greater than 15 degrees (FIG 1).<sup>7,8</sup>
- Hallux valgus is more common in adult women. It is often bilateral, and in many cases it is associated with other foot deformities, such as lesser toe or hindfoot or midfoot deformities that may exacerbate the pathology.<sup>14</sup>
- Hallux valgus is often a progressive disease that compromises the physiologic function of the first metatarsophalangeal (MTP) joint and potentially the entire forefoot.

ANATOMY

- The first metatarsal is the broadest and shortest of the five metatarsals, and the distal condyle of the first metatarsal head articulates with the proximal phalanx of the great toe. In addition, the plantar aspect of the first metatarsal head articulates with the sesamoids, which are contained in the flexor brevis hallucis tendon.
- The relationship of the medial and lateral sesamoids is maintained by the intersesamoid ligament. In association with the ligaments of and muscle balance about the first MTP joint, the sesamoid complex contributes to stabilizing the first MTP joint.
- When functioning properly, the first MTP joint optimizes push-off of the hallux during gait.<sup>4</sup>
- While physiologically the first MTP joint has a wide motion arc in the sagittal plane, it exhibits very little flexibility in the coronal plane. Hallux valgus occurs with greater than physiologic coronal plane motion of the first MTP joint.
- The first metatarsal head receives its main dorsal blood supply from the first dorsal metatarsal artery, a major contributor to an extracapsular anastomosis at the first MTP joint. On the plantar aspect of the first metatarsal head, the blood supply is from a combination of capsular arteries, branches of the first plantar metatarsal artery, and the first dorsal metatarsal artery.<sup>15,17</sup>

PATHOGENESIS

- The pathogenesis of hallux valgus is not fully understood.
- In some patients, hallux valgus deformity may be due to congenital malalignment, neurologic conditions, systemic disease (such as rheumatoid arthritis), connective tissue disorders (with greater than physiologic ligamentous laxity), valgus deviation of the lesser toes, or trauma.<sup>3,4,12,13</sup>
- Several factors that may compromise the normal biomechanics of the foot have been implicated in the development of hallux valgus, including hereditary factors, shape of the first MTP joint, shoe wear, pes planus, and metatarsus adductus.<sup>1–3,10,18,19</sup>
- Controversy remains over the greatest primary cause leading to hallux valgus: valgus deviation of the hallux or metatarsus primus varus.<sup>5,7–11</sup>

PATIENT HISTORY AND PHYSICAL FINDINGS

- With loss of the physiologic balance of the first MTP joint, dynamic muscle function leads to progression of hallux valgus deformity in the majority of cases.
- Progressive hallux valgus may create other forefoot problems, including bursitis of the first MTP joint (FIG 2), callosities, and onychocryptosis (between the first and the second toe).
- Advanced hallux valgus may diminish first MTP joint function to the point that it leads to lesser toe deformity (claw and hammer toes) and associated transfer metatarsalgia (FIG 3).
- For ideal decision making in the management of hallux valgus, the following factors must be considered: pain, mobility and stability of the first MTP joint, and associated deformity.
- The site of the pain should be evaluated. The pain is often localized at the prominent medial eminence. At times, an inflamed...
bursa, a site of tenderness, overlies the prominent medial eminence. In advanced hallux valgus the pain should be referred to the lateral metatarsal head.

- Hallux mobility at the first MTP joint should be evaluated. Range of motion of the first MTP joint should be checked both in its resting valgus position and its correct neutral position. Any limitation may be a sign of first MTP joint incongruency or arthritis and should be evaluated radiographically.

- Stability of the first MTP joint should be assessed. Severe instability of the first MTP is a contraindication for use of the SERI technique.

- Associated lesser toe deformities, such as clawtoes, result in metatarsal overload and callus formation, often creating symptoms that exceed those directly related to the hallux.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A standard radiographic examination, including AP and lateral weight-bearing views of the forefoot, allows the assessment of arthritis and congruency of the joint; measurement of the HVA, intermetatarsal angle (IMA), and distal metatarsal articular angle (DMAA); and calculation of the metatarsal formula, especially the relation between the length of the first and the second metatarsal.

- Preoperative planning is performed using the preoperative weight-bearing radiographs of the foot. In particular, we assess the radiographs to determine the desired obliquity of the bone cut and the amount of mediolateral and dorsoplantar shift of the metatarsal head required to reduce the metatarsal head over the sesamoid complex and correct an increased DMAA (FIG 4).

NONOPERATIVE MANAGEMENT

- Comfortable shoes with a wide toe box and sole may reduce the pressure on the first metatarsal head’s medial prominence. In severe deformity, custom-made shoes or insoles with a metatarsal support may relieve symptoms attributable to transfer metatarsalgia and associated plantar callus formation.

- Nonoperative treatment of hallux fails to correct the deformity; it only accommodates to it. Given that hallux valgus deformity tends to progressively worsen, probably due to muscle imbalance about the first MTP joint, symptoms may abate only with surgical correction when conservative treatment proves inadequate.

SURGICAL MANAGEMENT

Indications for SERI Technique

- In our experience, the SERI ("simple, effective, rapid, inexpensive") technique is effective in correcting mild to moderate hallux valgus, with HVA and IMA not exceeding 40 degrees and 20 degrees, respectively.

- The SERI technique may be applied to congruent and incongruent hallux valgus deformity. The operation is indicated in case of hallux valgus presenting with any degree of DMAA and a mild degenerative arthritis of the first MTP joint.

- Specific contraindications to the SERI technique are severe degenerative arthritis, stiffness, or severe instability of the first MTP joint.
Before surgery, the patient’s foot or feet (simultaneous bilateral procedures) are scrubbed using disinfectant soap solution.

Several anesthetic techniques can be used. We usually prefer a sciatic nerve block using ropivacaine hydrochloride monohydrate 7.5 mg/mL.

The patient is placed in a supine position, with the lower extremity externally rotated with the foot’s lateral border contacting the operating table.

After the foot is exsanguinated, an Esmarch elastic bandage is used as an ankle tourniquet with adequate padding.

The SERI technique does not require a lateral soft tissue release, particularly with a flexible hallux valgus deformity, because the lateral soft tissues relax with lateral translation of the first metatarsal head. Even with slight stiffness of the first MTP joint we do not perform a lateral release, instead applying an intraoperative manual stretch to the adductor hallucis by forcing the hallux in a varus position.

Make a 1-cm medial longitudinal incision midaxially just proximal to the medial eminence through the skin and subcutaneous tissue, directly to the medial aspect of the first metatarsal (TECH FIG 1A). The capsule of the joint is spared.

Retract the soft tissues dorsally and plantarly using two 5-mm retractors (TECH FIG 1B).

If performed as described, the medial aspect of the first metatarsal neck will be adequately exposed.

Perform a complete osteotomy using a standard pneumatic saw with a 9.5 × 25 × 0.4-mm blade (Hall Surgical, Linvatec Corp., Largo, FL) (TECH FIG 1C). In the sagittal plane, the osteotomy is performed with 15 degrees of inclination from dorsal to plantar and distal to proximal. The inclination of the osteotomy in the mediolateral direction is perpendicular to the foot axis (ie, to the long axis of the second metatarsal bone) if the length of the first metatarsal bone must be maintained. If shortening of the metatarsal bone or decompression of the MTP joint is necessary, as in the case of mild arthritis, the osteotomy is inclined in a distal to proximal direction up to 25 degrees. More rarely, if a lengthening of the first metatarsal bone is necessary (ie, if the first metatarsal bone is shorter than the second or if laxity of the MTP joint is present), the osteotomy is inclined in a proximal to distal direction as much as 15 degrees.

With a small osteotome, mobilize the head.

Using a standard wire driver, insert a single-tipped 2.0-mm Kirschner wire retrograde through the incision into the soft tissue immediately adjacent to the proximal and distal phalanges of the hallux, in the longitudinal axis of the great toe (TECH FIG 1D).

The Kirschner wire exits at the medial tip of the toe close to the toenail. Regrasp it with the wire driver (TECH FIG 1E) and retract it so that its proximal tip rests at the level of the osteotomy (TECH FIG 1F).

Using a small grooved lever to prize the osteotomy (TECH FIG 1G), obtain the correction by moving the metatarsal head depending on the pathoanatomy of the deformity (TECH FIG 1H,I).

If pronation of the first metatarsal bone is present, obtain the correction with a derotation of the hallux to the neutral position of the first metatarsal head.

After correcting the HVA, IMA, DMAA, and pronation, advance the Kirschner wire antegrade into the diaphysis of the first MTP joint so that its proximal tip reaches the metatarsal base (TECH FIG 1J).

Expose the medial prominence at the osteotomy site on the distal aspect of the metatarsal shaft by two retractors and remove it using a pneumatic saw or a rongeur (TECH FIG 1K).

The wound requires only a single 3-0 absorbable suture to reapproximate the skin.

Bend and cut the segment of the Kirschner wire that is protruding from the tip of the toe in routine fashion.

In our experience, the SERI technique may be performed as simultaneous bilateral procedures or combined with concomitant correction of associated foot deformities.

PEARLS AND PITFALLS

- A 15-degree inclination in the osteotomy from dorsal to plantar and distal to proximal affords stability to the osteotomy to limit dorsal displacement of the metatarsal head with weight bearing.
- If shortening of the metatarsal or decompression of the MTP joint is necessary, the osteotomy should be inclined in a distal–proximal direction up to 25 degrees. More rarely, if lengthening of the metatarsal is necessary, the osteotomy should be inclined in a proximal–distal direction up to 15 degrees (FIG 5).
- An adjustment of the final intraoperative correction of the first metatarsal head in the mediolateral dislocation plane of the metatarsal head is dictated by the position of the K-wire in the metatarsal diaphysis. Greater correction warrants a more lateral placement of the wire within the metatarsal shaft. Greater plantar displacement of the metatarsal head necessitates placing the K-wire more dorsally into the soft tissue immediately adjacent the metatarsal head (FIG 6).
To correct the DMAA, the Kirschner wire must be introduced obliquely into the medial soft tissues in a mediolateral direction (FIG 7). Then, manual adduction of the hallux must be performed to rotate the metatarsal head, correcting the DMAA.

In our experience, an osteotomy performed proximal to the recommended position increases the risk of first metatarsal malunion and nonunion.

If the Kirschner wire is inserted into the phalanx rather than immediately adjacent to the phalanx, it has been our experience that the DMAA cannot be properly corrected.

Excessive shortening of the first metatarsal may lead to overload of the lesser toes.

Like most other corrective procedures for hallux valgus, the SERI technique is not indicated for hallux valgus associated with moderate to severe hallux rigidus.

POSTOPERATIVE CARE

After the completion of the surgery, a mildly compressive gauze dressing is applied to the wound and forefoot (FIG 8) and AP and oblique radiographs are obtained to confirm the placement of the osteotomy and the correction of any characteristics of the deformity.

Ambulation is allowed immediately using “talus” shoes. These shoes maintain the foot in the talus position of the ankle, allowing weight bearing on the hindfoot and discharging weight from the forefoot. Foot elevation is advised when the patient is at rest in the immediate postoperative period.

Kirschner wire fixation due to wire bending upon insertion produces a very stable and elastic stabilization, maintaining the same position obtained during surgery and favoring early healing of the osteotomy combined with early weight bearing.

After 1 month, the dressing, suture, and Kirschner wire are removed. Passive and active exercises with cycling and swimming are advised and comfortable normal shoes are worn, gradually returning to standard footwear.

As a rule, significant postoperative swelling does not last for more than 1 month.

OUTCOMES

With appropriate indications, the SERI technique of minimally invasive distal metatarsal osteotomy is simple, effective, rapid, and inexpensive, giving satisfactory results in more than 90% of cases.

This technique is easily repeated, without removal of the eminence and without open lateral release. It is minimally invasive but performed under direct line of vision and without radiations.

Normally, the osteotomies heal well, with callus evident after an average of 3 months.

The radiographic evaluation showed significant correction of the parameters over time (FIG 9).

No severe complications, such as avascular necrosis of the metatarsal head, nonunion of the osteotomy, or hallux varus, were observed.

All the metatarsal bones remodeled themselves over time, even in cases with significant offset at the osteotomy (few millimeters of bony contact). In our experience, the healing of the osteotomy and the remodeling capability of the metatarsal bone are not related to the offset at the osteotomy, but it is necessary to obtain a bony contact.

COMPLICATIONS

There was a 1.9% rate of delayed union of the osteotomy (over 4 months). In our experience, delayed union is not related to the amount of displacement or correction at the osteotomy.

There was a 2.1% rate of skin irritation or erythema about the Kirschner wire at the tip of the great toe.
There was a 12% rate of transfer metatarsalgia with plantar callosities under the second and third metatarsal heads, resolving by the use of insoles with metatarsal support.

There was a 0.5% rate of deep vein thrombosis.

REFERENCES

SURGICAL MANAGEMENT
- The primary indication for an Akin osteotomy is hallux valgus interphalangeus or in cases where residual hallux valgus causes pressure on the second toe on the load stimulation test. It is most commonly used to accompany a scarf or chevron osteotomy. An isolated Akin is contraindicated in the treatment of hallux valgus. We use a proximal medial closing wedge osteotomy that is fixed by a varisation screw (Depuy, Warsaw, IN).
- The osteotomy is fashioned within metaphyseal cancellous bone, ensuring excellent cancellous healing. The osteotomy, by being close to the apex of the deformity at the interphalangeal joint, allows for more powerful correction.

AKIN OSTEOTOMY
- We describe an eight-step method for performing the Akin osteotomy.
- The exposure is performed usually as an extension to the midline longitudinal incision from the metatarsal osteotomy. If performed as an isolated procedure, the exposure must allow visualization of the metatarsophalangeal joint proximally and the shaft of the proximal phalanx distally. The exposure of the shaft of the phalanx may require excision of overlying fatty tissue.
- After dissecting directly onto bone, complete the exposure by periosteal elevation above and below the phalanx.

Place two small pointed retractors above and below the phalanx to protect the extensor and flexor tendons (TECH FIG 1A).
- Position a 1-mm Kirschner wire in the midportion of the phalanx in the sagittal plane approximately 3 mm distal to the phalangeal flare (TECH FIG 1B).
- Traction on the big toe allows us to visualize the joint to ensure the wire is not intra-articular (TECH FIG 2A).
- Remove the Kirschner wire and mark the hole (TECH FIG 2B).

**TECH FIG 1** • A. Incision is made directly to bone with subperiosteal dissection above and below the proximal phalanx. B. Kirschner wire position on proximal phalanx parallel to phalangeal base.

**TECH FIG 2** • A. The joint is checked to confirm the Kirschner wire has not penetrated the articular surface. B. The Kirschner wire position is marked.
Make the proximal cut parallel to the phalangeal base (TECH FIG 3A). To maintain control of the osteotomy, score the lateral cortex but do not penetrate it with the saw blade, thus allowing it to act as a hinge. Perform the second osteotomy to produce a wafer of bone with the apex laterally (TECH FIG 3B). When removed it should look like a fine slice of lemon. Use direct pressure to close the wedge. This “greensticks” the intact but weakened lateral cortex.

Select the varisation staple (usually 8 mm; 10 mm in larger feet) and mark the tip of the distal end with a pen (TECH FIG 4).

Place the staple in position with the osteotomy compressed. Check that it is on the midportion of the phalanx in the sagittal plane (TECH FIG 5A). The distal staple leaves an ink mark; drill this mark with a 1-mm Kirschner wire (TECH FIG 5B) and then mark the hole. The position for the staple can then be identified by the two bone marks.

While maintaining compression, insert the staple in the predrilled holes. Check for stability of the fixation (TECH FIG 5C), and again axial traction confirms the staple is not in the joint.

Close the wound in layers with continuous Monocryl to skin, and apply a forefoot bandage to maintain the correction.
PEARLS AND PITFALLS

| Exposure | ■ The orientation of the osteotomy can be difficult if performed in the absence of a metatarsal osteotomy. Avoid the temptation to use a small incision, instead taking care to expose the metatarsophalangeal joint and the shaft of the phalanx. |
| Staple insertion | ■ Resistance may be encountered when inserting the staple due to the hard subchondral bone. Avoid using excess force when inserting the staple, as this may fracture the lateral “greensticked” cortex. Either repeat the Kirschner wire drilling or accept the staple 2 to 3 mm proud if a good hold is achieved. |
| Inadvertent lateral cortex fracture | ■ If the lateral cortex if fractured, then a compression screw is inserted from medial to lateral spanning the osteotomy. |
| Overcorrection | ■ The osteotomy is very powerful as it is at the apex of the deformity. Aim for a very fine segment of bone; it can be cut again if required. |
| Unable to greenstick the lateral cortex | ■ Often a rectangle of bone as opposed to a wedge has been removed. Forcing it to close will crack the lateral cortex. Instead use a gentle to-and-fro motion with the running saw while applying gentle compressive force. This thins the lateral cortex until the osteotomy closes without “bouncing back” once pressure is removed. |

POSTOPERATIVE CARE

■ See Chapter FA-7 on scarf osteotomy.

OUTCOMES

■ The most common indication for an Akin osteotomy is in combination with a metatarsal osteotomy for hallux valgus. Outcomes are therefore reported together with satisfaction rates at between 85% and 95%.1,2,4 Very few studies have concentrated solely on the Akin.

COMPLICATIONS

■ Complications of this osteotomy are rare3 but can include nonunion, nerve damage, infection, displacement of the osteotomy, and overcorrection or undercorrection. Failure to recognize propagation of the lateral cortex may increase the risk of subsequent displacement.

REFERENCES

SURGICAL MANAGEMENT

- The primary indication for a Scarf osteotomy is symptomatic hallux valgus deformity with an intermetatarsal angle of less than 20 degrees. The first metatarsocuneiform joint should be stable. It is a versatile osteotomy that can allow shortening, lengthening, rotation, displacement, or plantarization of the first metatarsal head. Thus, indications include symptomatic hallux valgus with or without mild transfer symptoms, juvenile hallux valgus with an abnormal distal metatarsal articular angle, arthritic hallux valgus not severe enough for a fusion, and revision surgery in suitable cases.

Preoperative Planning

- AP and lateral weight-bearing radiographs of the foot are evaluated for metatarsal length, intermetatarsal angle, hallux valgus angle, distal metatarsal articular angle, and interphalangeal angle for cases that may require a proximal phalangeal osteotomy to obtain complete correction. Congruency of the joint, presence of osteophytes, the size of the bony medial eminence, and position and condition of the sesamoids are noted.

Positioning

- Surgery is performed on an outpatient basis.
- Prophylactic antibiotics are administered.
- A thigh tourniquet is applied.
- The patient is positioned supine with a sandbag under the ipsilateral buttock so the big toe points to the ceiling.

SOFT TISSUE RELEASE AND BUNIONECTOMY

- Approach the metatarsal through a medial longitudinal incision extending from the first tarsometatarsal joint to the medial flare of the proximal phalanx (TECH FIG 1A). This can be extended distally if a phalangeal osteotomy is required. Identify the dorsal medial cutaneous nerve and incise the medial capsule sharply in a single longitudinal direction. Expose the medial eminence and resect it 1 mm medial to the sagittal sulcus (TECH FIG 1B). Overresection can lead to a postoperative varus deformity. Expose the metatarsal shaft using subperiosteal sharp dissection, taking care to protect the plantar neck vascular bundle to the metatarsal head (TECH FIG 1C). The proximal plantar exposure can be performed safely without any disruption to the plantar blood supply. Use a large Langenbeck retractor to protect and retract the plantar flap. The tarsometatarsal joint is identified but does not need to be exposed.
- Perform a lateral release of the first metatarsophalangeal joint by exposing the first web space with aid of a lamina spreader as an “over the top” technique. This does not compromise the plantar blood supply. Use a banana blade to perform the sharp dissection (TECH FIG 1D). Release the tendinous insertion of the adductor hallucis muscle onto the fibula sesamoid and proximal phalanx. Release the suspensory metatarsal–sesamoid ligaments and make multiple sharp perforations in the lateral capsule at the joint line if required. Apply a varus force to the hallux, completing the capsular release (TECH FIG 1E).
- This release can also be performed through a separate first web space incision if preferred.
SCARF OSTEOTOMY

- Make the cut starting with the medial longitudinal cut. This is begun distally 5 mm from the articular surface and 2 to 3 mm from the dorsal surface of the metatarsal and finished 5 mm from the tarsometatarsal joint, 2 to 3 mm from the proximal plantar surface of the metatarsal (TECH FIG 2A). Make the longitudinal cut in the same plane as the plantar orientation of the metatarsal (TECH FIG 2B). This allows a degree of plantarization of the metatarsal head. Using a large Langenbeck retractor helps to visualize the plantar metatarsal surface. Perform the transverse cuts at 60 degrees to the longitudinal cut as a chevron. Both cuts are directed proximally, avoiding convergence laterally, which would hinder translation (TECH FIG 2C). When performing the distal cut, elevate the hand to complete the lateral cut (TECH FIG 2D). Separate the two fragments, taking care not to lever the fragments. These steps may need to be repeated if there has been failure to complete all the cuts, but take care to avoid double cutting. Release of the capsule from the lateral side may be needed if it is preventing displacement (TECH FIG 2E).
Perform displacement or rotation with guidance from the preoperative radiographs by using a clamp on the distal lateral cortex (TECH FIG 3A). Use a compression clamp to hold the displacement (TECH FIG 3B). Up to two thirds of lateral displacement can be obtained while maintaining a strong lateral strut and good bone apposition.

Obtain screw fixation using Barouk screws (Depuy, Warsaw, IN). These are cannulated, self-tapping screws with a long distal thread and a threaded head to allow compression and burial of the head. Place the distal screw first. Pass the guidewire from the proximal fragment obliquely into the head (TECH FIG 4A). Directly visualize the guidewire in the joint, and withdraw it to be flush with the articular surface so that it can be measured (TECH FIG 4B). A screw at least 4 mm less than the measured amount is used to avoid intra-articular penetration. During the drilling over the guidewire, ensure that the drill countersink is seated fully to avoid inadvertent fracture of screw placement (TECH FIG 4C). Directly inspect the joint. Compress the osteotomy further with the clamp. Place the second guidewire for the proximal screw in the midline in an oblique direction to reach the plantar cortex of the distal fragment (TECH FIG 4D). Measure it by withdrawing the guidewire so as to be flush with the cortex. Retraction of the plantar tissue protects and allows direct visualization of the wire and the drill. This screw length equals the measurement from the wire. Directly visualize the screw to confirm compression and length (TECH FIG 4E).

TECH FIG 2 • (continued) C. Transverse cuts, avoiding convergence. D. The hand is elevated to complete the distal transverse cut. E. Release of the capsule from the proximal end.

TECH FIG 3 • A. Method of displacement of the fragment. B. Compression clamp applied after displacement.
Resect the medial distal aspect of the dorsal fragment (TECH FIG 5) and check the osteotomy for stability.

Imbricate the medial capsule with a strong absorbable suture while holding the hallux in a neutral or slightly abducted position with the aid of a swab (TECH FIG 6).

Confirm the reduction in the intermetatarsal angle, screws, and relocation of the sesamoids with image intensification with the foot flat on the image intensifier (TECH FIG 7). Assess the need for a proximal phalangeal osteotomy.

Close the wound in layers with continuous Monocryl to skin and apply a forefoot bandage to maintain the correction.
PEARLS AND PITFALLS

| Ensure adequate soft tissue release on the dorsal fragment. | After completing the cuts successfully, if displacement is still difficult, then check that the periosteum is not tethering the distal lateral corner of the proximal fragment. |
| Divergent transverse cuts | Avoid convergent transverse cuts, as this will make displacement difficult. |
| Rotational osteotomy to correct distal metatarsal articular angle | If using the Scarf osteotomy to correct the distal metatarsal articular angle, then excise a wedge of bone from the proximal, lateral, plantar fragment to allow for displacement and to avoid impingement onto the second metatarsal. A shorter Scarf can also be used. |
| Longitudinal cut | The direction of the longitudinal cut can depress the metatarsal head, depending on the requirement. |
| Transverse cut | Double cutting the transverse cuts can shorten the osteotomy in cases where the joint is very stiff or there is very severe hallux valgus deformity. |
| Screws | Direct visualization of the metatarsophalangeal joint is made to avoid joint penetration. Take care to avoid seating the proximal screw too deep into the very thin dorsal cortex, as this may reduce screw hold. |
| Proximal plantar exposure | This is a safe exposure and does not compromise the blood supply to the metatarsal. It is a vital step: once completed, it allows orientation of the longitudinal cut parallel to the plantar surface; identification of the flare of the first tarsometatarsal joint ensures the transverse cut is not intra-articular; and a clear view of the lateral plantar surface allows the surgeon to pass the guidewire under direct vision and check the screw length. |

POSTOPERATIVE CARE

- If safe, patients are discharged home on the day of surgery with strict advice to elevate the foot whenever resting for the first 2 weeks.
- In most cases they are allowed to bear weight on their heel and lateral forefoot in a hard-soled postoperative shoe.
- Cast immobilization is not required.

- The wound is inspected at 2 weeks, at which time the hallux is restrapped and patients are taught simple passive and active toe flexion-extension exercises.
- At 5 weeks postoperatively the osteotomy is assessed with radiographs. If there is some consolidation at the line of the osteotomy the patient is instructed to wear a wide shoe or sneaker and to progress to full weight bearing as tolerated.
Strapping of the hallux is discontinued at this time. Delayed union or nonunion is rare with this osteotomy.

OUTCOMES

- The Scarf osteotomy is now a widely used method of correction for hallux valgus; it is particularly popular in Europe. Satisfaction rates range from 88% to 92%,2,3,8,9 equivalent to those of the chevron osteotomy,4,5 including patients defined as having severe hallux valgus. In a review of five recent publications4,6,8–10 the hallux valgus angle was improved on average by 16 degrees (range 11 to 21), the intermetatarsal angle by 6.4 (range 3 to 10), and the AOFAS score by 45 (range 37 to 55).
- A learning curve for performing the Scarf osteotomy has also been noted, with higher complication rates seen in early series.1

COMPLICATIONS

- The main complication seen is stiffness, which occurs in up to 5% of cases.7 Other complications include wound problems, infection, undercorrection, overcorrection, fractures, chronic regional pain disorder, and deep vein thrombosis. Delayed union and osteonecrosis are rare complications. Fracture risk can be reduced by preserving the lateral strut when placing the proximal screw and by using a long longitudinal cut.

REFERENCES

**SURGICAL MANAGEMENT**

- The distal soft tissue procedure and proximal metatarsal osteotomy has been widely used for bunion corrections for more than 30 years. It is a reliable, reproducible procedure that can be used to treat a wide range of bunion deformities.
- The procedure is indicated for a hallux valgus deformity with an incongruent metatarsophalangeal joint, an intermetatarsal angle of more than 10 to 12 degrees, and a distal metatarsal articular angle of less than 10 degrees.

- It is carried out in three main steps:
  - Release of the contracted lateral capsular structures: the adductor hallucis tendon, the transverse metatarsal ligament, and the lateral joint capsule
  - By freeing up these three structures the sesamoid sling can be replaced beneath the first metatarsal head.
  - Preparation of the medial joint structures
  - Exposure and plication of the medial joint capsule
  - Excision of the medial eminence
  - Exposure of the base of the first metatarsal and proximal crescentic metatarsal osteotomy

**RELEASE OF THE LATERAL JOINT STRUCTURES**

- Make a 2.5-cm incision on the dorsal aspect of the first web space between the first and second metatarsal heads.
  - Deepen this incision through the subcutaneous tissue.
  - Place a Weitlander retractor to expose the web space.
  - On the floor of the web space lies the adductor hallucis, which passes obliquely to insert into the lateral sesamoid and the base of the proximal phalanx (TECH FIGS 1 AND 2).
- Identify the capsule between the subluxated fibular sesamoid and the lateral base of the first metatarsal head.
- Use a scalpel to release the capsule. By extending the incision distally in this interval, detach the adductor hallucis tendon from its insertion into the base of the proximal phalanx.
- Detach the adductor tendon from the lateral aspect of the fibular sesamoid, dissecting proximally until the flexor hallucis brevis muscle tissue is noted (TECH FIG 3).
- Place a Weitlander retractor between the first and second metatarsal heads, placing the transverse metatarsal ligament under tension (TECH FIGS 2 AND 4).
- Transect this ligament.
- While carrying out this step, it is important that only ligamentous tissue is cut because directly beneath the
ligament lies the common nerve to the first web space and the accompanying vessels.

- Release the lateral joint capsule.
- Make an incision through the dorsal aspect of the joint capsule at the level of the joint line, and pass the knife blade to the plantar aspect of the metatarsal (TECH FIGS 5 AND 6).
- With the blade well seated against the bone, pass the scalpel proximally, stripping the origin of the capsule off the metatarsal head over a distance of about 1.5 cm.
- This creates a flap of the lateral joint capsule to be used later in the repair (TECH FIG 7).
- Bring the hallux into about 25 degrees of varus, which ensures that no lateral contracture remains.

TECH FIG 3 • The adductor tendon has been detached from the lateral aspect of the fibular sesamoid and is being held in the forceps.

TECH FIG 4 • The transverse metatarsal ligament is placed under tension using a Weitlander retractor.

TECH FIG 5 • The scalpel has been placed through the dorsal aspect of the lateral joint capsule of the first metatarsophalangeal joint.

TECH FIG 6 • Diagram of Techniques Figure 5, illustrating the lateral joint capsule of the first metatarsophalangeal joint.

TECH FIG 7 • The origin if the lateral joint capsule has been stripped off the metatarsal head, creating the flap of tissue held in the forceps.

PREPARATION OF THE MEDIAL JOINT CAPSULE

- Approach the medial joint capsule through a longitudinal incision in the midline starting at the middle of the proximal phalanx and proceeding proximally just past the medial eminence.
- Identify the plane between the subcutaneous tissue and the joint capsule; take care to work along this plane.
- Dissecting dorsally at first, pull the skin flap away from the capsule to expose the dorsal medial cutaneous nerve, which is then carefully retracted.
Next, dissect the skin flap off the plantar half of the capsule until the abductor hallucis muscle and tendon are identified.

- Take care in this area, because the plantar medial cutaneous nerve lies just plantar to the abductor tendon.

- The capsulotomy that we prefer starts with a vertical cut in the medial joint capsule, made 2 to 3 mm proximal to the base of the proximal phalanx.

- Make a second, parallel cut 3 to 8 mm proximal to the first cut, depending on the severity of the hallux valgus deformity. A more severe deformity requires more resection of tissue from the medial joint capsule (TECH FIG 8).

- Bring together these two parallel capsular cuts dorsally through an inverted V-shaped incision.

- On the plantar side, make an upright V-shaped incision through the abductor hallucis tendon that ends at the tibial sesamoid (TECH FIG 9).

- Remove this capsular tissue (TECH FIG 10).

- While making the cut through the abductor hallucis tendon, keep the tip of the knife blade inside the joint to avoid damaging the plantar medial cutaneous nerve.

- Make an incision through the joint capsule on the dorsal aspect of the medial eminence.

- Peel the capsular flap proximally and plantarward until the medial eminence is completely exposed (TECH FIGS 11, 12, AND 13).
The medial eminence can be removed with a 16-mm osteotome or with a saw blade. This is strictly the choice of the operating surgeon.

After performing the osteotomy, inspect the metatarsal to be sure there are no rough edges of bone. Rongeur off any bony prominence.

The osteotomy to remove the medial eminence is started 1 to 2 mm medial to the sagittal sulcus and is performed in line with the medial aspect of the metatarsal shaft (TECH FIG 14).

The medial eminence can be removed with a 16-mm osteotome or with a saw blade. This is strictly the choice of the operating surgeon.

After performing the osteotomy, inspect the metatarsal to be sure there are no rough edges of bone. Rongeur off any bony prominence.

**APPROACH TO THE PROXIMAL CRESCENTIC OSTEOTOMY**

- Perform an osteotomy to remove the medial eminence.
  - Start the osteotomy 1 to 2 mm medial to the sagittal sulcus; the osteotomy is in line with the medial aspect of the metatarsal shaft (TECH FIG 14).

- The medial eminence can be removed with a 16-mm osteotome or with a saw blade. This is strictly the choice of the operating surgeon.

- After performing the osteotomy, inspect the metatarsal to be sure there are no rough edges of bone. Rongeur off any bony prominence.

- Make an incision directly over the extensor hallucis longus tendon, from just proximal to the metatarsal cuneiform joint distally about 2.5 to 3 cm.
  - Usually a large vessel crosses this plane; cut or cauterize it when the approach is made.
  - Mobilize the extensor tendon and retract it either medially or laterally to expose the metatarsal shaft.
  - As the metatarsal shaft is exposed, it is not necessary to be subperiosteal.
  - Working just above the periosteal plane allows the tissues to move easily.

- Identify the metatarsal cuneiform joint.
  - Make a mark on the metatarsal 1 cm distal to the joint; this is where the crescentic osteotomy will be created.
  - Make a second mark on the metatarsal 1 cm distal to the osteotomy site; this is where the screw will be placed that stabilizes the osteotomy (TECH FIGS 15 AND 16).
  - To confirm that the osteotomy site is correct, note the flare on the lateral aspect of the metatarsal that marks the junction of the diaphyseal and metaphyseal bone.
  - This is located about 1 cm distal to the metatarsal cuneiform joint.

- Advance a guide pin for the 4.0-mm cannulated screw a short distance into the metatarsal, beginning at the marked site.
  - The pin should be angled at about 50 degrees to the long axis of the metatarsal in the sagittal plane (TECH FIG 16). At this angle the pin and subsequent screw will pass into the plantar aspect of the proximal metatarsal fragment and will not violate the joint.

- Carry out the osteotomy using a crescent-shaped saw blade.
  - This blade comes in two lengths. It is easier to start with a shorter blade and then use the longer blade if necessary to complete the osteotomy (TECH FIGS 16 AND 17).
Positioning of the foot in preparation for the osteotomy is a critical part of this procedure. Sit at the side of the table holding the foot in one hand. Hold the foot in a neutral position in regard to dorsiflexion–plantarflexion and inversion–eversion. Place the saw with the concavity facing proximally, toward the heel. The angle of the saw blade should be neither perpendicular to the bottom of the foot nor perpendicular to the metatarsal, but about halfway between those positions (TECH FIG 16).

Start the osteotomy cut by applying firm pressure to the blade. After making the initial cut into the bone, carefully evaluate the position of the saw blade to be sure that it will cut through the lateral cortex of the metatarsal shaft. Sometimes in a wide metatarsal the blade will not penetrate both cortices. If the medial cortex is not completely cut, it is safe and simple to complete the osteotomy in this area. However, it is difficult and potentially dangerous to complete an osteotomy laterally, as there is a major artery in the space between the first and second metatarsals that could be harmed.

Make the cut by moving the saw in a medial–lateral direction along the arc of the saw blade. While cutting, apply a little bit of pressure to the blade toward the heel, as this helps to stabilize the blade in the plane of its cut. Once the cut is established, moving the saw blade back and forth without a lot of pressure plantarward will produce a nice smooth cut.

It is important that the cut passes all the way through the metatarsal so that the distal portion of the bone is totally free and has no bony attachments to the proximal fragment. If a medial piece of bone is still present, use a 4- to 6-mm osteotome to cut through the bone. Pass a knife blade along the medial side of the cut to be sure that the cut is completely free of any bony or periosteal attachment.

CORRECTION OF THE OSTEOTOMY

Correcting the osteotomy is the most technically demanding part of the bunion procedure. The objective is to stabilize the base of the metatarsal while rotating the distal portion of the metatarsal around the osteotomy site.

The first step is to push the proximal portion of the cut metatarsal in a medial direction so that it is at the medial excursion of the metatarsal cuneiform joint. This can be accomplished with a Freer elevator (TECH FIGS 18 AND 19).
Grasp the metatarsal head firmly with your other hand and rotate the distal aspect of the metatarsal in a lateral direction around the osteotomy site.

Examining the osteotomy site demonstrates that the distal fragment rotates no more than 2 to 3 mm around the “crescent” (Tech Figs 18 and 19).

Hold the osteotomy site in this alignment and drill the previously placed guide pin across the osteotomy site until the plantar cortex is engaged.

Once this occurs, the osteotomy site is reasonably stable.

Measure the guide pin to determine the screw length, which is usually 28 to 30 mm.

When learning to perform this procedure, or if there is a question as to the alignment of the osteotomy, at this point obtaining a radiograph is warranted.

If the guide pin is not providing adequate stability, a second pin or Kirschner wire can be used for supplemental fixation while evaluating the radiograph.

If the radiograph shows that the intermetatarsal angle is not sufficiently closed down, remove the guide pin and remanipulate the osteotomy site until the intermetatarsal angle is adequately corrected.

While holding the osteotomy site corrected, overdryll the guide pin with the appropriate-sized drill for the cannulated screw set (TECH FIG 20).

Usually it is adequate to advance the drill to a position just past the osteotomy site, so that the guide pin does not back out when the drill is removed.

Use a countersink, mainly on the distal side of the screw hole, to make the screw head less prominent. However, excessive countersinking can cause the screw head to be pulled through the screw hole site and produce instability of the osteotomy site.

Place a partially threaded 4.0-mm cannulated screw across the osteotomy site and carefully tighten it (TECH FIG 21).

Be cautious as the screw is tightened because the island of bone is only about 5 or 6 mm and can be cracked if the screw is tightened too firmly.

Check the stability of the osteotomy site by moving the distal fragment in the sagittal plane, looking for any motion at the osteotomy site.

Mild instability of the osteotomy can be addressed by carefully tightening the screw or by adding a small-diameter Kirschner wire for supplemental fixation.

Occasionally a small plate may need to be added to the first metatarsal to secure the osteotomy if there is gross instability.
RECONSTRUCTION OF THE MEDIAL JOINT CAPSULE

The first step in reconstructing the medial joint capsule is to hold the great toe in correct alignment:
- Neutral dorsiflexion–plantarflexion
- 0 to 5 degrees of varus
- Rotate the toe to correct pronation, which brings the sesamoids back underneath the metatarsal head.
- Reduction of the sesamoids has been achieved if they are visible along the plantar aspect of the medial eminence.
- Pull the proximal joint capsule distally to see whether the proximal and distal flaps of the capsule juxtapose one another (TECH FIG 22).
- If they do, then the capsular flaps are approximated.
- If insufficient capsule has been removed, then more capsular tissue needs to be removed before it is plicated.
- The capsular flaps should not be overlapped in a “pants over vest” fashion, as this creates too much bulk over the medial eminence.
- To repair the medial capsule, place four to six sutures of 2-0 chromic into the joint capsule with the toe held in correct alignment.

The first suture is placed as plantar as possible and incorporates the abductor hallucis tendon (TECH FIG 23).
- The suture line progresses dorsally (TECH FIG 24).
- Once the sutures are placed and tied, check the alignment of the toe.
- The toe should be in neutral position as far as varus and valgus is concerned, or possibly in a little bit of varus.
- In general, if the final alignment of the toe is in more than 5 degrees of valgus, extra capsular tissue should be removed.
- Return your attention to the first web space.
- Sew the adductor hallucis tendon (already tagged with a suture) to the flap of capsule that was stripped off the metatarsal head.
- If the toe had been positioned in a little too much varus when plicating the medial capsule, tension can be placed on this web space repair to prevent a hallux varus from occurring.
- Thoroughly irrigate the wounds with antibiotic solution and then close them with interrupted silk.
- Apply a sterile compression dressing and then release the tourniquet.

TECH FIG 22 • With the toe held in neutral position, the medial capsular flaps are checked for proper alignment.

TECH FIG 23 • The first suture for repairing the medial joint capsule is placed as plantar as possible; it incorporates the abductor hallucis tendon.

TECH FIG 24 • A total of four to six sutures are used to repair the medial joint capsule.
POSTOPERATIVE CARE

- The initial postoperative dressing is changed 1 to 2 days after surgery.
  - A dressing incorporating firm gauze and adhesive tape is used to hold the toe in correct alignment.
  - The patient is permitted to ambulate in a postoperative shoe.

- The patient is seen about 8 to 10 days after surgery, at which point the sutures are removed and a radiograph is obtained.
  - Based on the alignment of the toe in this radiograph, it is determined how the toe is dressed—namely, into a little more varus or valgus, or held in a neutral position.

- The dressings are changed on a weekly basis to ensure that the alignment of the toe remains correct.
  - At 3 to 5 weeks after surgery another radiograph is obtained to confirm the alignment of the toe.
    - If the alignment is not correct, it can still be corrected by pulling the toe into more varus or valgus, depending on what the radiograph dictates.

- After 8 weeks the dressings are removed and the patient is started on range-of-motion exercises.

OUTCOMES

- Proximal metatarsal osteotomy and distal soft tissue release decreases the bunion deformity to an average of 10 degrees and decreases the intermetatarsal angle to an average of 5 degrees.
  - A 90% to 95% rate of patient satisfaction has been reported, as well as improvements in pain level and improvements in overall function.

COMPLICATIONS

- Recurrence of hallux valgus deformity
- Hallux varus
- Dorsiflexion of metatarsal osteotomy
- Nonunion of osteotomy site
- Delayed union of osteotomy site

REFERENCES

DEFINITION

- Symptomatic hallux valgus associated with a first intermetatarsal angle greater than 15 degrees is typically corrected with a proximal first metatarsal osteotomy and distal soft tissue procedure when nonoperative treatment fails.
- Multiple techniques for the hallux valgus deformity correction have been described.\(^5\)
- In 1918 Ludloff\(^4\) described an oblique osteotomy from the dorsal–proximal to distal–plantar aspects of the first metatarsal, and the procedure was performed without internal fixation.
- The procedure recently gained renewed attention when Myerson\(^1,6\) recommended adding internal fixation and modified several parts of the technique.
- The modified Ludloff osteotomy has been extensively studied with biomechanical and mathematical investigations.

ANATOMY

- The special situation distinguishing the first metatarsophalangeal (MTP) joint from the lesser MTP joints is the sesamoid mechanism.
  - On the plantar surface of the metatarsal head are two longitudinal cartilage-covered grooves separated by a rounded ridge. The sesamoids run in these grooves.
  - The sesamoid bone is contained in each tendon of the flexor hallucis brevis; they are distally attached by the fibrous plantar plate to the base of the proximal phalanx.
  - The head of the first metatarsal is rounded and cartilage-covered and articulates with the smaller concave elliptical base of the proximal phalanx.
  - Fan-shaped ligamentous bands originate from the medial and lateral condyles of the metatarsal head and run to the base of the proximal phalanx and the margins of the sesamoids and the plantar plate.
  - Tendons and muscles that move the great toe are arranged in four groups:
    - Long and short extensor tendons
    - Long and short flexor tendons
    - Abductor hallucis
    - Adductor hallucis
  - Blood supply to the metatarsal head
    - First dorsal metatarsal artery
    - Branches from the first plantar metatarsal artery

PATHOGENESIS

- Extrinsic causes
  - Hallux valgus occurs almost exclusively in shoe-wearing populations, but only occasionally in the unshod individual.
  - Although shoes are an essential factor in the cause of hallux valgus, not all individuals wearing fashionable shoes develop this deformity.
- Intrinsic causes
  - Hardy and Clapham\(^2\) found, in a series of 91 patients, a positive family history in 63%.
  - Coughlin\(^5\) reported that a bunion was identified in 94% of 31 mothers whose children inherited a hallux valgus deformity.
  - The association of pes planus with the development of a hallux valgus deformity has been controversial.
  - Hohmann was the most definitive proponent that hallux valgus is always combined with pes planus.
